mations increase faster than the stresses, both for tension and for compression, and that the modulus for tension is slightly larger than for compression.[31]

Tests have been carried out recently in the Research Laboratory of the Portland Cement Association covering the modulus of elasticity of concrete in both tension and compression, using the most accurate technique and apparatus. As a result of these tests F. R. McMillan, M. Am. Soc. C. E., has stated to the writer under date of January 11, 1930, that he does not accept the exponential law, as Hooke's law applies up to normal working stresses and generally considerably beyond these; also that the modulus in tension is substantially equal to that in compression.[32]

These conflicting opinions are due no doubt to the fact that so many circumstances influence the result. Some of these are the permanent set, previous loading, how the load is applied, whether in steps or continuously, repeated loading and unloading in order to obtain the final deformation for a certain load, the time element, internal stresses due to temperature, shrinkage, etc. In view of these facts it appears to the writer that the usual assumption, that Hooke's law holds, is to be preferred for the proposed exponential law for stresses which do not exceed the normal working stresses.

It is well known that Hooke's law does not hold for stresses approaching the breaking value and that this must materially influence the stress distribution in concrete arches the writer has pointed out elsewhere.[33] Bach has shown that for cast iron the modulus of rupture in bending is about 1.64 times the tensile strength and he explains that fact by showing that the modulus of elasticity is not constant and is not the same for tension as for compression.[34] This difference brings about a shifting of the neutral axis toward the compression side, so that, at failure, the compression at the extreme fiber is 73% greater than the maximum tensile stress. Recent tests on unreinforced concrete beams show that the modulus of rupture in bending is about 1.65 to 2 times as great as the tensile strength.[35] The exponential law using the same constants, $k$ and $m$, for tension as for compression, as the author does, cannot explain this great discrepancy between the modulus of rupture in bending and the tensile strength, as the following calculation shows. The bending moment derived from the exponential law, Equation (9), is given by Bach[36] as,

$$M_e = \frac{2\,m}{2\,m+1}\,\sigma\,b\,\frac{h^2}{4} \qquad (112)$$

in which, $\sigma$ is the maximum fiber stress, which occurs at the surfaces, the same for tension as for compression, since $k$ and $m$ are the same for both kinds of stresses; $b$ is the width; $h$, the height; and $m$, the exponent for $\sigma$ in Equation (9). For Hooke's law, $m = 1$ and,

$$M_h = \frac{b\,h^2}{6}\,\sigma \qquad (113)$$

[36] "Elasticität und Festigkeit," Ninth Edition (1924), p. 276.

The ratio of $M_e$ to $M_h$ is,

$$R = \frac{6}{4 + \frac{2}{m}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (114)$$

If $m = 1.3$, $R = 1.08$, or the bending moment is only 8% greater than that found by Hooke's law. For $m = 2$, which is much too large, $R = 1.2$, which is still much too small. (Mr. Walker[37] gives $m = 1.11$ as an average and Bach[38] gives values of $m$ ranging from 1.145 to 1.207.) It is evident that the exponential law, with the same constants for tension as for compression, cannot explain the discrepancy between the modulus of rupture and tensile strength. When $k$ and $m$ are different for tension and for compression, as is the case with the cast iron investigated by Bach, to which reference has been made, the exponential law gives about 89% of the actual bending moment at failure, while Hooke's law gives only about 61%, assuming, in both cases, that the maximum bending stress equals the tensile strength.

The attempt to deal with the time effect, or the so-called plastic deformation, and its influence upon the stress distribution, is interesting. The author assumes that the exponential law holds for the elastic deformation and that another exponential law,

$$\rho = k\, \sigma^p\, t^q \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (115)$$

holds for the plastic deformations. From one set of tests by Fuller and More, the author finds $q = 0.42$, while from another set of tests by Mr. Earl B. Smith, he finds $q = 0.18$; these latter tests appear to have been started when the concrete was only two weeks old, so that during the test the modulus of elasticity, strength, etc., must have been changing rapidly, making the results problematical.

The separation of elastic and plastic deformations seems an artificial procedure. Tests show the combined deformation only, and the stress-strain curve depends upon previous loading, so that the same specimen can not be subjected repeatedly to tests without introducing new factors which influence the result to an unknown extent. Moreover, the plastic deformations disappear in due course of time, and are not in any sense permanent, except when the elastic limit has been exceeded. Bach reports[39] bending tests on wooden beams, which, when stressed to 2 100 lb. per sq. in. for 1.5 min., showed a remanent deflection of 0.10 mm. when the load was removed. After 22 hours of continuous loading, the remanent deflection was 0.34 mm. immediately after the load was removed, and 51 hours later this deflection had decreased to 0.14 mm. Tests on other wooden beams showed that this decrease in the remanent deflection was still going on after 162 hours of no load.

If the stress-strain curve is linear for plastic as well as for elastic deformations, Hooke's law applies, and the time factor affects the deformations but not the load stresses. The effect of the time factor is then to lower the modulus of

[37] *Bulletin No. 5*, Structural Materials Research Laboratory, Lewis Inst., Chicago, Ill., 1920, p. 88.

[38] "Elasticität und Festigkeit," p. 84.

[39] *Loc cit.*, p. 111.

elasticity and to decrease—very materially—the temperature stresses, since these are not suddenly applied. In order to investigate indeterminate structures properly, one would need to know the deformation as a function of the variable stress and time, and this function would probably be so complicated and its determination so uncertain, judging from the disagreement between authorities regarding the ordinary modulus of elasticity, that engineers would have to rely upon some approximate and simple function, such as Hooke's law, modified by the introduction of a time effect, such as the author suggests.

C. A. P. TURNER,[40] M. AM. SOC. C. E. (by letter).—Experience has led the writer to suppose that plastic flow after the removal of the forms was so small as to be incapable of determination by measurement with an ordinary 20-in. level. Mr. Straub apparently computes the plastic deflection of a 140-ft. arch as 3 in.; and a 300-ft. arch of like relative dimension should be in the neighborhood of 6 in. for a time-flow period of more than 1 000 days.

For the purpose of making some independent observations, the writer ran a line of levels on a series of thirteen concrete arches that had been standing for about five years. Each has a rise of 1 to 4 and a span length, from center to center, of 304 ft. The third, eighth, ninth, and tenth spans differed little from the design grade. In other words, the floor was practically straight regardless of the fact that the levels were taken at a temperature 10 or 15° below freezing. Other spans were not quite as close to grade on the curb line, but, since the curb was not exactly true, the total variation of ½ in. ± was not to be wondered at. The conclusions from these levels are as follows:

1.—That plastic flow capable of being measured definitely by a Y-level has not occurred in these thirteen spans.

2.—That, with a rise of 1:4, temperature changes affect the floor alignment only a negligible amount, although they may result in some slight difference in the elevation of the end abutments and the intermediate spans under wide ranges of temperature.

3.—That because the elevation and alignment of the floor were determined during construction by a 20-in. level, any alleged computation of changes of level which cannot be measured by the same instrument are either imaginary or without practical value.

4.—That the inadmissibility of the proposed theory from the practical standpoint arises from the misleading nature of the laboratory experiments upon which Mr. Straub founded his painstaking algebraic work.

Messrs. E. B. Smith, F. R. McMillan, and A. H. Fuller and C. C. More were mistaken in supposing they had discovered a general phenomenon of plastic flow in concrete as applied to the practical structure. They had merely misinterpreted the law of static equilibrium of internal stress in its various manifestations.

Nearly all materials used for construction purposes are in a state of internal strain. These are of two kinds, residual and elastic. Static permanence of form subsists as long as internal elastic and residual strains are in equi-

[40] Cons. Engr., Minneapolis, Minn.

librium. Any cause upsetting this equilibrium is accompanied by a change in form and external dimensions of the specimen. Thus, a steel bar as received from the mill has been squeezed between the rolls and it leaves the mill in a state of internal strain. Cutting a series of saw kerfs across the top or bottom of the bar as it passed through the rolls will cause a slight curvature along the length of the bar. Similar treatment of bars bent cold in a horseshoe shape discloses the opposite nature of reactions of residual and elastic strain. This enables observers to account for the elevation of the primitive yield point of steel under over-strain and to dismiss fatigue as a phenomenon of residual strain unrelated to elastic stress and the selection of working stresses in rational design.

Contrary to algebraic theory, range of stress from tension to compression of a moderate amount, so far from injuring sound metal improves its elasticity, ductility, and tenacity as found by Bauschinger. This is brought about by the gradual elimination of residual strain by the work of the applied loads. The increase of the elastic constants is limited to 5% for $E$, nearly 20% for $K$, and no change in the modulus for shear.

Temperature change tends to reduce or eliminate residual strain and likewise also range of stress of moderate intensity. Conversely, range of stress greater than five-eighths the primitive yield point increases or accumulates residual strain raising the yield point value.

The resistance of concrete follows the same statical principles involved in the discussion of steel. The 3 by 24-in. cylinders tested by Smith present equal cross-sectional areas subject to the rapid curing of the surface on the one hand and the slower hardening of the interior on the other. This condition differs widely from the 72 to 100-in. square sections of the arch, in which the surface effects are almost negligible.

Laboratory specimens, therefore, disclose a change of form accompanying the redistribution of internal strain which is practically wanting in larger cross-sections, as evidenced by the survey of the 300-ft. arches previously mentioned.

Briquettes cured in water for two or three years present tensile resistance equal to those cured in the dry if tested immediately; but if kept until half dried the resistance may be reduced 50 per cent. When fully dried, the resistance is restored, thus throwing some light on the time tests of Messrs. Fuller and More.

The residual strain in the McMillan tests arises from a different cause. In the initial crystallization of concrete, expansion takes place, inducing tension in the embedded steel. If the rods are as small as $\frac{3}{4}$ in. or less the tension as measured may be 7 000 to 10 000 lb. per sq. in. This tension in steel induces residual compression in the partly cured concrete envelope, having a reaction in residual strain opposite to elastic compression. Shrinkage accompanies the drying out of the concrete with elimination of steel tension, but the residual strain in the concrete remains until otherwise dissipated. Hence, the tensile element of resistance to flexure of the newly cured beam consists of the joint resistance of the residual strain in the concrete plus

some tension in the steel. This residual strain is erroneously treated in textbook theory as direct tension in the concrete. A few repetitions of the load and it is largely dissipated. Temperature changes and time produce a like effect. Hence, the inadmissibility of applying such data to the practical problem of the arch rib.

In "Novum Organum", Bacon insists on clearing the metaphysics of technical science by observation, experiment, and experience. In his classification of the tendencies of the human mind to err he lists, under "Idola Tribus", the proneness of the human mind to suppose in Nature, an order and regularity greater than exists; to support preconceived opinion by affirmative observation, while omitting consideration of negative or opposite phenomena; to generalize from a few observations on the one hand or to give reality to mere abstractions or figments of the mind on the other hand. Under "Idola Theatri", he cites fallacious modes of thinking which from accepted systems of philosophy and erroneous demonstration, leaps to general conclusions.

No line of scientific endeavor needs clearing of the metaphysics of these two classes of error so badly as the common views regarding the elastic resistance of materials. The "Idola Tribus" of this viewpoint appears in the lack of recognition of change of form caused by residual strain under the abstraction of the mind of the research fellow that it is nothing more than a measure of elastic strain.

Readings of deformation under load by an extensometer at the junction of a concrete slab and column are abnormally large. Considering such measurements as elastic strain instead of shrinkage recovery, an observer reached the conclusion that the stress just inside the column was approaching infinity. He stated that, because of this newly discovered fact, in a very short time when the elastic stress finally reached infinity, concrete buildings would fall apart and thus eliminate themselves from the field of competition.

Although shift of load in double bending by the combined action of torsional and bending couples is recognized in the old "Natural Philosophy" of Thomson and Tait, it is unheard of in the standard university textbook of to-day. The wide divergence between bending moment computed from steel stress and applied moment is attributed to the tensile strength[41] of concrete after it is broken in tension.

In line with Bacon's "Idola Theatri", colleges of engineering teach the student the formula of Hooke's law and feel they have accomplished enough in bringing the conception of the young engineer regarding elasticity up to within two centuries of advanced thought in physical science. The application of Hooke's law in flexure is then made by a system of partial differentiation arbitrarily assuming not only that shear strain does not follow Hooke's law, but that it is to be applied only to the horizontal components of the principal stresses, thus fixing the neutral axis at the gravity center of the section instead of at its natural locus along the length of the beam. Upon such half-way application of Hooke's law the student is taught computation of resistance to external shear force near the supports of continuous and simple beams, involving an inconsistency of 200 or 300 per cent.

[41] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1560.

Because longitudinal extension is accompanied by lateral contraction, the student is left in doubt as to whether this lateral deformation involves work. If it does not, is there not something wrong about Hooke's law? And if it does, is not the phenomenon in contravention of the law of conservation of energy? In the absence of instruction in the theory of the thermo-elastic properties of matter these are the confusing doubts which occur to the post-graduate student as observed in the technical press.

Confusion arises from a common but inexact statement that the internal work of deformation equals the external work of the load, when, in fact, this equality is limited to the specific direction of the applied force only. The total internal work is measured by the shift of the intrinsic internal heat energy of vibration from kinetic to potential, or *vice versa*, and is nearly double the external work. Hence, the textbook error in computing temperature stress.

EDWARD GODFREY,[42] M. AM. SOC. C. E. (by letter).—This paper is valuable, not so much because it proposes a new theory for the solution of the arch problem, but because it demonstrates the inapplicability of all elastic theories to concrete arches as well as the practical impossibility of fitting a workable theory to the many sided problem of the concrete arch that will fit accurately into every condition.

For many years the writer has held that the elastic theory is not applicable to concrete or masonry arches.[43] The reason for this is fundamental. In fact, there are many reasons, and they are all fundamental.

The elastic theory pre-supposes a homogeneous and perfectly elastic material in the arch. Concrete is far from homogeneous and far from being perfectly elastic. It would seem superfluous to point out specifically why the elastic theory as applied to the arch required these conditions, but at the expense of appearing pedantic they will be emphasized, for this theory has taken a hold on the profession that seems impossible to shake.

Every engineer knows that to satisfy the elastic theory it is not sufficient that a structure shall show merely what is commonly thought of as elastic properties; that is, it is not sufficient that an arch, for example, can be sprung by a load, and when that load is removed, it will return to approximately the original shape. This, in fact, is all that can be said of a concrete arch. It is about all that was proved by the famous Austrian tests cited by the author. The amount of the spring that "agrees with theory", could be made to agree with many other theories by merely assuming or working out a modulus of elasticity to fit.

The average modulus of elasticity as found by specimen tests, in the Austrian series of tests on blocks, was about 2 700 000 lb. The "practical" value as determined from analysis of a plain concrete arch was 1 430 000 lb.[44] or nearly 100% difference. There were no fixed-ended arches among them. There was a long plain concrete arch and a long Monier arch. These are

[42] Structural Engr., Pittsburgh, Pa.

[43] "Concrete," by Edward Godfrey, M. Am. Soc. C. E., 1908, p. 14; *Transactions*, Am. Soc. C. E., Vol. LXX (1910), pp. 64–65.

[44] *Engineering News*, April 9, 1896.

the tests which the Engineering Profession points to when the elastic theory is questioned as to its applicability to reinforced concrete arches and on the basis of which fixed-ended arches are confidently designed. Because a plain concrete bow between solid abutments deflected in an elastic curve, reinforced concrete arches between settling abutments are designed with fixed ends.

A uniform load on an arch, and an agreement with a theory in the observed measurements under such load, are far from being sound arguments for the extension of that theory to include unsymmetrical loading. Every engineer knows that a material to be elastic in the meaning of the theory, must be first homogeneous. Some of the Austrian tests were on brick and stone masonry. By no stretch of terms can these be considered homogeneous; hence, agreement with theory means nothing, if that theory is an elastic theory.

Concrete is not homogeneous. The properties of the stones are not the same as those of the mortar. One batch of concrete will differ from another. Interior concrete will differ from exterior concrete. Shrinkage will affect the thin parts more than the thick parts. The unstressed shape of the arch can never be known. When the arch is wet, it will expand, altering the stresses; yet the elastic theory must assume entire homogeneity as well as constancy of condition.

To be elastic the concrete must return to its original shape after being stressed; yet concrete takes a permanent set of an unknown amount and of an amount varying with age and other conditions. It is quite impossible to evaluate these conditions. On this fundamental basis, the elastic theory for arches is eliminated from serious consideration, as Mr. Straub points out.

Fixed-endedness is a vital part of the elastic theory. This means absolutely rigid abutments; it means no horizontal movement and no rotation. Either of these influences varies, materially, the stresses in the arch. Horizontal movement is to be expected in any arch not abutting against vertical rock faces. Rotation, even in an arch of 119 ft. span founded on rock, was reported in a progress report by the Special Committee of the Society on Concrete and Reinforced Concrete Arches.[45]

In still another respect concrete fails to meet the mathematical or engineering criterion of an elastic substance. To be elastic in this sense there must be a constant ratio between stress and strain for all intensities of stress within the allowable limits. This is a fundamental assumption of the elastic theory. Concrete is far from meeting this criterion.

All these fundamental bars to the elastic theory as the solution of the concrete arch problem have been known and emphasized for many years. The elastic theory persists, however, and the most elaborate mathematical computations are carried out on the basis of this theory. There is scarcely any other problem in engineering in which such intricate mathematical processes are utilized. In the face of all the intricacy of the elastic theory and the difficulty of designing an arch by this method it is only to be expected that the advocates should show strong justification for its use and

[45] *Proceedings*, Am. Soc. C. E., March, 1924, Society Affairs, p. 292.

close agreement between theory and fact in the matter of stresses. This, they are unable to do, as repeatedly emphasized by the author.

It will be urged, as it has been, that these objections to the elastic theory are on the high ground of a demand for perfection, that even steel is not perfectly elastic. It is a far cry from the trifling departures from perfect elasticity and perfect fitting of the unstressed steel arch in the position for which it is designed, to the 100% departures from ideal conditions proved to exist in the case of concrete.

There is a psychological hazard in complex theory. The mere application of the theory, the working out of an intricate problem begets a confidence that is not engendered by an approximate method. Factors of safety are cut to finer limits when stress coefficients are worked out to the fifth decimal place (which is not unheard of), based on erroneous premises. When a method of design is frankly set up as an approximation, the designer will naturally take this into account in choosing a factor of safety. The writer has noted factors of safety given in tenths and hundredths (exceeding unity) where the structure that was "safe" had failed. The psychology of engineering may be of as much importance as its mathematics. After all, engineering is not merely the working out of a mathematical problem, no matter how nicely that problem may develop under the solution applied by higher mathematics.

It is of supreme practical importance that designing be simplified where possible. Comparatively few engineers, perhaps less than 1% of the men engaged in designing, could follow the solution of the concrete arch problem by the elastic theory.

One of the principal considerations in the design of an arch is provision in the cross-section of the arch ring for the thrust due to full uniform live load. This is, in fact, the first consideration in point of time. Symmetrical uniform load is not usually the critical condition of loading, however. If full load on an arch were the critical loading, it would matter little what theory were used. Furthermore, it would make little or no difference whether the arch were considered as fixed-ended or hinged-ended. The simplest "row-of-blocks" method would give the same answer as the most complex elastic theory. It is simply a matter of resolving the forces, applied loads, and end reactions, into the proper equilibrium polygon.

Mr. Straub points out the fact that his theory and the elastic theory are in practical agreement for the condition of uniform live loading. It is when unsymmetrical loading and provision for such loading are taken up that the several theories diverge. The author points out that when the real properties of concrete are theoretically taken into account—the non-elastic properties, so to speak—it is not possible to determine the distribution and intensity of stress on a concrete cross-section, given the direct compression and the bending moment. It is necessary in the solution, the auther shows, to know the point of application of the force producing the bending moment. This not only complicates the solution of the problem on the author's proposed theory, but makes it practically impossible to determine the distribution of live load that will constitute the critical condition for design. The fact is that the problem of determining the critical position of live load for maxi-

mum extreme fiber stress introduces such complications into the elastic theory itself that the question is touched upon but lightly in treatises and papers on that subject.

It is significant that arch tests that are used to sustain the elastic theory are not made on critical loading on the arches. It is such testing that would be useful in checking up the theory and furnishing a basis for confidence in it.

The crux of the situation as to concrete arch design centers on the assumption of fixed-endedness, invariably made when the elastic theory is applied. There would be no use whatever for the elastic theory in the design of concrete arches, if the arches were assumed as hinged-ended; and here is another of the anomalies of theoretical engineering. The fixed-endedness of an arch pre-supposes massive, immovable abutments, and yet theoretical treatments of elastic arches gives little or no attention to the proportions of the abutments that are necessary to give the needed rigidity.

It is usually difficult to provide sufficient width, economically, in an abutment to bring the line of thrust within the middle third of the base, assuming the arch to be hinged-ended; and this assumption means a practically fixed line of thrust through the abutment. By the methods of the elastic theory the line of thrust through the abutment for unsymmetrical load, may strike through the upper edge. A large and sometimes prohibitive addition in the mass of the abutment, would be demanded, if this were properly taken into account. The extra concrete required in this case to give the abutment its needed stability far outweighs the saving of a few inches in the thickness of the arch ring which, theoretically, is effected by the methods of the elastic theory and assumed fixed-endedness.

J. H. GRIFFITH,[46] M. AM. SOC. C. E. (by letter).—The writer is impressed with the fundamental character of this paper and by the fact that much thought and careful study have been given to its preparation. Apart from the author's elaboration of his thesis he calls attention from time to time to the disparities existing between the scientific and technologic viewpoints in interpretations of the phenomena of elasticity, plasticity, viscosity, and other properties of matter. Notwithstanding the profound researches upon the subjects by Dr. Eugene Cook Bingham and by Charles Terzaghi, M. Am. Soc. C. E., the author feels the questions at issue are mooted ones. The writer would like to discuss more particularly in this connection some of the divergencies between scientific and technologic opinions with the view to a reconciliation. Without a certain unity and purpose little progress can be made in research work. It may be stated that the writer's recent research has been limited largely to studies of the phenomena of earth resistance. In this case, however, the anomalous behaviors encountered in studies of the phenomena of plasticity and viscosity are rather more pronounced than those which usually occur in the instances of concrete, freshly quarried rock, or green timber.

Maxwell's definitions upon the fundamental properties of matter under consideration are pertinent to the discussion; he remarks:[47]

[46] Prof. of Experimental Eng., Iowa State Coll., Ames, Iowa.

[47] "Theory of Heat," p. 295.

"Suppose that stresses of the same kind, but of continuously increasing magnitude, are applied to a body in succession, as long as it returns to its original form when the stress is removed, it is said to be perfectly elastic. If the form of the body is found to be permanently altered when the stress exceeds a certain value, the body is said to be soft or plastic, and the state of the body when the alteration is just going to take place is called the limit of perfect elasticity. If the stress be increased till the body breaks, or gives way altogether, the value of the stress is called the strength of the body for that kind of stress. If breaking takes place before there is any permanent alteration of form, the body is said to be brittle. If the stress when it is maintained constant causes a strain or a displacement in the body which increases continually with the time, the substance is said to be viscous. When this continuous alteration of form is only produced by stresses exceeding a certain value, the substance is called a solid, however soft it may be. When the very smallest stress if continued long enough will cause a constantly increasing change of form the body must be regarded as a viscous fluid, however hard it may be. Thus, a tallow candle is much softer than a stick of sealing wax: but if the candle and the stick of sealing wax are laid between two horizontal supports, the sealing wax will in a few weeks of summer bend with its own weight while the candle remains straight. The candle is therefore a soft solid, and the sealing wax is a viscous fluid."

From the critical viewpoint, it is natural to ask: "Is concrete a viscous fluid or a plastic solid?" According to the author's intimation concrete has no sensible elastic limit except it be that at the origin of the stress-strain curve, these curves being usually drawn continuously concave toward the axis, which is commonly taken horizontal. If concrete is a plastic solid as implied in the author's title, then according to Maxwell's definition, as mentioned, it should have a sensible elastic limit differing from that at the origin, which, however, the standard treatises do not show. This fact is tacitly admitted by the author in his citation relating to Bach's researches.

The writer has found in his own researches that if the test load is applied slowly enough on cylinders of earth taken from their natural beds, the stress-strain curves from the data are similar to those of concrete and cast iron in that they are continuously curved toward the strain axis. When the stress-strain readings, however, are taken quickly, but without appreciable impact, say, in the space of 15 to 30 sec., there is a sensible elastic limit, with the stress-strain curves ensuing in a manner quite similar to those found for steel columns.[48] On the other hand, in the case of steel columns, when considerable refinement is used in making the strain measurements, there is not, strictly speaking, a perfectly constant modulus of elasticity, nor a true elastic limit for steel. The existence of these functions is more or less a relative matter, and is conditioned to a large extent by the time-rate of application of the load. One of the great educational advantages in observing earths, apart from the immediate technologic needs, is that, being a "visco-elastic" material, the behavior of earth shows in a magnified way what may be expected to occur in other apparent matters so that an investigator can often anticipate phenomena and properly interpret them dynamically. A perfectly elastic matter, so-called, gives a specific and limited rather than a general behavior exhibiting all the properties of matter. A good illustration of that is afforded in the instance of

[48] See *Technologic Paper No. 101*, U. S. Bureau of Standards, for curves.

heterotropic crystals compared with isotropic or amorphous matter, such as many soils.

Researches by Dr. Abram F. Joffé, of Leningrad,[49] a collaborator of Röntgen, have a direct bearing upon most of the points under discussion. His researches upon atomic and crystal structure substantiate the opinions which have long been held as to the approximate nature of Hooke's law of proportionality of stress to strain. He sustains the judgment of George Green,[50] with Cauchy, one of the recognized founders of the theory of elasticity, and of Boussinesq, who conceived the importance of developing stress functions in series as considered later. Boussinesq[51] developed many functions in series. He regarded ordinary matter as an intermediate type between the so-called perfect fluid and perfect solid. He so arranged his functions[52] that this intermediate matter would merge with the perfectly continuous matter of the theory of elasticity as an extreme case. Dr. Joffé gives many interesting statements bearing upon Hooke's law and the so-called elastic after-effect. In one instance he was in some doubt as to whether the particular type of crystal could be considered as a solid. His remarks on the relation of the elastic after-effect to hysteresis should be considered in connection with the author's interpretation of the phenomenon.

Many of Dr. Joffé's observed phenomena studied by means of the X-ray spectrometer and electrical processes may be observed upon the macro-structures as well. It is known from the strain measurements conducted at the Washington Monument by the late Dr. Becker and Dr. Van Orstrand[53] that steel is in a continual state of flux, the observations being conditioned by the intensity of loading, its rates of application, and the degrees of magnifications of the different strains. It is also a fact of experience that both green and seasoned timber flows continually an infinitesimal amount with the time. On account of this it is necessary for the U. S. Forest Service to adopt certain rates of deformation in order that test data on timber may be properly interpreted and compensated. It is shown by Withey and Aston[54] that a maximum strength of 100% on long leaf yellow pine timber, under momentary or short-time loading, will be reduced to only about five-eighths of the value with a continuous application of the loading for a period of 700 hours.

The writer has observed in his own researches that earths cut from the natural beds flow continually in almost imperceptible, but easily measurable, amounts. This flow continues for many days without reaching statical stability when the viscous sub-matrix or "binder" ceases to function from a complete "grain gearing" under the applied load. When there is complete particle gearing, twelve particles are in contact around a particle nucleus, as in the case of annealed glass, and in conformity with the structures of granular

matter discussed by Dean C. S. Slichter[55] and the late Professor Osborne Reynolds[56] for the different orders of matter considered in their respective fields of investigation. In the case of experimental piles sunk into the earth there is a tendency for the pile to resume the unstrained position after the load is removed if time is given. It is also well known that when proof loads are applied to steel and cast-iron members well within the elastic limit the stress-strain curves tend to straighten conformably to Joffé's observations and presumably owing to the fact that the crystals of the metal tend to approach the configuration of maximum density already cited.

If matter flows very slowly, but still perceptibly, like a glacier, with the phenomenon of flow occurring from the beginning of the time of stressing, it would seem appropriate, in the writer's opinion, that the behavior should be called viscous instead of a plastic phenomenon in accordance with the scientific nomenclature. It is questionable whether this flow should be regarded as hysteresis according to the author's point of view, which is the lag experienced in the case of cyclic stress and similar phenomena in other fields of science. The supposition of a truly reversible process in any of Nature's laws is, of course, a purely analytical fiction made for convenience mathematically. One may accept it as an induction of experience that there is always some degree of dissipation of energy. In the extreme case of light transmission, Professor Osborne Reynolds reached the conclusion that the viscous dissipation is sufficient to reduce the total wave energy to one-eighth in 56 000 000 years.[57]

The phenomenon of a flux of matter disappears entirely when there is an absence of the viscous sub-matrix in the particle interspaces which possesses the nature of a grain lubricant. This occurs in the case of dry sand and gravel under pressure partly from the particles getting on dead centers, as in the case sometimes occurring for locomotive drivers, and partly from the building up of frictions under loading. According to Boussinesq the particles gain an elasticity of bulk. The writer demonstrated this by loading tracing cloth cylinders, 4 in. in diameter by 14 in. high, filled with gravel and tested to destruction. The cylinders became as hard as flint as the grain frictions built up under loads of 800 to 900 lb., thus affording a good hypothesis as to why tool steels harden when heated above the critical range of temperature and are quenched in oil or water. The hoop tension supplied by the outer shell of contracting material causes a gain in bulk elasticity from the up-build of pressure and inter-crystal friction.[58]

Inasmuch as the author's criticisms of the theory of elasticity evidently relate to the theory as used by technologists, and there is often a wide discrepancy here between that and the classical theory developed by scientists and engineers, the writer will discuss some of the fundamental principles of the rigorous mathematical theory to correct some of the impressions commonly held. Hooke's law, as the author has shown, should be properly interpreted. This law should be regarded a limiting aspect. It strictly applies

[58] Johnson's "Materials of Construction," Fifth Edition, p. 634.

solely to infinitesimal strains; it does not take cognizance of finite strains as sometimes used by technologists, except to a first and sometimes a very rough approximation as the author remarks in effect. George Green,[59] in formulating his dynamics of potential, conceived that the functions could be developed in power series. The idea is clearly set forth by William H. Burr, M. Am. Soc. C. E., who remarked more than forty years ago:[60]

"It is a matter of experience that strains always vary continuously and in the same direction with the corresponding stresses. Consequently, the stresses are continuously increasing functions of the strain, and any stress may be represented by a series composed of the ascending powers (commencing with the first) of the strains multiplied by proper coefficients. When, as is usually the case, the displacements are very small, the terms of the series whose indices are greater than unity are exceeding small compared with the first term, whose index is unity. These terms may consequently be omitted without essentially changing the value of the expression. Hence, follows what is ordinarily termed * * * Hooke's Law."

Since there is but one fundamental method of analytical continuation known to mathematicians, the various methods used being equivalent to Taylor's, the French mathematician, Boussinesq, proceeded along strictly logical analytical lines in his development of functions by Maclaurin's well-known formula, this being a special case of Taylor's formula, in handling the finite displacements of granular materials. A good illustration of such a development is illustrated in Love's development of strains by Taylor's theorem of continuation. For large strains he obtains expressions of the types:[61]

$$(\delta_{xx}) = \frac{\partial \mu}{\partial x} + \frac{1}{2}\left[\left(\frac{\partial \mu}{\partial x}\right)^2 + \left(\frac{\partial v}{\partial x}\right)^2 + \left(\frac{\partial w}{\partial x}\right)^2\right]$$

$$(g_{yz}) = \frac{\partial w}{\partial y} + \frac{\partial v}{\partial z} + \frac{\partial \mu}{\partial y}\frac{\partial \mu}{\partial z} + \frac{\partial v}{\partial y}\frac{\partial v}{\partial z} + \frac{\partial w}{\partial y}\frac{\partial w}{\partial z}$$

for finite normal and shearing stresses. When the strains are ultimately small in accordance with Professor Burr's description, the higher order derivatives vanish, as he states, leaving the ordinary expressions used by engineers and elasticians, or,

$$\delta_{xx} = \frac{\partial \mu}{\partial x}$$

$$g_{yz} = \frac{\partial w}{\partial y} + \frac{\partial v}{\partial z}$$

Since the author raises the question of the propriety of the usage of initial, tangent, and secant moduli, the writer also calls attention to the fact that Professor Burr gives the correct analytical expression of a modulus as the derivative of stress with respect to strain. This may be constant for a plastic material below the elastic limit; it is a variable for viscous materials generally and for plastic materials above the elastic limit. From the critical standpoint the modulus must also be defined with respect to the state of matter existing. For example, the late Professor William Kent when discussing

[59] "The Mathematical Theory of Elasticity," A. E. H. Love, Fourth Edition, pp. 11–12.

[61] *Loc. cit.*, p. 60.

thermo-dynamic relations in his well-known "Mechanical Engineers' Handbook", treats the subject of moduli at constant pressures and at constant volumes; but since a scientist must deal with a number of variants in defining the states of matter in conformity with such well-known laws as Willard Gibbs' phase relation, van der Waal's, Berthelot's, Keyes', and the hundred others proposed,[62] it is correct to speak of moduli at constant temperatures, at constant density, or in terms of chemical composition, three states usually being sufficient. In the theory of earth resistance the pressure and density are the important variants. In the correct usages of the theory of elasticity as distinguished from the many nascent soil theories being proposed it is necessary to use a number of variants; pressure, volume, temperature, density, and chemical variants arise as instanced in the case of simultaneous water, ice, and steam phases. Kelvin and Kirchhoff were particularly concerned with isothermal and adiabatic straining in defining the existence of a potential function.[63]

The author's exponential functions for stress-strain relations and time-yields are of the nature of pioneer work; such relations have the support of C. Bach and other German authorities. G. S. Williams, M. Am. Soc. C. E., and A. N. Talbot, Past-President, Am. Soc. C. E., have made considerable use of expressions of this kind notwithstanding their empirical forms. There is a deviation here to be noticed between the author's types of empirical equations and those of the rigorous theory of elasticity. The rigorous expressions are the well-known equations of motion (or rest in particular) of the theory of elasticity.[64] They are analytically equivalent to Newton's second law, force = mass $\times$ acceleration, resolved along the particular co-ordinate axes chosen. The labor involved whether by Mr. Straub's analyses or those of the theory of elasticity is relatively enormous. The plan used extensively by the writer in laboratory measurements has been to make direct correlations of the experimental data with those of the theory of elasticity on the various types of structures studied either by the approximate or rigorous methods. One way of proceeding is to measure the functions and reduce them to empirical laws for provisional use, following Newton's plan of "no hypotheses". By the ordinary process of curve fitting, using the theory of elasticity as the limiting case, the true relations are discovered. This is similar to the curve-fitting in the theory of columns, in which Euler's theory and the short column formula are limiting cases to fulfill. The method is really what Poincare in his "Theory of Potential" calls a sweeping-out process ("méthode du balayage"); in other words it is one of successive approximations. The laws found, however, are laws in fact of the kind mentioned by Halbert P. Gillette, M. Am. Soc. C. E.;[65] they agree with the observations and satisfy the equation of motion. Attention should be paid to the fact that the author has developed the right-hand members of the equations of motions

[62] Washburn's "Principles of Physical Chemistry," Second Edition, see Index.

[63] Perry's "Applied Mechanics," Chapter 15, pp. 366–367. In the author's case the strain is in effect applied at constant temperature, volume, and composition, so that the modulus should be defined at constant pressure and constant density.

[64] "The Mathematical Theory of Elasticity," A. E. H. Love, Fourth Edition, Chapter XXI, p. 451, also Chapter XVIII.

[65] *Engineering and Contracting*, March, 1929, p. 109, third column.

or rather the primitive deflections which must be differentiated twice in getting the accelerations, subject to the conditions that his functions must be continuous. When the functions are not absolutely continuous as often occurs in practice they are "smoothed-out" to make them so. As far as the experimental methods are concerned, that of G. E. Beggs, M. Am. Soc. C. E., which is suggestive of the older barrel-hoop method of Eads, leaves little to be desired. Love gives the kinds of equations needed for the arch.[66] Cylindrical co-ordinates are usually the simplest to use.

In working out correlations with dynamics according to the no-hypothesis method of Newton, it often helps to keep in mind the doctrine of self-similitude enunciated by his contemporary, Swedenborg.[67] As a simple example it may be mentioned that the single potential function, $\frac{1}{r}$ ($r$ = distance from body to point), is fundamental in the theories of astronomy, earth resistance, elasticity, and hydrodynamics, in Osborne Reynold's theory of attraction, and in Dr. Joffé's theory of the atom in which direct correlations are carried out consonant with the writer's plan of no-hypotheses.[68]

CHARLES W. COMSTOCK,[69] M. AM. SOC. C. E. (by letter).—In this paper the author has considered (and to some extent confused) two questions which, in general, are unrelated, namely, the stress-strain relation and the plasticity of materials. The material specifically referred to throughout the paper is concrete but, except for numerical values of certain constants, no reason appears why the arguments should not apply equally to all structural materials.

Rather more than one-half the paper deals with "the proposed theory of elasticity" and illustrative applications. Here, the author has steered wide of Scylla only to be engulfed by Charybdis. He rejects the linear stress-strain relation, but accepts without question the old Bernouilli hypothesis of conservation of plane sections, which not only has no theoretical or experimental justification, but is known to be incorrect except where there is no shear.

This important point is treated very casually. The author attempts no justification of the hypothesis, nor does he write as if he regarded it at all seriously. For example, he states:

"From Fig. 6(*b*), it may be seen that, assuming conservation of plane sections during bending,

$$\varepsilon_z = z \frac{d\,\phi_E}{d\,s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)"$$

There is no other reference to it in the text. Figs. 6(*b*), 8(*a*), 16(*b*), and 17(*b*), indicate that the deformation is considered as a simple rotation of plane sections about their respective axes, the positions of which are to be determined. As to Fig. 16(*b*), the assumption is probably correct since there is no shear; as to the others, and, in general, it is not true.

[69] New York, N. Y.

Having selected this starting point the author has thenceforth followed the conventional and usual routine for the analysis of arches, merely substituting for the linear stress-strain relation the exponential relation which was first suggested by Bach as a consequence of his experiments on cast iron.

There is no occasion to comment on the algebraic transformations which lead ultimately to Equations (32). These can contain no more truth than does the assumption on which the entire analysis is founded. It would seem that the author has been misled by the increased complexity of his formulas into expectation of correspondingly greater precision. This is a not infrequent misconception.

The "proposed theory of plasticity" is a repetition of the proposed theory of elasticity with the introduction of a time factor which, however, runs unchanged through the entire analysis to re-appear in Equations (62) just as originally introduced in Equation (34).

It is not clear why the "elastic" and "plastic" deformations should have been separated. Assuming the stress-strain relation known it is of no importance whether or not the whole or any part of the strain disappears on removal of the applied forces. The stress distribution is the same in any case.

The expression, "theory of elasticity," originated at a time when somewhat limited experimental data indicated that small strains were elastic in the ordinary sense of the word, and that such strains were directly proportional to the respective stresses.

The mathematical theory of elasticity is a highly developed branch of mathematical physics, singularly free from the speculations and incongruities which permeate so much of modern physical theory. Its fundamental differential equations rest directly on the laws of statics and are no more questionable. In passing from stress to strain it is always carefully stated that linear relationship is assumed. No other assumptions are made. The theory has been extensively and intensively developed through the past hundred years and has been logically set forth in many scholarly treatises in all languages, so that there is now no reason why any interested person should be unfamiliar with its possibilities or its limitations. It is equally true whether or not there exists any real material for which the stress-strain relation is linear.

Most of the alleged defects of this theory are chargeable, not to inadequacy of the theory itself, but to its attempted application outside its ostensible field or, more often, to the injection of unjustified and unjustifiable hypotheses.

If one has to deal with a material for which the stress-strain relation is known to be other than linear, the difficulties are enormously increased, but no progress can be made by the assumption of stress or strain distributions which do not fulfill the fundamental conditions of the problem.

The equations applicable to a particular problem are sometimes extremely involved. Many years ago the writer convinced himself that, at least in part, this was because of the large number of variables resulting from the use of three components of each magnitude. In view of the directional character of both stress and strain it seemed that quaternion analysis should be an

improvement over the usual method of Cartesian co-ordinates. This the writer attempted with some degree of success. The results were not all that were hoped for, but they were encouraging, and it is still believed that Sir William Rowan Hamilton's brilliant conception will afford solutions which have baffled the more common mathematical methods.

It is not clear why the author should have selected 1.3 as his value of $m$. Mr. Straub states: "Data obtained from typical experiments by Dr. E. Probst have been used by the writer as a basis for analysis in the basic equation * * *." He then gives equations in which $m$ for compression is 1.105, and for tension, 1.03; yet in all his numerical illustrations he uses $m = 1.3$.

Likewise with respect to $p$; from the experiments of Mr. Earl B. Smith he finds $p = 1.73$, while from the observations of Freyssinet he concludes, after making an assumption as to shrinkage during setting, that $p = 1.25$. However, he uses 1.3 for numerical illustrations.

As regards $q$, he finds from the work of Messrs. Fuller and More the value, 0.42, from Smith's experiments, 0.18, and from Freyssinet's observations, after a questionable allowance for shrinkage, 0.40.

Unless the author has a mass of experimental data not cited in his paper, his choice of numerical values would appear to rest on a rather flimsy foundation. If he has such data, full presentation of them, together with the reasoning process by which he determines the most probable values of the constants for use in his formulas, would certainly be of quite as much interest as the formulas themselves.

The form of the author's Equation (34) is open to question. In accordance with it, deformation under any stress whatever must increase progressively for all time, and should end in failure of the structure. It is doubtful whether this conclusion will find general acceptance.

Even if it is true that strain is a function of both stress and time, it is not clear on what ground the author justifies the assumption that it may be expressed as the product of two functions, one of stress only and the other of time alone.

For concrete, of which the properties certainly change with time, at least during its early history, a more probable assumption would be Equation (33), in which, $m$ should be a function of the time. The form of the function, $m$, should be such that it would become practically constant after a finite lapse of time.

It is doubtful if there exist to-day sufficient data of adequate precision to justify an attempt to formulate the stress-strain-time relation for concrete.

The conclusions drawn by the author are based on his formulas. These, in turn, rest on the false hypothesis of conservation of plane sections and on insufficiently established stress-strain-time relations. The conclusions may be true, but they are not proved.

A. A. EREMIN,[70] ASSOC. M. AM. SOC. C. E. (by letter).—This paper, by giving consideration to the natural behavior of concrete, is a step forward in the design of concrete arches. The subject is well treated and

[70] Asst. Designing Engr., Bridge Dept., State Highway Comm., Sacramento, Calif.

the development of the formulas is clear and can be easily followed. There are, however, a few phases that could be discussed and possibly extended.

It has been known for a long time that strain is not proportional to stress in such materials as concrete, stone, and cast iron; or, in other words, they do not follow Hooke's law. In 1896, C. Bach[71] published a paper on the variable modulus of elasticity for concrete at different stresses. Many attempts have been made since that time to develop the formulas for structural members with variable moduli of elasticity. Even for a beam with simple loading, the time required for the calculation of the stresses by means of these formulas, was prohibitive. Bach[72] proved that, in the formulas containing the variable moduli of elasticity, the position of the neutral axis varies with the stresses and also with the change in the external concentrated loads and bending moments.

Max Ritter[73] analyzed an arch by the ordinary elastic method with the constant modulus of elasticity and also by the method with the variable modulus of elasticity, using the exponential expression for strain similar to that used by the author. In conclusion, he stated that for the arch in which no tension occurs there is no practical difference in the stress obtained whether a constant or a variable modulus of elasticity was used. This supports the author's conclusion that "for smaller structures the usual procedure for stress analysis is probably satisfactory". It is interesting to note that Ritter in his study of arch stresses limited his conclusion to the arches in which no tension occurs because, like Mr. Straub, in the formulas for variable modulus of elasticity, he assumed that the exponential expression for strain of concrete in tension is the same as in compression. This assumption greatly simplifies the calculations although, at the same time, the formulas developed cannot be used for pure bending stresses without appreciable error.

The actual stress diagram in the plain concrete in pure bending will be shown by the curved line, $AB$, Fig. 31.[74] When a constant modulus of elasticity is used the stress-strain line will be the straight line, $A'B'$, and the neutral axis will pass through the center of gravity of the section (Fig. 31).

The stress-strain diagram for concrete varies with the grade of cement, aggregate, water ratio of mix, the method of pouring of green concrete, and the age of the concrete. Various curves for the stress-strain diagram due to these factors will be similar, but will show a marked variation in tension and compression, Line $AB$ (Fig. 31).

Some of the European specifications adopted the straight-line variation of the moduli of elasticity of concrete, as shown by the lines, $A''O$ and $OB''$ (Fig. 31). This is somewhat nearer the actual stress-strain diagram and the constant ratio of the moduli of elasticity in compression and tension, simplifying the formulas for stresses. In the general study of elasticity and plastic flow of concrete under pure bending stresses for which numerical values are not essential, the assumption could be made that the modulus of elasticity

[71] "Hütte," des Ingenieurs Taschenbuch, 1, 1920, p. 500.
[72] "Elasticität und Festigkeit," 1911, p. 236.
[73] *Schweizerische Bauzeitung*, January, 1907, p. 25.
[74] "Strength of Materials," by Prof. S. P. Timoshenko, Russian Edition, 1916, p. 234.

of concrete in tension varies at the same rate as in compression, since this permits considerable reduction in the formulas.

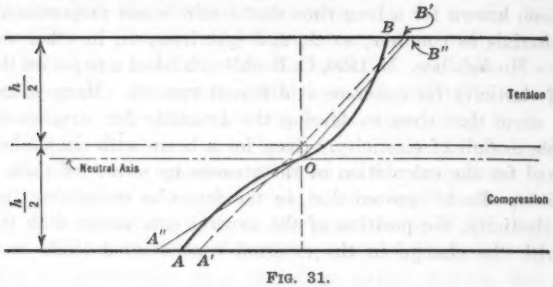

FIG. 31.

In the author's "First Conclusion" he states that:

"It is incorrect to assume that in general plastic flow in statically indeterminate concrete structures causes a redistribution of bending moments tending to relieve the overstressed parts of the structures."

The overstressed part of a statically indeterminate structure is distinguished by excessive deformation which will affect other parts of the structure similar to some external disturbances which were discussed by the author in his "Second Conclusion".

Take, for instance, a beam with one end fixed and the other end simply supported, as shown by the author in Fig. 21. The overstressed part in the middle of the span will produce excessive deflection of the beam, and, at the same time, the reversed bending moment at the fixed end will be increased. Due to plastic flow, a redistribution of the stresses will occur, similar to that caused by the settlement of a support.

Kern analyzed a concrete arch with fixed ends and found that the resultant stresses due to dead load, rib-shortening, and temperature changes, computed by his method[75] with variable moduli of elasticity, are smaller than those computed by the ordinary method with constant moduli of elasticity. He thus proved the author's "Conclusion" that temperature "stresses computed by the ordinary elastic theory are * * * on the side of safety."

In conclusion, it may be stated that Mr. Straub has made a valuable contribution to engineering literature, and that further theoretical and experimental study of elasticity and plastic flow of concrete arches is highly desirable.

DR. ING. J. MELAN[76] (by letter).—In applying the elastic theory based on Hooke's law to the design of concrete structures, it is recognized that only approximate values of deformations and stresses are obtained. The assumed proportionality between deformation, or shortening, and stress actually does not exist in materials used for masonry structures: First, because the ratio of stress to strain is not a straight-line relation; that is, the modulus of elasticity

[75] *Beton u. Eisen*, 1930, p. 29.
[76] Tech. Univ. of Prag, Prag, Czecho-Slovakia.

is not constant for all stress intervals; and, second, because permanent plastic deformations occur which are dependent on the age of the concrete and the period of loading. The inaccuracy of computation is less, however, the longer the concrete is allowed to set before it is loaded.

It is not easy to set up mathematical laws accounting for the stress-deformation relations of concrete. Hence, the treatment given this subject by Mr. Straub who proposes such relations, is of particular interest.

As a basis for elastic deformation, he uses the Bach-Schüle law, $\epsilon = k\,\sigma^m$, and for plastic deformation he develops another equation of the exponential type as follows, $\rho = K\,\sigma^p\,t^q$, in which, the deformation is a function of the stress, $\sigma$, and the time, $t$. According to available data for time-yield experiments, although these are few, this assumption seems to define the law of plastic deformation for concrete quite well. The coefficient and exponents are dependent on the composition of the concrete and its age.

The theory derived for fixed-ended continuous arches based on the foregoing equations is mathematically sound, assuming that plane sections remain plane and if the arch undergoes only compressive stresses, and no tensile stresses or only small ones, as a result of the loading and deformation. With these stipulations, the conclusions drawn by the author are also correct. However, the conclusion that the early removal of centering from a reinforced concrete arch is advantageous to the structure, cannot be accepted without reservation. It has not been demonstrated in practice, and conflicts with the rules of construction maintained to the present time, deviation from which may prove to be a dangerous venture.

In any case, Mr. Straub's treatment provides a valuable and meritorious supplement to, and a more thorough analysis of, the theory of concrete arches.

FREDRIK VOGT,[17] ASSOC. M. AM. SOC. C. E., and HERBERT J. GILKEY,[18] M. AM. SOC. C. E. (by letter).—The author concludes his paper with the words:

"Much more experimental work, especially of a quantitative nature, is desirable and necessary in order to establish definitely the laws of plastic flow for concrete of various mixes and ages."

This is doubtless true, and for that reason the development of an imposing mathematical analysis upon assumptions of questionable validity appears to be premature at this time. Important problems regarding the qualitative as well as the quantitative nature of flow are still unsolved.

To what extent, for example, is flow plastic and to what extent is it elastic? Most structural materials have a distinct elastic recovery when a stress of any intensity is released. Professor F. B. Seely[19] alludes to the energy of this elastic recoverance as hyper-elastic resilience, as distinguished from elastic resilience (to which the term, resilience, is generally applied). Concrete has this same power of partial recovery within all ranges of stress. That it exists to an appreciable extent, there is no question.

For dead-load stresses the elastic recovery is of no importance, since there will be no release of load; but it is important in connection with stresses due to

[17] Docent, Norges Tekniske Höiskole, Trondhjem, Norway.
[18] Prof., Civ. Eng., Univ. of Colorado, Boulder, Colo.
[19] "Resistance of Materials," pp. 15 and 361.

temperature changes in statically indeterminate structures since these changes have an annual or a seasonal period.

From observations too limited to generalize other than to state that appreciable recovery is a reality, the writers have found that concrete, after unloading, will immediately recover an amount about equal to the initial elastic deformation. In addition to this first recovery there seems to be a slow additional recovery of part of the flow.

Another unsettled problem is the connection between volumetric changes (shrinkage and swelling) due to moisture changes and the flow due to load. The author states that:

"Shrinkage is distinguished from plastic flow in that it is a change in dimensions independent of external forces acting on the specimen."

Let the change in length of an unloaded specimen at constant temperature be termed shrinkage (or swelling). Then, the difference between this shrinkage and the change in length of a specimen exposed to a continuous load is termed flow. The writers know of no evidence that the flow determined in this way is independent of the shrinkage, or, to go a step further, independent of moisture changes and changes in the fine structure of the concrete, such as re-crystallization, etc. On the contrary, there is some reason for suspecting that there may be a connection between the two phenomena. It is a striking fact that concrete specimens under continuous compressive loading, stored in air, flow several times as much as if stored under water.[80] The writers have described, elsewhere,[81] the result of their own experimental work on the subject. In air, the shrinkage and the compression due to the load co-operate in reducing the length, while in water the swelling under water counteracts the compression due to load. The influence of the load taken separately, that is, the flow, is several times as great in the case of co-operation with shrinkage as it is when counteracted by swelling, even after the direct shrinkage and swelling (as determined from unloaded specimens) have been deducted.

While the difference is due in part no doubt to the difference in physical condition, it seems possible and probable that the loaded or unloaded state in combination with the dry or wet condition may have a distinctive influence upon such internal phenomena as re-crystallization. Attempts have been made to supplement the available information by duplicate tests under continuous tensile loading in both air and water. The tensile flow tests have not been satisfactory on account of the low range of strain that is available in tension. It is to be noted that, with moduli of elasticity nearly equal in tension and compression, and the ultimate tensile strength about one-tenth the ultimate compressive strength, the tensile deformation available is only about one-tenth of that for compression.

Bending of beams under continuous loading was easier to handle and gave results that were in all respects similar to those obtained in compression. The beams represent a mixed condition with both tension and compression present, and the results are, therefore, more difficult to interpret.

[80] See the experiments made by R. E. Davis, M. Am. Soc. C. E., Report on Arch Dam Investigation, *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 211.

[81] *Proceedings*, Am. Soc. for Testing Materials, Vol. 29, Pt. II, 1929, p. 706.

If the flow and shrinkage or swelling are interrelated and interdependent, the fact will have an important bearing upon the stresses due to flow. This is particularly true in bending and where temperature alternates the stresses. It also has a bearing on the question of recovery.

The author has based his deductions on a formula for the total deformation,

$$\varepsilon_{\text{total}} = \varepsilon + \rho = k\,\sigma^m + K\,\sigma^p\,t^q \quad \ldots\ldots\ldots\ldots\ldots\ldots (116)$$

as an extension of the Bach-Schüle exponential formula for the initial deformation given by the first term.

The Bach-Schüle formula gives a fair approximation to the stress-strain diagram for high stresses, but it is well known that it is not valid for low stresses. For example, with $\sigma$ approximating zero, the exponential formula gives moduli of elasticity, $E$, approaching infinitely large values if $m$ is greater than unity, as it is for concrete.[82] This result is not in agreement with experience and greatly limits the formula in its application. Similar limitations are probably applicable to the second term. It is more important that the exponential term, $t^q$, with $q$ positive, shall give an ever-increasing flow which approaches no limit or stopping point. The factor, $t^q$, reaches infinitely high values with increasing age. As a result, an arch bridge, according to the formula, would deflect until it was flattened to the point of failure. Obviously this does not happen, and the law must be different even if the formula gives a fair approximation during the first few weeks or months. In Fig. 14 the check with some experimental results is shown for a period of less than five months, but this does not justify the use of the formula for a period of more than nine years, as was done in Fig. 24. Nor has the author limited his analysis to nine years; he has extended it until the time interval becomes infinite as regards the point of contraflexure for the beam with which he deals. In other words, he has extended it until the deflection, according to his formula, also becomes infinite.

The author's "Second Conclusion" states:

"If there is an external disturbance * * *, such as the settlement of a support, the plastic flow causes a gradual redistribution of stresses such that the structure approaches (but never reaches) its original state of equilibrium (no settlement of support)".

This conclusion results from assuming a flow which will cause the modulus of elasticity to approach zero as time goes on. With a secant modulus,

$$E = \frac{\sigma}{\varepsilon} = \frac{\sigma}{k\,\sigma^m + K\,\sigma^p\,t^q} = \frac{1}{k\,\sigma^{m-1} + K\,\sigma^{p-1}\,t^q} \quad \ldots\ldots\ldots (117)$$

and, with $q$ positive, $E$ approaches zero as $t$ becomes infinitely great. Thus, the deformation due to a given load increases indefinitely with time, and the effect of initial external disturbances becomes smaller and smaller in comparison with the increasing strains from the regular or primary loading. Finally, they become relatively so small that their influence may be considered to be negligible.

[82] Compare, for instance, the German Handbook, "Hütte," Vol. I, Twenty-fifth Edition, p. 541.

Conclusion 2 can only be reached on the basis of the assumed formula for flow. If the flow does not actually increase indefinitely, but if instead it approaches a limiting value, $E$ will remain a finite value, and the result will be entirely different. If, for example, the flow increases the deformation to three times the initial value, then the influence of the settlement of a support on the stresses will be reduced to one-third of what it was at first, but not to zero since the deformation due to the settlement can be eliminated by one-third of the initial force. Compared with this major result the influence of small deviations from the straight stress-strain diagram becomes unimportant.

As stated by the author, the temperature changes and shrinkage are among those external disturbances the influence of which is reduced by the flow. However, this is only true for slow temperature changes and not for rapid or moderately rapid changes. Of course, annual fluctuations cannot receive the benefit of the flow during more than a few months since their action is reversed.

That the flow does decrease with time is shown quite conclusively by the Davis and Troxell experiments.[83] These tests show that the flow is asymptotic and that it follows the exponential formula expressed by the author for only a short time. This result is also supported by the experiments of the writers, of which previous mention was made.

The experiments by Professor Davis, already mentioned, indicate that the tendency of flow is to straighten out or flatten the stress-strain diagram where the initial deformation shows a modulus of elasticity, $E$, decreasing with increasing stress, or where the exponent, $m$, is greater than unity in the Bach-Schüle formula. In Table 28[84] of the report of the Committee of Engineering Foundation on Arch Dam Investigation, Column (10) gives the ratio of flow to initial elastic deformation. Within each group the ratio is, generally speaking, lower for high stresses than for low ones and the original curving of the stress-strain diagram (decreasing $E$ with increasing stress) is counteracted to some extent by the flow. The effect of flow is to reduce to a smaller, but more constant, value of $E$. Experiments made by the writers support these findings. If they are correct, the conception of stresses and changes of stresses due to flow and the effect of flow on the stresses can be stated rather simply: If the flow gives a total deformation approximately proportional to the stress and greater than the initial deformation (that is, if $E$ is lowered by the flow and the stress-strain diagram is straightened out), then:

(*a*) The errors in the usual computations caused by the fact that the stress-strain diagram is not straight, as usually assumed, are reduced by the flow. Particularly in compression, such as in arched bridges, the original error is comparatively small since the stress-strain diagram is fairly straight for compressive working stresses, and the error is on the side of safety.

(*b*) Stresses due to slow temperature changes and shrinkage are reduced due to the flow. They can be computed approximately by assuming a constant value of the modulus of elasticity, but this modulus must include the initial deformation and the flow due to temperature forces; that is, it is lower than

[83] *Proceedings*, Am. Soc. for Testing Materials, Vol. 29, Pt. II, 1929, pp. 695–699.
[84] *Proceedings*, Am. Soc. C. E., May, 1928, Pt. 3, p. 213.

the modulus for short-time tests. The same applies to stresses due to slow settlement of supports. The stresses due to load only are not dependent upon the modulus of elasticity if the stress-strain diagram is straight.

With respect to Conclusion 4 it should be mentioned that the straightening of the stress-strain diagram gives the same action as when $m > p$ in the author's notation and this will produce, as he has stated, an effect just opposite to that which he has found. This will also make the author's Conclusion 3 rather doubtful.

As the discussion must imply, the writers consider the paper to be misleading in its present form. Nevertheless, they do feel that the concept is excellent. If, as stress and flow phenomena relating to concrete become better understood, a similar analysis based upon a sounder premise could be made, there is no question but that it would be a contribution to the subject. Already, much additional information has been contributed[85] toward the fuller and better understanding that should be the basis for such an undertaking.

DR. ING. E. PROBST[86] (by letter).—The very interesting theoretical investigations by Mr. Straub have as their purpose the development of a method of computing stresses in concrete arches which conform to the actual conditions more closely than those assumed in applying the usual elastic theory based on Hooke's law.

It has long been recognized that concrete does not possess a linear relation between longitudinal deformation and stress. Furthermore, it has been known that, for concrete, plastic deformation occurs which is a function of both stress and time. Mr. Straub evaluates these relations from experimental data compiled by various experimenters and expresses the elastic deformation by the exponential formula, Equation (9). He expresses the plastic deformation as a function of two independent variables, the stress and the time, in the form,

$$\rho = K\,\sigma^p\,t^q \qquad (118)$$

The exponents, $m$, $p$, and $q$, in these equations, are dependent upon the age as well as upon other properties of the concrete. Mr. Straub recognizes that, in assuming these values, considerable uncertainty exists, but believes that as a result of systematic investigations it would be possible to pre-determine these parameters with considerable certainty.

Particular care must be exercised in evaluating experimental results because frequently the investigations do not account for all influencing factors satisfactorily, and subsequent computed elimination of such factors as change in length due to shrinkage or temperature variation may lead to deceptive conclusions regarding the magnitude of longitudinal deformation.

Experience has proved that it is practically impossible to fabricate in the field concrete which has uniform properties. Nevertheless, the static computation for the structure must be completed before erection begins because the dimensions of the structural members are dependent on such computations. Thus, properties of the fabricated concrete must be assumed, which, in the most favorable circumstances, are only mean values. Computed stresses, therefore,

[85] See, for example, *Proceedings*, Am. Soc. for Testing Materials, Vol. 29, Pt. II, 1929, pp. 695–699.

[86] Prof., Technische Hochschule, Karlsruhe, Germany.

are not common with those actually occurring in the completed structures even though careful application is made of the laws which relate, respectively, deformation to stress and stress to time. In addition, there is frequently a distortion of the stress condition as a result of cracks in the concrete which are often unavoidable.

Finally, it is assumed that the stress-strain relations are the same for concrete in tension as in compression, although it is recognized that this is not true in fact. The actual relation between the external and internal forces of an arch are set up by introducing Equations (9) and (118). It is thereby possible to compare the deviation of computed stresses by the proposed method with those by the customary method of computation.

The application of the elastic and plastic theory proposed by Mr. Straub is to be recommended in the design of structures of unusual dimensions and which justify a more complicated and time-consuming method of computation in order to obtain an actual conception of the stresses.

Under normal circumstances the method of computation based upon the usual theory of elasticity will suffice, although it will give only approximate values because of the approximate relations assumed, such as Hooke's law, the law of superimposition, Maxwell's reciprocal theorem, and others.

In his "Conclusion", the author correctly points out that the frequent assumption made with regard to statically indeterminate structures, namely, that as a result of "plastic flow" a displacement of moments takes place tending to relieve overstressed regions, is incorrect. Equalization of the stressed condition in a manner resulting in relief of the overstressed parts of the structure, so that the resistance of the material in the parts originally less stressed carries a larger load, can occur only with a structural material having properties such as steel.

In the writer's opinion these very valuable scientific investigations by Mr. Straub serve to provide a more thorough conception of the stress conditions of concrete structures. They supply a valuable supplement and amplification to the theory of arches.

PAUL BAUMAN,[87] M. AM. SOC. C. E. (by letter).—The introduction of Bach's exponential formula in the fundamental equations of internal equilibrium of a concrete structural member leads to the results shown in Figs. 9 to 13, inclusive. In assuming the exponent, $m$, to be 1.30, the author exaggerates the influence of the commonly committed error due to $m$ = unity in concrete design; but his elaborate paper is undoubtedly of greater interest from a theoretical than a practical standpoint, thereby making any limit between minus and plus infinity permissible. In this connection it may be noted, however, that the exponential formula, Equation (9), is meant to be an interpretation of experimental results rather than a physical law, as the answer that $k$ becomes infinitely great for an infinitely small stress, for example, is doubtlessly wrong. Furthermore, it is evident that the elastic behavior of concrete is not fully described by the exponential formula, as Poisson's ratio is also variable, thereby requiring supplementary information.

[87] Chf. Designer, Quinton, Code & Hill—Leeds & Barnard, Engrs. Consolidated, Los Angeles, Calif.

Both the linear and the exponential relations between stress and strain are approximations, the latter merely being a closer one, provided the exponent, $m$, is correctly chosen or experimentally determined. The merit of the first one is that it errs on the side of safety. As long as the physical process of deformation due to stress is as little explored as it is to-day, particularly with a material as erratic as concrete, it seems advisable to keep on erring by the application of Hooke's law and the law of superposition in structural design.

The tendency of self-preservation in concrete if subjected to a bending test is evident as well as in any other crystalline conglomerate. Immediately before failure occurs lasting deformations take place, starting at the extreme fibers and gradually moving toward the neutral axis. The stress distribution then corresponds to a relatively great exponent, $m$, resulting in an increase in stress areas as compared to the triangular distribution, thereby permitting the section, relatively speaking, to resist a greater moment under smaller maximum stresses. Simultaneously, the neutral axis, due to a difference in strain between tension and compression, which becomes more pronounced near the point of exhaustion of tensile strength, will shift from the axis of gravity so as to disengage the critical fibers somewhat on the tension side.

Recent research on crystals at the Institute of Technology at Pasadena, Calif., has probably shed more light on what is going on when deformation takes place than any similar work heretofore. According to these findings crystals are built up of small elements or blocks, each consisting of several molecules which undergo translatory and rotary motions when deformation takes place, thereby governing the behavior of the crystal. These elements are either plastic or brittle and form the basis of classification of crystals into: (1) Macroscopic plastic and microscopic plastic; (2) macroscopic plastic and microscopic brittle; (3) macroscopic brittle and microscopic plastic; and (4) macroscopic brittle and microscopic brittle.

Needless to say these findings could not be directly applied to such complicated crystalline conglomerates as concrete, but they are indicative nevertheless of what is going on when deformation takes place. In all probability concrete would be classified as macroscopic plastic and microscopic brittle; that is, the elastic limit of elementary blocks coincides with the breaking strength.

In view of the uncertainty of the tensile strength of concrete and of the steadily growing tendency to reduce the size of structural members with a simultaneous increase in span, it will perhaps be a relatively short time only before plain concrete will be barred from use in members subject to failure due to tensile stresses originating from any cause whatsoever. One cannot set a safe limit to tension in plain concrete if there is a possibility of serious vibrations affecting it, which, unfortunately, is the case everywhere on earth.

In 1903, a reinforced concrete frame bridge, as shown more or less diagrammatically in Fig. 32, was built for a National Exhibition in Dresden, Germany, and subsequently was subjected to a test[88] resulting in its failure. A

[88] Dr.-Ing. W. Gehler, Betonbeiblatt No. 9, *Deutsche Bauzeitung*, 1904.

concentrated load varying from zero to a little more than 77 500 lb. (Fig. 33) was applied at the center of the girder span, and records were kept of the vertical deflection, $d$, of these girders directly under the load. The strain, $E_s$, in the reinforcing bars directly under the load was measured and from these values the steel stresses were computed. Finally, the deformation of the posts, that is, the angular deflection at the top, horizontal deflection at center, and settling of bases, was observed.

As in this discussion the change of modulus of elasticity with the change of loading is of prime interest, it will suffice to confine these studies to the top girder only.

In Fig. 33 the deflections, $d$, and the corresponding steel stresses are given for $P$ varying from zero to 77 500 lb. Lines $A$, $B$, $C$, $D$ and $A$, $B'$, $C'$, $D'$ very closely approximate the observed deflections and steel stresses, respec-

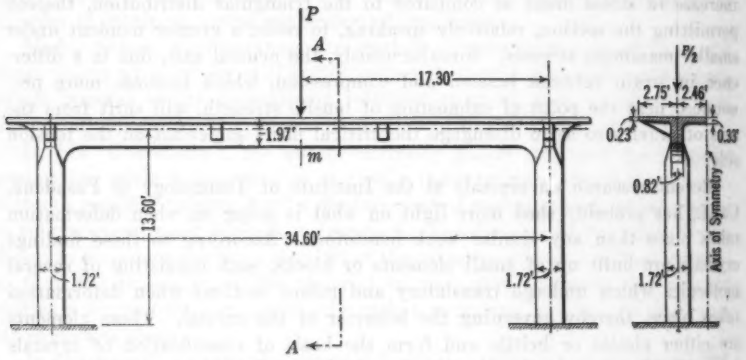

FIG. 32.—SKETCH OF REINFORCED CONCRETE FRAME BRIDGE.

tively. The significance of these straight-line zones becomes evident if it is remembered that, according to the old theory of elasticity, the deflection of the top girder, due to bending, is:

$$d = \int \frac{M\, d\, M}{E\, I\, d\, P}\, d\, s = \frac{P\, l^3}{48\, E\, I} - \frac{M\, l^2}{8\, E\, I} \ldots\ldots\ldots\ldots (119)$$

or that it is equal to the deflection, due to $M_0 = \frac{P\, l}{4}$, of a simple beam of equal span, minus the influence of the corner moment, $-M$. Substituting $\mu\, M_0 = \frac{\mu\, P\, l}{4}$ for $-M$:

$$d = \left(\frac{2 + 3\,\mu}{96}\right) \frac{P\, l^3}{E\, I} = C\, \frac{P\, l^3}{E\, I} \ldots\ldots\ldots\ldots (120)$$

because $\mu$ is, for one and the same frame structure, a constant. This is the equation of the curve through Lines $A$, $B$, $C$, and $D$ (Fig. 33) and,

$$\tan \alpha = \frac{d\,(d)}{d\, P} = C\, \frac{l^3}{E\, I} \ldots\ldots\ldots\ldots (121)$$

is its slope. Since this slope is constant between Lines $A$ and $B$, $B$ and $C$, and $C$ and $D$, respectively, it follows that the product, $E\,I$, is also constant within each of the three zones. The physical meaning of this is that in Zone $A$-$B$ the full concrete section is active on the tension as well as the compression side of the neutral axis; in Zone $B$-$C$ the first hair-cracks occur in the concrete under tension, partly eliminating its activity; whereas, in Zone $C$-$D$, the limit of proportional deformation of steel is reached and failure begins. As the rigidity of the structure inside each zone remains unchanged (tan $\alpha$ = constant), the product, $E\,I$, is an index of rigidity. To determine $E$ of the compound material, that is, for concrete and steel or reinforced concrete, Equation (121) may be written, $E \tan \alpha = \dfrac{C\,l^3}{I}$.

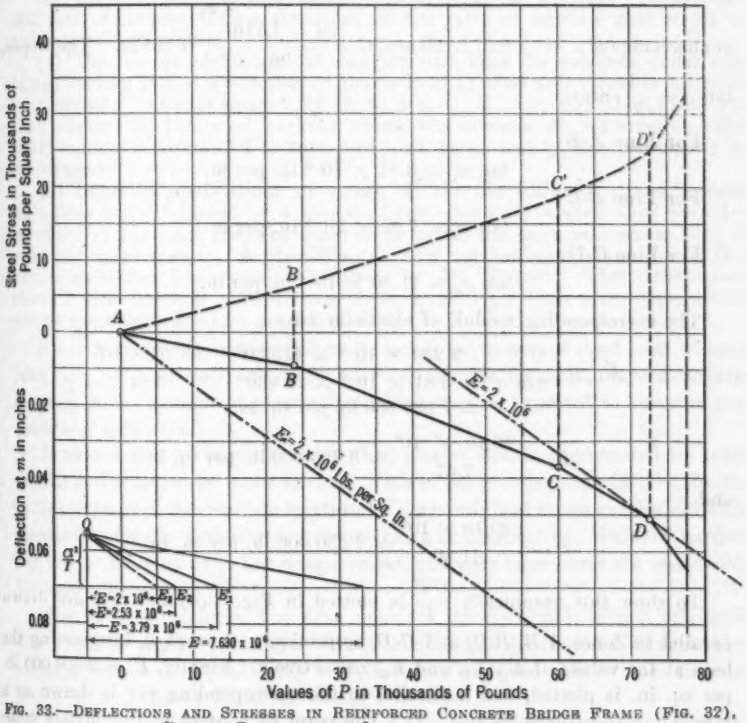

FIG. 33.—DEFLECTIONS AND STRESSES IN REINFORCED CONCRETE BRIDGE FRAME (FIG. 32), DUE TO CONCENTRATED LOADS AT THE CENTER.

In Fig. 32, $I$ = 22 930 in.$^4$; that is, the moment of inertia of the full concrete section of the top girder; $l$ = 34.60 ft. = 415.30 in.; and $C = \dfrac{2 + 3\,\mu}{96}$. Using Gehler's "short-cut" for the determination of $\mu$,

$$\mu = \frac{h\,I}{l\,I_p} \qquad (122)$$

in which, $I_p = 15\,140$ in.$^4$ and $h = 13.62$ ft. $= 163.40$ in. Therefore,

$$\mu = \frac{163.40 \times 22.930}{415.30 \times 15\,140} = 0.597$$

As there is always some uncertainty as to the degree of restraint of the posts at the base, the average between fully restrained and fully hinged is taken.

For full restraint:

$$\rho_1 = 2 + \mu = 2.597 \text{ and } -\mu_1 = 0.385 = \frac{1}{\rho_1}$$

whereas, for a fully hinged base,

$$\rho_2 = 3 + 2_\mu = 4.194 \text{ and } -\mu_2 = \frac{3}{2\,\rho_2} = 0.358$$

or an average of $\mu = -0.372$. Hence, $C = \frac{2 - 1.116}{96} = 0.00922$. The slopes, $\tan \alpha = \frac{d}{P}$, are:

For Line *A-B*:

$$\tan \alpha_1 = 3.81 \times 10^{-6} \text{ in. per lb.}$$

For Line *B-C*:

$$\tan \alpha_2 = 7.67 \times 10^{-6} \text{ in. per lb.}$$

For Line *C-D*:

$$\tan \alpha_3 = 11.50 \times 10^{-6} \text{ in. per lb.}$$

The corresponding moduli of elasticity are:

$$E_1 = \frac{C\,l^3}{I \tan \alpha} = \frac{9\,220 \times 10^{-6} \times 415.30^3}{3.81 \times 10^{-6} \times 22\,930} = \frac{29.10 \times 10^6}{3.81}$$
$$= 7\,630\,000 \text{ lb. per sq. in.}$$

$$E_2 = \frac{29.10 \times 10^6}{7.67} = 3\,790\,000 \text{ lb. per sq. in.}$$

and,

$$E_3 = \frac{29.10 \times 10^6}{11.50} = 2\,530\,000 \text{ lb. per sq. in.}$$

To show this graphically $\frac{C\,l^3}{I}$ is plotted in Fig. 33(*a*) and rays are drawn parallel to Zones *A-B*, *B-C*, and *C-D*, respectively, through 0, intersecting the base at the values of $E_1$, $E_2$, and $E_3$, respectively. Finally, $E = 2\,000\,000$ lb. per sq. in. is plotted, and a parallel to the corresponding ray is drawn as a tangent to the Curve *A*, *B*, *C*, *D*. The point of contact approximately coincides with the end of Zone *C-D;* that is, with the beginning of failure, thereby justifying the usual assumption of $E = 2\,000\,000$ in concrete design as it approaches the lower limit. This value, however, leads to an exaggeration of deflections as indicated by a parallel line through Point *A*. At the end of the first zone, that is, at Point *B*, the tension in concrete for a load of 23 800 lb. was computed and found to be 350 lb. per sq. in., or approximately one-tenth

the ultimate compressive strength of concrete. The maximum compressive stress at the center of the span, due to the ultimate load of 77 500 lb. was computed at 800 lb. per sq. in., whereas near the support it was in excess of 1 800 lb. per sq. in. Failure, however, occurred in the steel at *m* (Fig. 32).

It would be interesting, indeed, to have comparative data based on the author's new theory of elasticity.

G. C. STAEHLE,[89] ASSOC. M. AM. SOC. C. E. (by letter).—In a study of the effects of time yield or plastic flow upon concrete arches the following items are of outstanding importance:

(*a*) The modulus of elasticity of concrete, as determined by the ordinary quick loading of laboratory practice, increases progressively with age over a period of several months or more.

(*b*) The modulus decreases with age under sustained loading,[90] the amount and rate of decrease being functions of the ratio of applied unit stress to ultimate unit strength.

(*c*) The rate of advancing deformation with time for concrete under sustained loading is also a function of the ratio of applied unit stress to ultimate unit strength. (Experiments[91] by G. A. Maney, M. Am. Soc. C. E., indicate that, within the limits of working stress, the increase of deformation with time, commonly attributed to sustained load, is, in reality, due principally to shrinkage.)

(*d*) Repeated applications of stress, within the ultimate strength, each unloading being followed by a period of rest—even for a very short period—raise the proportional limit of concrete in much the same manner as that of steel and other metals. A plausible and very interesting explanation of this phenomenon has been previously given by Mr. Turner. The stress-strain relation thus becomes a linear one up to a relatively high percentage of the ultimate strength for this condition.

Bearing these four major points in mind, the ratios of dead load to total load, and of dead load and total load to ultimate strength, have a definite bearing on the amount of plastic flow which may be expected to occur in any particular structure.

It should also be borne in mind that plastic flow is accentuated by rapid drying and retarded by moist curing. This effect is influenced, in turn, by the initial wetness of the concrete mixture. Excessively wet mixes are, indubitably, responsible for the majority of extreme cases of plastic flow. Delayed hardening, due to freezing or to low temperatures, and poor aggregates are responsible for most other cases.

The writer's attention was first called to the noticeable effects of plastic flow about seventeen years ago. Since then he has encountered several other extreme cases, but in practically every instance has been able to trace the condition back to one of the three causes mentioned.

Concerning the many statements found in engineering literature as to the inelastic properties of concrete, the writer, in his own experiments, has found that, generally speaking, for initial and repeated applications of stress, perfect elasticity is obtained in ordinarily good concrete up to 40% of the

[89] With Portland Cement Assoc., Chicago, Ill.

[90] *Proceedings*, Am. Soc. for Testing Materials (1929), p. 695.

[91] *Engineering and Contracting*, June, 1930, p. 234.

ultimate strength at the age tested. This 40% is a minimum value based upon concretes having a nominal 28-day strength of 2 000 lb. per sq. in., and more, and applies from ages as early as 7 days for concrete having a nominal 28-day strength of 3 000 lb. per sq. in., and more. For 2 000-lb. concrete, it has been found to apply at an age as early as 14 days.

He has also found that linear relation of stress to strain up to a very high percentage of the ultimate strength may be obtained with the higher strength concretes on initial as well as on repeated applications of stress, the percentage decreasing with the strength of the concrete, but remaining well outside the range of the working stress for concretes having a nominal 28-day strength of 2 000 lb. per sq. in., and more.

Although 28 days is commonly accepted as a criterion in the adoption of working stress and elastic properties for design purposes, consideration should also be given to the increase of modulus with age and the coincident raising of the proportional limit during the process of hydration.

Arguing from these premises, it becomes questionable as to whether or not the author's attempt to provide for a variable stress-strain relationship in the design of concrete arches is of practical value.

A. FLORIS,[92] ESQ. (by letter).—Although the use of masonry arches in structures is very old, the correct interpretation of their statical behavior is of a comparatively recent date. In the development of their theory the French and German engineers took a leading part.

The introduction of the elastic theory in the analysis of masonry arches, based upon Hooke's law as an approximation, was a marked advance in the design of arches. This theory satisfied the requirements of practice, as long as the application of concrete arches to long-span bridges was somewhat restricted. However, the use of arches with great spans is increasing steadily and a more elaborate analysis of their stress condition is highly desirable.

It is very gratifying, therefore, that the author, in his pre-eminently able analysis indicates further improvements in the design of concrete arches, which are of a distinct and practical value. Basing his thesis on the Bach-Schüle exponential law of elastic deformation and deriving from available experimental data an exponential law for the plastic flow of the concrete under sustained stress, Mr. Straub builds a new theory of arches which is a decidedly better approximation to the actual stress condition than the method founded on the linear distribution of stress, which disregards the time element.

It cannot be expected that empirical formulas such as those used in the paper will be perfect. They can be improved, however, as more information on the behavior of the concrete under stress accumulates. The remaining theoretical part of the author's analysis, being based upon the logical application of the laws of mechanics, is accurate and sound.

In the near future, perhaps, further progress in the stress analysis of concrete arches will be made, but the credit of first developing a more exact theory of concrete arches belongs rightly to the author. The paper deserves the closest attention of the students of concrete arches.

[92] Civ. Engr., Los Angeles, Calif.

LORENZ G. STRAUB,[93] JUN. AM. SOC. C. E. (by letter).—Much information and constructive criticism has been offered in the generous response of discussion by members of the Engineering Profession. However, despite the earnest effort to point out and distinguish between real and hypothetical considerations, there remained a certain amount of confusion in some instances.

There is a general expression of the viewpoint that much remains to be discovered regarding the time-stress-strain relations of concrete. Some of those who discussed the paper believe the separation of deformation into elastic and inelastic deformation is without justification.

Mr. Jakobsen calls attention to valuable information concerning the stress-strain relations for plain concrete. However, the writer does not feel that "the separation of elastic and plastic deformations seems an artificial procedure". It is true that this is a difficult segregation and that most "tests show the combined deformation only", but it is doubtful in the case of concrete whether "the plastic deformations disappear in due course of time, and are not in any sense permanent, except when the elastic limit has been exceeded". If so, then concrete must be considered to pass the elastic limit at a stress far below the normal working stress; in any case, experience indicates continuous deformation to occur in concrete when subjected to normal loading conditions. More experimental data would be very valuable in this connection.

As pointed out by Mr. Jakobsen if the stress-strain curve is linear for plastic as well as for elastic deformation, Hooke's law applies, and the time factor effects the deformations but not the load stresses. In this particular case, if no account were to be taken of the effect of time-yield in connection with temperature deformation, shrinkage, yielding supports, etc., the ordinary elastic theory would suffice completely for making a stress analysis of the structures; but even for the hypothetical case in which the stress-strain curve is linear for both plastic and elastic deformation, an analysis of the stresses incurred as a result of temperature changes, yielding supports, etc., requires that distinction be made between plastic deformation and elastic deformation.

The writer is in full accord with Mr. Jakobsen's statement that the exponential law for elastic deformation will not fully explain the somewhat perplexing problem of determining why plain concrete beams fail at such high computed stresses, although the computations based upon the law indicate a variation in the right direction. It is highly probable that more accurate information concerning the physical properties will shed more light upon this subject.

In connection with his statement that the writer "apparently computes the plastic deflection of a 140-ft. arch as 3 in., * * *," it seems that Mr. Turner has not clearly understood the diagram in question. Fig. 30 concerns a very hypothetical case in which the ratio, $\frac{H_{DL}}{H_{RS}}$, is considered equal to 25. Under such circumstances, the line of thrust will be eccentric with respect to its normal position. It was considered, therefore, that the line of thrust was not allowed to return to its normal position as a result of plastic flow, but instead

[93] Associate Prof. of Hydraulics, Univ. of Minnesota, Minneapolis, Minn.

was maintained eccentric in consequence of continuous contraction of the arch rib (temperature change), resulting in progressive angle changes within the arch rib. Obviously, this is merely a simple computation made for the purpose of showing that, for the particular hypothetical case, continued deformation might occur without change in the stress distribution in the arch rib. Computations for the case in which all deformation subsequent to removal of forms is due to plastic flow would indicate a crown deflection of only a fraction of the amount referred to by Mr. Turner, most of which would take place in the first few months. There is no question that a certain amount of rib-shortening and, consequently, deflection of the crown, occurs progressively at least during the early life of an arch. This is particularly emphasized by the result of rib-compensation methods (hydraulic jacks operated at the crowns of arches during the early life of the structures), used in France[94] and Germany. The results of experimental investigation[95] on arches by Wilbur M. Wilson, M. Am. Soc. C. E., also show continued deformation incurred under constant loading conditions.

The writer is not in a position to say whether "Messrs. E. B. Smith, F. R. McMillan, and A. H. Fuller and C. C. Moore were mistaken in supposing they had discovered a general phenomenon of plastic flow in concrete as applied to the practical structure". Nevertheless, he does not doubt that they observed the phenomena of progressive deformation, and more recently that Raymond E. Davis, M. Am. Soc. C. E., and G. E. Troxell,[96] Assoc. M. Am. Soc. C. E., Mr. Oscar Faber,[97] and others observed that progressive deformation takes place in concrete over a period of many months under the influence of a continuously applied load. Mr. Turner's belief that a concrete arch having a cross-sectional area of 72 by 100 in. is very different from that of the ordinary test experiments, deserves careful consideration, because any such deviations are of great general importance in connection with experimental investigations of concrete.

Mr. Godfrey's timely emphasis of the psychological danger involved in the application of complex theories is worthy of special notice. Far too frequently fine-spun, precise analyses are worse than useless because of the false sense of security that they arouse in the design. Although he is no advocate of methodology in structural design, the writer desires to call attention to the noteworthy innovations in procedure for analyzing statically indeterminate structures which have recently been set forth by Hardy Cross, M. Am. Soc. C. E.[98] These should go a long way toward overcoming the mechanical methods of applying the theory of elasticity.

The concise, scholarly discussion by Professor Griffith considers many additional factors and does much to clarify the confused viewpoints in the interpretation of the phenomena of elasticity, plasticity, and viscosity. Professor Griffith's arguments make it seem reasonable that concrete should be called a "visco-elastic" material and that the occurrence of time-yield might

possibly better be called viscous flow rather than plastic flow. It is only reasonable that technologists and scientists should meet on a common ground as far as definition is concerned and, therefore, the remarks contained in this discussion are especially important.

The writer does not consider the skepticism held by Mr. Comstock entirely justifiable. It is quite true that shear deformations result in plane sections not remaining exactly plane after flexural deformations occur. In the case of the arch, however, as pointed out in the paper (see "General Relations" under "Derivation of Proposed Theory of Elasticity for Arches"),

"Since shear deformations have only slight effect on the change in conformation of a loaded arch rib in comparison to the effects of moment and rib-shortening deformations, the deformations due to shear will be neglected in the analysis."

It is fully agreed that in the case of pure flexures there will be a certain amount of approximation resulting from neglecting shear deformations, just as in the case of the usual approximate procedure of applying the ordinary theory of elasticity to beams. However, in the case of properly designed concrete arch ribs, the error introduced is unquestionably negligible.

Considering fixed-ended concrete arches, the writer cannot agree with Mr. Comstock's statement that "* * * it is of no importance whether or not the whole or any part of the strain disappears on removal of the applied forces". Where the deformation is progressive and dependent upon the concentration of stress, there results (in the case of arches and similar structures) a gradual displacement of the line of thrust which would not occur in the case of a perfectly elastic material. In this connection the writer wishes to emphasize the fact that, in order to make a satisfactory analysis where time-yield occurs, the entire structure must be taken into account and not merely its parts. In answer to Mr. Comstock's question why 1.3 was selected for the value of $m$, the writer wishes to refer to the paragraph following Table 3 in the paper:

"It is realized, of course, from the experimental data on the elastic properties of concrete that a variable relation of stress to elastic strain in which $m$ is as high as 1.3 is possibly never obtained in practice. However, an extreme value of $m$ has been chosen in order that the results may show characteristic trends more prominently. Also, since a value of $p$ of 1.3 in the proposed theory of plasticity is probably about correct for concrete 3 or 4 months old, this value makes a convenient starting point for an analysis in which the plastic properties of the material are considered."

The paper repeatedly emphasizes the need for more experimental data before a conclusive set of values can be chosen for the parameters in the proposed equations.

Furthermore, with reference to Mr. Comstock's statement that, "* * * it is not clear on what ground the author justifies the assumption that it [strain] may be expressed as the product of two functions, one of stress only and the other of time alone", the writer refers to Figs. 14 and 15. It will be observed that both these series of experiments indicate that the deformation is very well expressed by independent functions of stress and of time.

Unfortunately, not enough "time-yield" experiments extending over long periods are available at present, and the writer concurs in the opinion of Mr. Comstock that the value of $m$ does vary with the age of the structure. Not only is this true, but the values of $k$, $K$, $p$, and $q$ are also likely to vary with the age of the concrete, the latter even to a greater extent than $m$. No one questions that the modulus of elasticity varies with the age. However, the writer does not feel that this disproves the validity of the equations proposed. Extended experimental data may indicate—and the writer believes that this is not only possible but probable—that the parameters of the equations must be varied at intervals as the age of the structure increases in order to obtain satisfactory results, and it is possible that these variations might be quite large. In any case (although it is agreed that there is not sufficient experimental data to justify completely the general adoption of a stress-strain-time relation for concrete and that sometimes such studies may lead to preconceived notions), the writer feels that in not formulating reasonable relations based upon pioneer experimental studies an investigator is gathering information blindly without a definite purpose in view and, therefore, without recording all the facts desirable. This is true of much experimental data now available.

Considerable interesting and valuable information bearing upon the subject of this paper is brought to light by Mr. Eremin. Nevertheless, partial exception is taken to one of his statements referring to Fig. 21. If the properties of the material of construction are of a nature similar to those found from the experimental data available, there will be no appreciable redistribution of stresses in spite of the fact that excessive deflection occurs. It is true, however, that if the concrete at a particular point undergoes excessive yield similar to the condition which is likely to occur in the case of a steel beam, there would be a redistribution of stresses. Under such circumstances the effect would be similar to that of a settling support. However, although the center of a concrete beam may deflect progressively an excessive amount as a result of time-yield, this does not indicate a redistribution of stresses; on the contrary, the stresses are likely to remain practically unchanged.

The remarks by Dr. Melan and also those of Dr. Probst are of particular interest because of the broad experience of these men in connection with the design, construction, and experimental studies of arches in their respective countries. Dr. Melan's exception to the writer's conclusion regarding the early removal of forms is doubtless well founded and unquestionably such a procedure should not be adopted without careful precautions.

Dr. Vogt and Professor Gilkey rightfully emphasize the need of more experimental data before an acceptable method of analysis, such as proposed by the writer, can be adopted. It is well to call attention to the fact that the properties of concrete vary with the age. Consequently, as is evident from a comparison of data now available, the values of the parameters in the exponential equations, particularly the value of $q$, vary greatly with the age of the concrete. For a very green concrete the value of $q$ is quite low, while for an older concrete, $q$ is larger by several hundred per cent. Consequently, the writer does not recommend that a single value of $q$ be adopted for concrete for a long period of time. Just what values should be used will depend upon

information obtainable only by further experimental work. It is agreed that the writer probably made his analysis cover a longer period of time than should have been assumed for the experimental data available. These studies were intended only to indicate the trends rather than to present numerically accurate results.

The writer does not feel satisfied with Equation (117), presented by Dr. Vogt and Professor Gilkey, for use in studies of indeterminate structures such as concrete arches. It is true that this relation apparently indicates the approximate relation of stress to total strain, but the equation is not sufficient to prove the writer's "Second Conclusion" that,

"If there is an external disturbance * * *, such as the settlement of a support, the plastic flow causes a gradual redistribution of stresses such that the structure approaches (but never reaches) its original state of equilibrium (no settlement of support)".

The statement quoted requires the further verification of the fact that as a result of time-yield the line of thrust again approaches its original position. Equation (117) in itself does not show this.

Even if the value, $m$, is greater than $p$—a condition which is conceivable, but not probable—certain advantages are given by the early removal of the arch centering, although unquestionably certain disadvantages are also introduced. For example, if at the time the centering is removed there is a certain amount of displacement of the piers, a re-adjustment will take place tending to cause the arch to approach its original state of equilibrium (no movement of supports); on the other hand, if $m$ is greater than $p$, the disadvantage incurred is that the line of thrust will be pulled a short distance farther away from the center line of the arch rib than if $m$ is equal to or less than $p$.

Very interesting opinions and further data are given by Messrs. Bauman, Staehle, and Floris. It is to be hoped that more long-time experiments will be performed, in order to give a more accurate knowledge of many of the physical properties of concrete and their variation with the age of the material.

# THE CHESAPEAKE AND DELAWARE CANAL

By Earl I. Brown,[1] M. Am. Soc. C. E.

With Discussion by F. T. Chambers, M. Am. Soc. C. E.

## Synopsis

This paper is a record of the construction stages of the Chesapeake and Delaware Canal. The history of the project from 1764 is outlined, with a description of successive developments to 1927. The paper contains quantities, yardage, prices, total costs, and methods of procedure in connection with dredging operations. It also includes descriptions of several of the bridges that now cross the canal. The paper closes with a brief outline of hydraulic theory as applied to the project.

## Introduction

The Chesapeake and Delaware Canal was constructed during the period, 1825-1829, by the Chesapeake and Delaware Canal Company, organized for that purpose under authority of special legislation enacted by the States of Maryland, Delaware, and Pennsylvania. Each of these States, as well as the Federal Government, subscribed for stock in the Company.

The location selected (after prolonged investigations, and abortive attempts at construction on other locations) was an east and west line connecting St. Georges Creek on the Delaware River about 40 miles below Philadelphia, Pa., with Back Creek on Chesapeake Bay, about 54 miles east of Baltimore, Md. The length of the canal was about 14 miles, and the summit level 17 ft. above mean low water in the Delaware River. As originally constructed, the locks were 22 ft. wide and 96 ft. long, with a depth of 8 ft. over miter-sills. Extensive improvements were made about 1850 to 1855, when new locks were constructed, 24 ft. wide and 220 ft. long, with a depth of 10 ft. over miter-sills. The original Company operated it as a toll canal for 90 years.

[1] Col., Corps of Engrs., U. S. A., U. S. Engr. Office, Philadelphia, Pa.

On August 13, 1919, the canal was taken over by the Federal Government for the purpose of replacing it with a new sea-level canal of somewhat larger dimensions. The enlargement was effected during the years, 1922-1927, and normal traffic was maintained practically uninterrupted during that period.

Reconstruction involved the excavation of about 16 000 000 cu. yd. of earth, the construction of four highway bridges and one railway bridge, the relocation of the Delaware end of the canal, the construction of tide dikes, jetties, and other works of a miscellaneous character.

The deepest cut was through the summit divide where the general land elevation is 80 to 85 ft. above sea level. Practically all excavation was successfully done by pipe-line dredges. Most of the spoil was deposited in specially prepared basins on the adjacent banks, involving lifts of 80 to 95 ft.

All new bridges are of the vertical lift type, electrically operated. They were designed for heavy military loads, and the foundations were built in contemplation of a future deepening of the canal to as much as 30 ft. The navigable span provides an opening of 175 ft. clear width, and a vertical clearance of 140 ft. above mean low water, when open.

The canal was opened to traffic at sea level on May 14, 1927, with approximately full project depth of 12 ft. at mean low water and a bottom width of 90 ft.

## Historical

The two great bays, the Delaware and the Chesapeake, make deep indentations into the Eastern Coast of the United States. The northern end of Chesapeake Bay, inclining to the eastward, approaches close to Delaware Bay at a point where the latter, as the Delaware River, attains its farthest westerly meander; the distance between them at this point is only 20 miles. Both sides of the intervening peninsula are again deeply indented by tributaries which often approach to within a few thousand yards of each other at their head-waters. Chesapeake Bay, in this upper region, is marked by shores that are bluff, steep, and quite free from marshes; the outlets to its rivers are open and clean; the water is broad and fairly deep; the bottom is hard and usually sandy.

Delaware Bay has quite different characteristics, broad marshes border its shores with a width of 3 to 4 miles at places. The banks are so low that 2 to 3 ft. of water cover them at high tides; the outlets of its tributaries are obstructed by mud-bars. The high ground between the two bays is rather low in the broader parts of the peninsula farther to the southward, but at the canal it is 80 to 90 ft. above sea level.

The short distance at the upper end of the peninsula early invited plans for connecting the two bays by a navigable channel so that commerce would not be compelled to follow the sea route around, or make the portage across.

The second survey made for a canal in America is said to have been for connecting these bays near the present location. This was about 1764. Another survey followed in 1769, but the project was interrupted by the Revolutionary War. It was begun again in 1799, after the passage of an act by the Legislature of Maryland incorporating the Chesapeake and Delaware Canal Company. Similar acts were passed by Delaware and Pennsylvania

and each State contributed toward the purchase of stock. The Federal Government likewise took an interest in the matter and subscribed for stock to the amount of $450 000. Pennsylvania contributed $100 000; Maryland, $50 000; and Delaware, $25 000. The cost estimated at that time was $2 250 000, and the remainder ($1 625 000) was to be obtained by popular subscription.

The first route selected (see Fig. 1) was an unfortunate one, and the plans (which provided for a canal with fourteen locks from Elk River to Christiana River) had to be abandoned for financial reasons as well as for lack of a suitable water supply. The City of Philadelphia opposed it because of an idea that it was unduly favorable to Wilmington, Del.

Actual construction operations had been begun in 1804, but were suspended after about two years. In the meantime additional studies were made, particularly from 1822 to 1824. These led to the definite abandonment of the old route and the selection of the one actually followed, which is substantially that still in use. The Company was re-organized and refinanced, so that it was able to begin active field work in 1824 and to complete the work in 1829. It was a large undertaking for the period.

Stung by the rapid growth of Philadelphia and New York, N. Y., the City of Baltimore began to take an interest in finding a shorter route to the sea and to northern ports. In 1871 a commercial convention was held in Baltimore and a movement toward establishing a ship canal between Chesapeake and Delaware Bays was inaugurated. It appeared that a saving of approximately 320 miles would be effected by such a canal. As a result the House of Representatives requested information of the Secretary of War. In 1882, the River and Harbor Act directed that a survey be made of various routes. Several District Officers and Boards reported on possible alternate routes, but all finally came to the same conclusion, that the existing canal route was the most feasible.

As a net result the United States finally decided to buy the canal and to re-construct it so as to eliminate locks and increase its capacity. The immediate reason was to use the canal as a link in a proposed intra-coastal system along the Atlantic Coast. However, it has been generally agreed that the time would probably soon come when a ship canal along this route will be a necessity. This thought has guided all the working plans for the reconstructed canal.

## Description

The canal was acquired by the United States on August 13, 1919, for the purpose of constructing along its route a sea-level barge canal, with a depth of 12 ft. at mean low water for a bottom width of 90 ft.

The original canal had its entrance at Delaware City, Del., about 40 miles south of Philadelphia (see Fig. 1). Here a tide-lock maintained a canal level of 7.6 ft. above mean low water in the Delaware River. Thence, the canal extended between banks, partly natural and partly artificial, for a distance of 4.3 miles to the Town of St. Georges, Del., its level at some of the intermediate points being above that of adjacent marshes. Because the banks become higher near St. Georges the canal level there was raised 10 ft. by

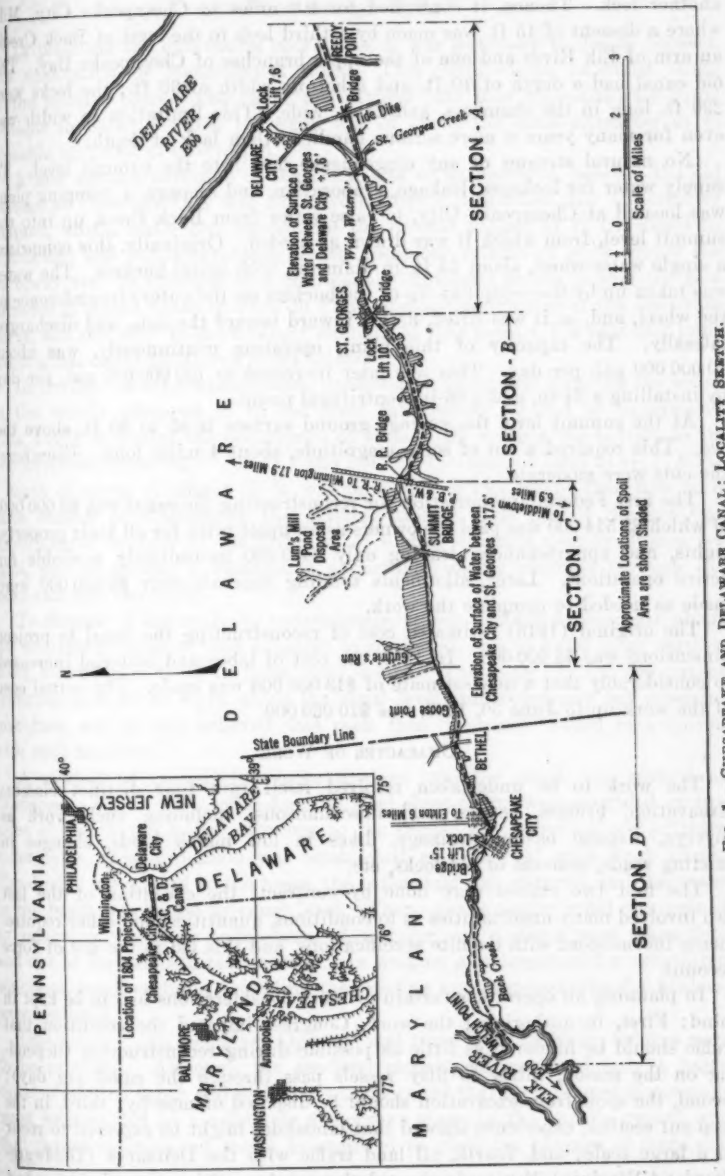

FIG. 1.—CHESAPEAKE AND DELAWARE CANAL: LOCALITY SKETCH.

another lock. Thence, it continued for 9.3 miles to Chesapeake City, Md., where a descent of 15 ft. was made by a third lock to the level of Back Creek, an arm of Elk River and one of the upper branches of Chesapeake Bay. The old canal had a depth of 10 ft. and a bottom width of 36 ft.; the locks were 220 ft. long in the chambers, and 24 ft. wide. This limitation in width was even for many years a more serious handicap than lack of depth.

No natural streams of any consequence flow into the summit level. To supply water for lockages, leakage, evaporation, and seepage, a pumping plant was located at Chesapeake City, to raise water from Back Creek up into the summit level, from which it was drawn as needed. Originally, this comprised a single water-wheel, about 35 ft. in diameter, with spiral buckets. The water was taken up by the scoop-like lip of the buckets on the outer circumference of the wheel, and, as it was lifted, flowed inward toward the axis, and discharged laterally. The capacity of this plant, operating continuously, was about 40 000 000 gal. per day. This was later increased to 100 000 000 gal. per day by installing a 24-in. and a 36-in. centrifugal pump.

At the summit level the average ground surface is 85 to 90 ft. above the sea. This required a cut of some magnitude, about 4 miles long. Elsewhere, the cuts were moderate.

The first Federal appropriation for reconstructing the canal was $3 000 000, of which $2 514 000 was paid the owners as an upset price for all their property, rights, and appurtenances, leaving only $480 000 immediately available for active operations. Later, allotments totaling approximately $8 000 000 were made as needed to complete the work.

The original (1916) estimated cost of reconstructing the canal to project dimensions was $8 000 000. In 1919, the cost of labor and material increased so considerably that a new estimate of $13 000 000 was made. The actual cost of the work up to June 30, 1927, was $10 060 000.

## Character of Work

The work to be undertaken resolved itself into four distinct classes: Excavation, bridges, jetties, and miscellaneous, including such work as surveys, disposal basins, drainage, dikes in low marsh lands, changes in existing roads, removal of old locks, etc.

The first two classes were done by contract; the execution of the last two involved many uncertainties as to conditions, quantities, and other requirements inconsistent with definite specifications, and this led to the use of force account.

In planning all operations certain primary considerations had to be kept in mind: First, in authorizing the work, Congress imposed the condition that traffic should be hindered as little as possible during reconstruction (depending on the season, thirty to fifty vessels pass through the canal per day); second, the spoil from excavation should be disposed of near-by; third, in the deep cut section, experience showed that landslides might be expected to recur on a large scale; and, fourth, all land traffic with the Delmarva (Delaware-Maryland-Virginia) Peninsula crossed the canal on the various bridges, and these communications could not be broken.

## Planning the Work

In planning the excavating operations, it was necessary to decide between wet excavation or steam-shovel work. This involved an extended study of the relative costs. The canal was divided into four approximately equal sections in each of which the work was of about the same character as to probable unit cost of excavation.

A new eastern entrance to the canal was to be provided, because the old passage at Delaware City was defective in that it debouched into a secondary channel, which, while deep enough for the present project of 12 ft., would be insufficient and would involve a greatly increased volume of work should the waterway ever be enlarged to a ship canal. A second reason is that the new entrance is placed south of Fort du Pont, one of the defenses of the Delaware River, and this adds to the military strength of that point. The new line joins the original canal about two miles inland.

In the light of all available facts, dredging (without first lowering the water in the canal) appeared to be the most satisfactory method of excavation. This would minimize the occurrence of slides. By cutting the bottom to its new proposed elevation (— 12 ft.) and holding the summit level at + 17.6 ft., a depth of water of almost 30 ft. was provided. Slides might then flow with little danger of obstructing the existing traffic. The use of dredges was objectionable because of the difficulty of finding suitable near-by dumps for spoil, and of getting a sufficiently powerful dredging machine through the locks and into the canal.

To dispose of the material conveniently, it was decided to purchase about 300 additional acres of land adjacent to the canal, and to build large earthen dikes around this tract to form spoil basins. The high lift for the pumps (ranging from 60 to 90 ft. above the canal level) precluded any but powerful machines, and it was believed that even then "boosters" would be required with each machine.

A method of introducing large dredges into the canal was devised at Chesapeake City. Two coffer-dams of steel sheet-piling were provided in two sides of the saving basin[2] adjacent to the canal. By removing one of these coffer-dams, communication was established at tide level with Back Creek. The dredge was placed in the basin, the coffer-dam was restored, and the water in the basin was raised to canal level. Then, access to the canal was gained by removing the other coffer-dam. Altogether, six dredges were taken into and out of the canal in this manner. In making arrangements for excavation contracts, small sections, including the existing and proposed sites for bridges, were excluded.

One railway, one secondary highway, and three main highway, bridges were to be provided. Although the sea-level project contemplated only a barge canal of limited depth and width, it was conceded that such limited dimensions must be regarded as a relatively temporary stage in the canal's growth and that future enlargement would be required to allow the passage of large sea-

[2] A saving basin is a basin provided alongside a lock into which the upper half of the prism of water between upper and lower levels may be drawn in emptying the full lock, and there preserved for use in filling the lower half when the lock is next filled. The net loss of water in a lockage is therefore only one-half, instead of an entire, lock full.

going vessels. Besides this idea of a larger canal, there were also traffic and foundation questions that led to the adoption of dimensions and clearances for all bridges such as would conform with a future depth as great as 35 ft. The bridges were intended to carry the heaviest military loads. Based upon these considerations, the characteristics imposed on design were: Depth of foundations of main piers, at least 40 ft. below mean low water; minimum horizontal clearance of navigable span, 175 ft.; minimum overhead clearance for fixed or vertical lift bridges, 140 ft.; floors with bridges closed, approximately at present road levels; and all bridges power-operated.

## Surveys and Plans

Surveying for the construction of the sea-level canal was begun immediately after the United States took the project from its former owners on August 13, 1919. The alignment adopted was that laid down by the Board of Engineer Officers convened in compliance with the River and Harbor Act approved March 3, 1909, and charged with making survey and reports for a continuous waterway from Boston, Mass., to Beaufort, N. C.[3] The task of preparing the requisite working plans and maps included three major surveys: (1) A topographical survey of the entire canal from Delaware River to Elk River, with all adjacent lands for studying the spoil-area problem, and for general information; (2) location of all property line corners to determine whether or not the existing rights of way were of sufficient width, throughout, to accommodate the sea-level canal; and (3) laying out the new canal on the ground, with cross-sections at 100-ft. stations along the center line, for detail work.

Stadia and plane-table methods were used in the topographical surveys and contours were located at 10-ft. intervals. The area covered was about 50 sq. miles and the average width was 2.5 miles. The survey was platted to a scale of 1:9 600, thus requiring three standard 27 by 40-in. sheets for the entire route.

In the next step all property acquired for the new canal was staked out and permanent monuments were placed at controlling and meander corners. The property lines, thus located, were platted on the working drawings to a scale of 1:1 200 so as to show the position of the new canal with respect to the right of way.

The general line of the sea-level canal is substantially the same as the old one, except at the east end, where it strikes the Delaware River about 1¾ miles below the Delaware City lock.

As a part of the layout work, range points for tangents and chords and points of intersection of tangents were monumented. Cross-section profiles were made at each 100-ft. station. Elevations were taken every 10 ft. horizontally at right angles to the center line for a distance of 500 to 800 ft. on each side. Soundings and wye-level measurements were made from the 12-ft. depth in the Delaware River to the Pennsylvania Railroad Bridge, the eastern end of "Deep Cut" Section, and from Guthries Run, the western end of "Deep Cut" Section, to Elk River (see Fig. 1). In "Deep Cut" where the

[3] H. R. Doc. 391, 62d Cong., 2d Session.

adjacent hills were from 20 to 100 ft. above the canal level, this method was supplemented by hand-leveling, trigonometric leveling, and checking on a wye-level line at the top of the slope along the steep banks.

These data were reduced and the plan was platted to a scale of 1:1 200 which covered 21 standard size sheets 27 by 40 in. The cross-sections were platted to a scale 1 in. equals 100 ft. horizontal and 20 ft. vertical. These drawings were the basis of all the necessary designing and computations for the contract specifications and for hired labor work.

## Excavation

The canal was divided for excavation purposes into four sections. (See Sections A, B, C, and D, Fig. 1.) Practically all the material to be removed in Section A was under water; hence, it was a dredging proposition. In passing the dredge from the new sea-level entrance to the intermediate level it was important not to permit the water in the embanked part of the old canal to escape. This was prevented by using excavated material to build a dam or dike across the dredged channel, thus leaving the dredge floating in a completely enclosed pond. Water from the canal was then admitted into this pond raising the dredge to canal level, which was retained by the dam. The dredge was then ready to continue on its way into the old canal and complete its work. The operation was reversed in coming out.

Section B contained practically no material above the canal surface, and it was clearly a dredging proposition. The only question to be decided was as to whether a dredge could be introduced into the canal through the locks or by other means.

In Section C (Fig. 1) the height of the banks averaged 50 to 75 ft. above the water of the summit level (17.6 ft.) The excavation was approximately 50% of the total required to complete the 12-ft. canal.

This section of the canal was called the "Deep Cut". It was here that the choice between wet and dry excavation was most difficult to make. The original builders of the canal had piled material from this cut close along its edges, thereby greatly overloading the banks and adding considerably to the material now to be removed for the enlargement. Approximately, 7 000 000 cu. yd. were to be taken from this cut, of which perhaps two-thirds could be removed by dry excavation after first deepening the summit level enough to lower it 10 ft. Even then the remainder below water level would have had to be dredged, and slides would very probably have been induced by this preliminary lowering. The occurrence of such slides in so shallow a channel would have practically closed it to all traffic. Section D was clearly a case for dredging. The combined length of all sections was 20 miles, and the total quantity to be excavated was 16 000 000 cu. yd.

*Contracts for Excavation.*—The first shovelful of dirt was raised under the new project June 27, 1921, when a preliminary trial contract for steam-shovel excavation was awarded for removing the overburden down to Elevation + 20 (see Table 1, Item 1). The material was transported by three trains of dump-cars to the disposal grounds in Lums Mill Pond which, previous to the acquisition of the canal by the Federal Government, had been used as a feeder

## TABLE 1.—Data Relating to Quantities and Cost of Excavation.

reservoir to supply water to the summit level. The retaining earth dam had been washed out by a freshet August 14, 1919, immediately after the Government had taken over the canal, and the spoil of the operation was used to good advantage in rebuilding the dam, which thus provided a spoil area for material dredged under later contracts.

After this preliminary trial of steam-shovel excavation, dredging was chosen for the remainder of the work. The "Deep Cut" was recognized as the key to the entire job. Therefore, specifications were prepared, after an allotment of $2 500 000 had been made, with a view to placing a contract for that part of Section C comprising the most difficult work between Guthrie's Run and Summit Bridge. About 5 000 000 cu. yd. of earth were involved in this contract. The specifications were made so as to permit the contractor to use either wet or dry excavation with any combination of methods he might choose.

Operations were begun on December 10, 1922, with a 26-in. hydraulic dredge which had previously entered the canal through the coffer-dam at Chesapeake City. At the same time another 26-in. dredge was brought in; but it was still under construction and did not start operating until one year later, December 11, 1923. (See Table 1, Item 11.) Previous to the beginning of dredging operations a force of men with tractors, dynamite, etc., were at work clearing the north bank of trees, stumps, underbrush, and roots, and constructing a retaining bank and waste weir for the Guthries Run spoil area (Fig. 1). The first retaining banks and the waste weir were soon found to be inadequate because of the great quantity of water being pumped with the spoil. This made a more substantial construction necessary.

The method then chosen by the contractor to carry out this work was, briefly, as follows: A steam shovel and the dump-cars from the former contract were used to remove the top of the spoil bank of the old canal. With this material, a heavy earthen embankment varying in height up to 25 ft. was built parallel to the canal and not less than 300 ft. from it, to form one side of the basin into which the spoil was to be placed; usually the other sides were thrown up by a drag-line excavator. As the dredge had an average daily output of about 7 000 cu. yd. on this work, cross-dikes were run, as needed, to provide smaller basins into which it could discharge without interfering with the construction of the main dike farther along. The contractor purchased about 500 acres of land for this purpose which, added to approximately 300 acres owned by the United States, made a total of about 800 acres devoted to these spoil basins. The embankment on the canal side was about 24 000 ft. long. The waste water from the entire area was forced by a series of levees, weirs, and ditches to settling ponds north of a public road paralleling the canal. After a travel of 2 to 3 miles through these basins, the water returned to the canal quite clear. This return was quite essential because all the water in the canal had to be supplied by the Chesapeake City pumping plant, the capacity of which would not have been adequate otherwise.

The material encountered in this section consisted of strata of loam, sand, some gravel, hard blue mud, and clay. The hard blue mud and the clay could

not be broken up, but came through the pipe line in slices and lumps, piling up at the end of the pipe line without running off.

There was little delay caused from choking of the pipe line, although the lines were run up almost perpendicular banks from 60 to 80 ft. high. The greatest height over which material was discharged was 97.5 ft. above the water level in the canal. The major part of the rip-rap stone revetment of the old canal along the old tow-path was removed by a small bucket dredge, before the dredging began.

The only damage done to plant in boldly attacking banks of maximum height (aside from normal deterioration) was an occasional broken spud or hoisting cable. The character of material was such that instead of flowing to the intake pipe of the dredge under a gradual slope, large masses of it would either slide or break off and fall into the water without warning; this caused waves which would occasionally break the spuds before they could be hoisted. No structural damage was done to the plant. The difficulty was partly overcome by washing the banks down by flowing water or jets; but the most successful method was by the use of blasting powder, first drilling a series of holes along the required slope line to depths varying from 10 to 25 ft. and about 20 ft. apart. The explosion of this powder would usually cause the earth to fall into the head of the cutting in a more gradual manner.

The part of Section C from the Pennsylvania Railroad Bridge to Summit Bridge was awarded in two separate contracts. On July 21, 1924, a 22-in. hydraulic dredge started at a bend in the old canal 1 600 ft. west of the Pennsylvania Railroad Bridge and worked east, leaving the old canal to the north (Fig. 1). Since the only available spoil area was Lums Mill Pond, it was necessary to lay a submerged pipe line across the old canal to dispose of the dredged material without interrupting traffic. On August 25, 1924, another dredge started at the same bend and worked west, spoiling in the same area through a pipe line from 1 000 to 4 000 ft. long, with the discharge at Elevation + 42.5 ft. The total quantities excavated on this contract are given in Table 1 (Items 12 and 13).

Operations were begun on a new contract on March 6, 1925, by a dredge, working west from a point 1 200 ft. east of Summit Bridge (Fig. 1) where the overburden had previously been removed to Elevation + 20 by the steam shovel. An area just east of the public road leading from Summit Bridge to Glasgow, Del., purchased for spoiling purposes, was enclosed by 6 000 ft. of levee. (See Table 1, Item 14.)

Section B is about 3 miles in length, extending from St. Georges to the Pennsylvania Railroad Bridge. A 22-in. hydraulic dredge entered the canal through the coffer-dam at Chesapeake City, proceeded east to St. Georges, and began operations on October 1, 1923. (Table 1, Item 7.) The course of the old canal was followed westward from St. Georges to Lorewood Grove. At this point the tow-path was cut through and the new canal diverged gradually to the north to eliminate bends. The greatest divergence was approximately 300 ft. passing through Otter Island and a point of high land with an elevation of + 37 ft. on the north, then crossing the old canal to the south of the

Pennsylvania Railroad Bridge. This provided an improved approach to the new bridge to be constructed for the Pennsylvania Railroad.

This course necessitated the clearing of some woodland by removing the trees and stumps with dynamite and tractors, and grubbing the underbrush and roots ahead of the dredge. The dredged material consisted of sand, clay, and gravel and was deposited with little difficulty in the coves and behind the old tow-path. A small dipper dredge was used to remove the rip-rap stone from the old tow-path in the line of the new canal and to construct approximately 2 500 ft. of retaining bank.

Dredging operations on Section A began at Reedy Point, Del., with a 23-in. hydraulic dredge, working westward through the low marshland and the upland to the Delaware City-Port Penn Road. At this point operations were suspended on December 16, 1924, to prevent the flooding of several hundred acres of low land lying to the south. After resuming dredging operations at the Delaware City-Port Penn Road on July 7, 1925, the contractor's dredge continued westward to join the old canal at "Wide Waters." The mud, sand, and gravel dredged up to the road was deposited in spoil areas on the north side of the canal. Two of these were low, swampy places on the Fort du Pont Reservation, which required the construction of approximately 3 800 ft. of pipe line. The only difficulty encountered was caused by the sand that settled behind stones lodged in the line. The bulk of material dredged from the canal prism in this stretch was deposited along the face of the dike as a reinforcement and protection against erosion from tides and wind.

Before a dredge could enter the old canal at "Wide Waters" it was necessary to construct a levee behind it, 600 ft. long, with the top at Elevation +14.0, from the high land on the south to the old canal bank on the north. The water from the canal was let into the basin, thus raising the dredge to canal level, at which it then continued operations westward to St. Georges. The material dredged through "Wide Waters" was principally vegetable matter, which would rise to the surface of the water in lumps and float off like small islands. A mixture of mud, sand, clay, and gravel that impeded progress was encountered near St. Georges. The material was deposited in the coves along the south side of the canal and on the low lands to the north.

Three hydraulic dredges were in operation on this contract at different times; one of them did 45% of the work and completed the contract on December 30, 1924. It passed out of the canal the same way that it entered. The quantities dredged under this contract are listed in Table 1 (Items 2, 3, and 4).

Section D was awarded in two separate contracts (see Table 1, Items 18, 19, 20 and 21). That of the Atlantic, Gulf, and Pacific Company covered the whole section except a small stretch from a point just west of the locks at Chesapeake City. A total of 830 700 cu. yd. of mud, sand, clay, gravel, and some sandstone was excavated from the 4¼ miles of channel from Elk River to Chesapeake City. It was deposited in the coves on both sides of the channel without difficulty other than that usually attending dredging operations. The channel was completed to Chesapeake City on December 31, 1923.

Two dredges were admitted into the canal separately through the cofferdam at Chesapeake City and worked east along the lines of the old canal to

Guthries Run, a distance of 2½ miles. From a point 600 ft. east of the old canal waste-gates at Chesapeake City to the Maryland and Delaware line the material consisted of a tough red clay with a small percentage of sand and gravel, which was easily disposed of in the coves to the south and behind the old tow-path on the north side. From the Maryland and Delaware line east to Guthries Run the land rises from the canal level to Elevation +45. The contractors purchased two tracts of land for disposal areas, one on each side of the canal. To enclose these basins required approximately 12 000 ft. of levees which were constructed with dredged material in a series of steps from canal level to Elevation +50. The material was mostly sand, loam, and gravel, with a small percentage of red clay. Considerable difficulty was encountered in maintaining the levees, and several washouts that released thousands of cubic yards of sand, made re-dredging necessary; but this did not impede traffic in the canal to any great extent.

On January 8, 1925, a 26-in. dredge began work 600 ft. east of the waste-gates, which work was extended west to the old drawbridge at Chesapeake City, a distance of 1 800 ft. On February 28, 1925, work was suspended and the dredge was moved to Section C until May 12. Work was resumed on May 13, and the contract was completed May 17, 1925. The material, consisting of red clay and sand, was deposited in Broad Creek spoil area.

There were eight separate contracts for excavation awarded from June, 1921, to March, 1925, four to W. H. Gahagan, Incorporated, two to the Arundel Corporation, and two to the Atlantic, Gulf and Pacific Company. The plant in operation consisted of one steam shovel, seven powerful hydraulic dredges, two bucket dredges, two scoop dredges, two dragline banking machines, and a number of small gasoline tugboats used for transporting men and towing fuel-oil barges, etc., to and from the various plants. Each dredging company proved its efficiency to cope with such a large undertaking in the smooth and satisfactory manner in which every obstacle encountered was met and they completed all contracts in advance of the specified time. The total quantities removed from the canal prism under these contracts were 16 202 000 cu. yd. of material at a cost of $3 311 000, or, approximately, 20 cents per cu. yd.

Excavation work was suspended after May 17, 1925, to await the completion of the highway bridges. Owing to a delay in the construction program there were four bridge sites at which no excavation was done under contract: St. Georges, 700 ft.; Pennsylvania Railroad Bridge, 500 ft.; Summit Bridge, 500 ft.; and Chesapeake City, 1 200 ft.; or, a total of 2 900 ft. of channel.

Only one man lost his life on all excavation contracts. He slipped from the pontoon line of one of the dredges and was drowned. The damage to plant other than broken spuds and the usual wear and tear attending dredging operations was slight. The regular boat traffic through the canal was not interrupted to any great extent except when the dredges were being taken in and out of the canal through the coffer-dam at Chesapeake City, which required two or three days for each operation.

In the meantime, Government plant began the removal of the old original locks at St. Georges and Chesapeake City, constructed between 1824 and 1829. A dam of timber and steel sheet-piling was first constructed at Chesapeake City

to retain the canal level so that the lock could be kept in operation and yet all dredging of the channel around it could be completed except at the dam.

*Leased Plant.*—By January, 1926, sufficient progress had been made on the bridges and the removal of the old locks to resume dredging operations. A 15-in. hydraulic dredge and its attending plant was leased at $700 per day. It was the only hydraulic dredge available that could pass through the canal locks. Accordingly, it began work at Chesapeake City, where the old locks had been located, and dredged to project dimensions (Fig. 1). It was then moved to Summit Bridge, but could not pump the material to the elevation of the spoil area. Next, it was moved to the Pennsylvania Railroad Bridge and worked from that point to St. Georges, doing maintenance dredging until June 30, when it was released. It removed about 34 700 cu. yd. of mud, sand, gravel, and clay, under improvement and 217 000 cu. yd. under maintenance, at a total cost of $106 000.

When it was found that the 15-in. dredge could not complete the reconstruction of the canal and that a more powerful one would be required, negotiations were started for a 26-in. dredge to be leased for 60 days for $169 000 and at $1 500 per day thereafter. The dredge was available immediately and was started from New York City on March 30, 1926. It foundered en route off the New Jersey Coast during a storm on March 31, and was a total loss.

*Final Contract.*—After various unavoidable occurrences had impeded the progress of the work, plans and specifications were prepared to complete the work by contract. Bids were invited and the contract was awarded to the Atlantic, Gulf and Pacific Company, at 38.5 cents per cu. yd. for improvement and 33.4 cents per cu. yd. for maintenance dredging.

It was necessary to construct a coffer-dam at St. Georges to make a basin 190 ft. long and 140 ft. wide to raise the dredge to the upper canal level (Elevation +17.6) without interfering with traffic in the canal. Work was started about July 15, 1926, and was completed August 24. The old lock wall was used as the south side of the coffer-dam. The east side consisted of two rows of 35-ft. steel sheet-piling 15 ft. apart. These were tied together on the inside by cross-rows of steel piles spaced 20 ft. apart, thus forming pockets that were filled with earth. An opening for the dredge to enter was provided in the east end of the coffer-dam.

The north side was of the same construction with the two rows of piles, 14 ft. apart and from 14 to 35 ft. long, extending for a distance of about 70 ft. to high banks. Then a dirt bank, with wooden piles and sheathing as a core, extended up the side of the bank to Elevation +20.0. The west end of the coffer-dam was the old roadbed.

A 20-in. hydraulic dredge began operations on August 3, 1926, pumping a dam across the new entrance to the canal 15 200 ft. from Delaware River. This formed a basin by which to raise the dredge from tide level to canal level at Elevation +7.6. The dredge then cut through a dam constructed under a previous contract, entered the canal at "Wide Waters", and continued westward on maintenance dredging to St. Georges, entering the coffer-dam on August 25.

The time required to pass the dredge through the coffer-dam to the upper level was five days. Leaving St. Georges, it proceeded west to the Pennsylvania Railroad Bridge and began operations on improvement dredging at that point. It was engaged there until September 27, when it was found that the bridge piers were settling before project dimensions had been obtained in the draw-opening. The dredge was withdrawn and placed on maintenance work between the railroad bridge and Summit Bridge until October 11, while steps were taken to restore the bridge to condition. From October 12 to November 13, 1926, improvement dredging was completed at Summit Bridge, and the dredge continued westward on maintenance work until January 24, 1927.

*Canal Lowered to Sea Level.*—On January 25, 1927, the dredge was moved to Chesapeake City to dredge up to the retaining dam in preparation for lowering the water in the canal to sea level. The wickets were opened in the locks at Chesapeake City and Delaware City, on February 1, 1927, and, as the make-up water escaped, the dredge continued to work through the old roadbed. It reached the retaining dam on February 7, and was then moved back to complete the maintenance dredging between Chesapeake City and Bethel while a force of men removed the retaining dam. This was practically completed by February 20; dredging was resumed at that point on February 22 and completed on February 28, except a part of an old lock wall that could not be removed by the hydraulic dredge.

When the canal surface reached sea level a great number of small slides occurred along the banks of the canal, which usually did little or no damage to the channel. At a point 3 500 ft. west of Summit Bridge a slide occurred on the north side about 600 ft. long. It moved gradually into the channel, forming a shoal of the same length; 50 083 cu. yd. of material were removed from this slide by dredging from March 1 to March 22. The total net yardage removed under contract by this dredge was 1 211 000, of which 352 000 was for improvement and 859 000 for maintenance.

A 30-in. hydraulic dredge arrived at the Delaware River entrance of the canal on December 22, 1926, and began dredging on maintenance work at the 12.0-ft. contour in Delaware River. It worked west for a distance of 15 200 ft. and began removing the dam constructed by the first dredge at the same time the first dredge was removing the one at Chesapeake City.

The removal of this dam required about three days and the material was deposited in the Delaware City branch of the canal, thus forming another dam to prevent the tide-water from entering by way of that channel. The dredge was moved to St. Georges on February 10, 1927, for improvement dredging at that point, but was delayed to some extent because of the difficulty encountered in removing the steel piles from the coffer-dam. The removal of these and the great amount of timber and débris in the old roadbed required eleven days. The dredge was then moved to the Pennsylvania Railroad Bridge (February 23) and removed the last obstruction to navigation in the canal, thus making it possible to pass through at sea level for the first time.

In addition to dredging done under contract at the railroad bridge, 12 000 cu. yd. of over-burden were washed from back of the piers into the canal

to relieve the back pressure; this was later re-dredged. The total net yardage removed under contract by this dredge was 509 000, of which, 87 300 was for improvement and 421 700 for maintenance.

The entire contract was completed on March 22, 1927, after a net total of 1 720 000 cu. yd. of material had been removed and re-deposited in the same spoil areas that had been used under previous contracts. The cost was $568 600, of which $167 500 was for improvement and $401 100 for maintenance.

*Cleaning Up.*—There were two places in the canal that could not be dredged by the hydraulic method, a bed of boulders 150 ft. long and 50 ft. wide on the south side of the channel at Goose Point, Del., and a part of the old lock at Chesapeake City. For this work, a dipper dredge was leased for a period of 60 days at $500 per day. No great difficulty was experienced in removing the boulders, although some weighed as much as 7 tons. These were loaded on the decks of scows and placed on shore by derricks. In addition to the removal of the boulders and lock wall, several small slides were dredged from the channel, loaded in scows and dumped in front of a 22-in. hydraulic dredge to be rehandled. The total for this item was 11 600 cu. yd. of material (largely rock) removed at a total cost of $32 300.

On March 22, 1927, a slide occurred on the south side of the canal at Guthries Run and a 20-in. dredge was leased for 90 days at $1 500 per day for the purpose of removing this and any other slides that might develop. While the removal of this slide was in progress, the one previously removed and another just west of Summit Bridge were gradually moving channelward and had to be re-dredged.

The canal was completed to project dimensions on May 31, 1927, although it had been provisionally opened to commercial traffic on February 25, 1927. During this time its use had been restricted to daylight periods of high water and to boats of 9-ft. draft and vertical clearance of 45 ft. The canal was formally opened on May 14, 1927. The total quantities and costs involved on all kinds of dredging work is given in Table 1.

## Land Slides

Old records indicate that when the canal was originally cut through the summit divide, and for several years thereafter, much trouble was experienced from sliding banks in that particular section, especially in the first mile west of Summit Bridge. (See Fig. 1.) The slides finally became quiescent and remained so until they were again set in motion by the operations of re-construction. Fig. 2 is a view of the original canal. Sliding was undoubtedly caused partly by the practice of the original builders of disposing the spoil very close to the edge of the cut. In some places this spoil was piled up so as to raise the height of the bank from 100 to 110 ft. above sea level; that is, 20 to 30 ft. above the original level. This additional burden undoubtedly contributed to sliding, but the primary cause was the slow deformation of the clay subsoil.

Borings made along the entire length of the canal showed that beneath a top layer of green sand impregnated with some mica, there were various combi-

nations of sand and mud, all of which indicated the decomposition of a heterogeneous collection of rock. Pockets of vari-colored clays were apparently interspersed with similar sands. The results of some borings were interpreted to indicate the presence of quicksand. A Board of Engineers expressed the view[4] (based on the results of borings) that some slips due to water at the upper surface of some of the clay strata, as well as some due to water-saturated material, might be expected during and after the proposed reconstruction. It was fully expected, therefore, that there would be some trouble from sliding banks during and after reconstruction and that they might, at times, interfere somewhat with navigation. The Board believed, however, that slides could readily be handled by following a policy later adopted on the Panama Canal; namely, to provide means of removing them as they developed until the banks became quiescent. A few minor slides did develop during the dredging operations, but owing to the precaution taken to maintain the canal at the high level during the construction period, no damage was done, and traffic was not obstructed by them.

Serious trouble did not develop until after the canal had been lowered to sea level, and again opened to traffic. About ten days after the surface level had been lowered, a section of the south bank near Mile 9 suddenly gave way and partly closed the channel. This was promptly removed by the dredge which had just completed improvement work. In the meantime, several slides were observed to be in motion within the region of the old slides in the first mile west of Summit Bridge, and close enough to the new bridge to cause some anxiety. These moved very slowly, and gave time for a careful examination to be made of their progress and effects. Usually, they were manifest first by the appearance of cracks on the surface of the ground at a distance of 15 to 20 ft. back of the edge of the bank, and parallel with it. The material between the crack and the edge of the bank would then sink almost vertically, the rear portion somewhat more rapidly than the front, so that the original ground surface of this slice of moving material would slope away from the canal. At the same time that this settlement was taking place, there was a general upheaval and breaking up of the material at and near the toe of the slope, extending 15 to 20 ft. above the water surface and encroaching slowly on the channel. The general effect is shown in Fig. 3. After one slice of the banks had settled 8 to 10 ft., a similar crack would appear back of the old one and a new settlement would begin. A series of three or four slices would present the form of a giant stairway.

In addition to the encroachment on the channel laterally, there was also an upheaval of the bottom of the canal, so that both boat traffic and tidal flow would soon be seriously hampered unless dredges were promptly put in operation to remove the invading material. Boring samples were found to be unreliable when checked against the material actually encountered. Excavation showed the material comprising the canal prism in the deep cut to be of three general classes. From the surface down to about Elevation +50 the material was largely a yellowish, loamy sand containing much ferruginous

[4] H. R. Doc. No. 391, 62d Cong., 2d Session, pp. 91-93.

FIG. 2.—PART OF ORIGINAL CANAL IN SECTION C, WHERE SLIDES OCCURRED.

FIG. 3.—VIEW OF SLIDING BANKS IN SECTION C.

matter. It was interspersed with many layers of yellow or reddish iron ore, forming hard concretions. The lower portion of this sand was water-bearing.

Below this, extending from Elevation +50 to about Elevation +5, there was found a compact blue mud, largely of argillaceous material, but containing some siliceous matter. This mud was quite compact, and, although damp, was practically impervious to water. On weathering, it disintegrated into a fine, grayish dust. It is evidently material laid down in a previous era of submergence under fresh water, since it contains no marine fossils.

Immediately below this mud, and showing at about high-tide level, there is a thin layer of lignite which rests on a thick stratum of clay. This underlying bed of clay is moist and plastic and is composed of almost pure kaolin, usually of a whitish or grayish color, but occasionally colored red. Lying 80 ft. below the surface of the ground, it is under considerable pressure. The excavation of the canal prism naturally disturbed the distribution of pressure in the vicinity of the cutting. Being plastic, this material readily changes shape to conform to the new distribution of pressure, and it is this slow deformation of the clay stratum which gives rise to the slides.

No method of preventing the slides is known; drainage would have no effect. It is quite probable that the banks will eventually reach a state of equilibrium as they did formerly; in the meantime, however, much expense will be involved in their removal, and navigation will experience the hazard of occasional interruption. It is fortunate that the section most likely to slide is comparatively short and does not involve the entire deep cut.

### Jetties

After initiating the excavation work, the next step was the construction of jetties at the outlet of the new entrance in Delaware River. The bottom of the river at this point is very soft mud of considerable depth, apparently about 35 ft. The tidal currents flowing back and forth across the front of this entrance would wash the soft material into and quickly fill a dredged cut if it were not prolonged into deep water by confinement between jetties, which concentrate the canal flow and protect the canal cut from the river currents. Studies were made to determine the character of the bottom, and of various types of jetty suitable for the very soft bottom encountered. The decision was to use a rubble-mound stone jetty founded upon a brush mattress. Since brush mattress construction is not well known among contractors in this vicinity, and since the structure was expected to settle an indeterminate distance into the soft mud, it was decided to construct these jetties by hired labor, the brush and stone being purchased by contract.

The two jetties are each approximately 1 350 ft. long and extend from the shore line into a depth of about 25 ft. of water. They are spaced 500 ft. apart at the shore end and 800 ft. apart at the outer end. The tops of the jetties are 10 ft. wide and are at a height of 10 ft. above mean low water.

The brush mattresses extending the entire length of the jetties are 2 ft. thick and 60 to 80 ft. wide. They were sunk as built by a 2-ft. layer of small stone placed upon them, and upon this small stone was placed the larger stone forming the body of the jetty. The large stone varied in size from 10-ton

blocks to "one-man" sizes. These jetties, which were completed April 1, 1926, have not yet (November, 1929) shown any signs of settlement. This is an indication of the great efficiency of the brush mattress as a support. The cost of the jetties was approximately $350 000.

### St. Georges Creek Tide Dike

The eastern part of the canal between the Pennsylvania Railroad Bridge and a point about 1 mile west of Delaware City occupies the bed of old St. Georges Creek. The new entrance to the canal, starting at Reedy Point on the Delaware River, follows a straight line running westerly in direction until it intersects the bed of the old creek near the former line of the canal at a point about 1½ miles south of Delaware City. In its natural condition, St. Georges Creek extended through a wide marsh area, much of which has been incorporated in the right of way for the canal.

This marsh area was protected from inundation by tides from the Delaware River by levees along the river banks. The opening of the new entrance channel of the canal would have had the effect of admitting the tide into this protected area; hence, in connection with studies for the details of the project, the necessity for modifying it so as to provide protection for the marshes became apparent at an early date. Furthermore, a county road running approximately parallel with the old canal and crossing the marshes (the Dutch Neck Road), was to be crossed by the new entrance, yet this road was not deemed sufficiently important to justify providing a separate bridge. It was decided to provide for these necessities by the construction of a light earthen dike parallel to the new canal on its south side, which would shut the tides out from the remainder of the marshland on the south and would carry the Dutch Neck Road to the Delaware City-Port Penn Road, enabling one bridge to serve both. The construction of this dike had not been provided for in the project document, and, therefore, its cost had not been included in the estimates.

A study was made of the most suitable methods of constructing the proposed dike, and two were considered practicable and economical. It was expected that the dredging contractor might arrange with marshland owners to use some of it for spoil, in which case the spoil itself could be used to construct the bank, but such arrangements could not be consummated. It was then decided to attempt to get a bucket dredge into the marshes for the purpose of constructing the dike by throwing up a suitable embankment, but as the marsh had no outlet by which a dredge could enter, it appeared necessary to construct the new canal entrance up to a point where a supply of tide water could be introduced, and this maneuver was successfully accomplished, with but little effect on the marshlands. The dredge cut its way in through a small narrow channel, which it filled behind itself. The construction of the dike was then conducted under an emergency contract made under proper authority.

This contract was at $3.90 per lin. ft. of completed dike. Work was begun on February 8, 1924, by a bucket dredge which had been pulled over the canal bank and had dug its way down St. Georges Creek to the site of the work.

Progress was slow, however, because the material was mostly vegetable matter and compacted badly. A second bucket dredge was put on the work on May 10, and, by the end of June, the dike was deemed of sufficient height to protect the meadow under ordinary tidal conditions. Operations were then resumed on the new canal on July 7, allowing the tide water from the Delaware River to flow into the low land between the dike and the old canal. On July 16 an extremely high tide topped the dike and caused two breaches which flooded the low land to the south. The bucket dredge continued working on the weak places, but flooding conditions continued to grow worse until September 27, when the Federal Government took over the work of completing the dike. Unfortunately, the material comprising the marshes had proved utterly unfit to support the dike against the pressure of the tides; the weight of the tide water consolidated the bed of the marshes, causing it and the dike to settle so rapidly that this, combined with heavy rains and high tides, soon caused breaches.

Prior to beginning this work it was known that the material comprising the marsh was of a peaty nature of considerable depth, but it was believed that there was a sufficient quantity of mud in it to make it form a substantial dike. Subsequent experience has shown that such was not the case. Moreover, it was exceedingly improbable that any previously projected dike would have been successful, because, lacking previous experience with this material, the design would have been faulty.

The peat comprising the body of this marsh is a spongy vegetable growth, bound together by a matted mass of roots. When a piece of it is separated from its natural submerged bed, it floats. Large chunks occasionally come to the surface and float away. It is also very compressible and acts in a manner similar to rubber. These characteristics made it impossible to build a dike from the dredged material, and better fill had to be brought from the outside. As soon as this heavier material was placed on the marsh it compressed and settled, until, finally, it acted like rubber or a compressed spring. It buckled laterally under the weight and forced the surrounding material up. This action would continue until the entire quantity of the lighter material in a vertical section had been completely replaced by the heavier material.

If these difficulties could have been foreseen before introducing a dredge into the marsh, the heavy material would have been brought in by carts or by narrow-gauge trains. Both these methods were used in subsequent operations, thus supplying data on which to base an opinion of the difficulties that would have attended the construction from the beginning of the entire dike by either method. Carts were fairly successful, but too slow, because enough of them could not dump at the end of the fill to make rapid progress. When parts of the dike turned over, or moved laterally (settling at the same time), no damage was done when carts were used. The use of narrow-gauge trains was not possible until enough solid material had been put in place by other methods to keep the track from sinking, and wrecking the plant.

When the first breaches occurred in the dike, attempts were made to close them by sand-bags. These bags were usually successful in preventing a breach

from widening or deepening, but were never successful in effecting a complete closure.

The next attempt at closure was to build the remaining sections of the dike up to a grade safely above high tides by adding sand and other heavy material through bleeders in the pipe lines of the dredges. Then, after all unharmed parts of the dike were thus strengthened and reinforced, the discharge was directed so as to build from the two ends, at the same time pumping as much heavy material as possible into the breach. Two large breaches were finally successfully closed in this manner, but even then the dike continued to settle, and soon became in danger again of being overtopped by high tides. A steam shovel was then procured, with 36-in. gauge locomotives, necessary dump cars, track, etc., and the work of hauling solid material by train from a near-by hill was begun. The cost, including attempts to close breaches, was about $300 000.

## Highway Bridges

The re-construction of the canal required changes in six bridges, one carrying railway traffic and five highway traffic. An additional structure was required over the new entrance south of Delaware City, now called the Reedy Point Bridge, but originally designated the New Cut-Off Bridge. There were wooden jack-knife swing bridges at four of the points, and those at Chesapeake City, Summit Bridge, and Saint Georges were on highways vital to traffic on the peninsula. The Summit Bridge was an iron horizontal swing drawbridge. By arrangement with the State of Maryland it was decided not to replace the structure at Bethel, known as Maryland Pivot, which was removed as soon as dredging operations made it necessary. Bids for a new bridge over the part of the old channel in Delaware City proper were deemed unduly high and it was decided not to construct a new bridge there, since traffic did not require it, but to alter the foundations of the existing structure at that point and to strengthen it sufficiently for present needs.

The new bridges were designed to serve the canal, not only as constructed under the present project (that is, at sea level with a 12-ft. depth and 90-ft. bottom width), but also as projected for the future, dredged to tide-water with a depth of possibly 30 ft. and a bottom width of 150 to 175 ft., with provision for a horizontal clearance of 175 ft. and a vertical clearance of 140 ft.

The vertical lift type of bridge was selected for all locations on the basis of lower first cost and maintenance expense. Furthermore, fireproof floors could thus be provided economically, and most of the vessels would require the bridge to be only partly open, thus reducing further the operating expenses and delays to land traffic. Operation is by direct current from storage batteries that are charged by a motor generator set using commercial alternating current; emergency operation is by gasoline engine which can either drive the generator or raise the span by direct connection through a belt to the gear train.

All bridges are of the through truss type and were designed to accommodate highway traffic adequately for future years with the continued growth

of motor transportation, and to carry safely loads incidental to troop movements. The clearance diagram and design loads for the bridges at Chesapeake City, Summit, and St. Georges, are shown in Fig. 4. Sidewalks 4 ft. 6 in. wide were provided outside the trusses. The roadway clearance of the Reedy Point Bridge is 4 ft. narrower than that of the other three; otherwise, the clearances are the same.

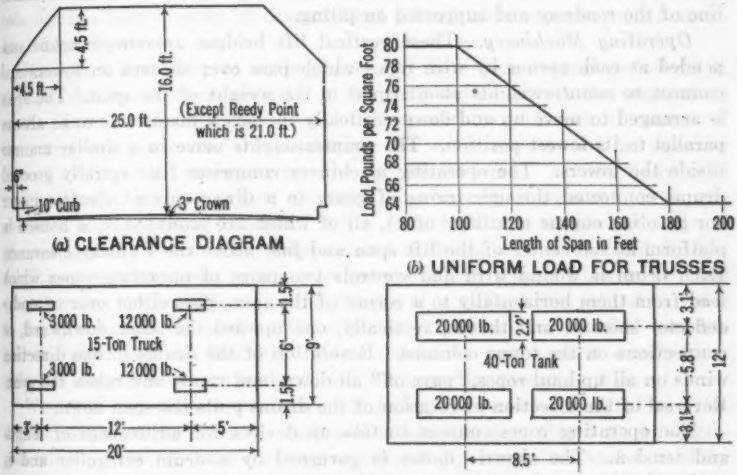

FIG. 4.—LOADING DIAGRAMS AND CLEARANCES FOR BRIDGES AT CHESAPEAKE CITY, SUMMIT, AND ST. GEORGES, CHESAPEAKE AND DELAWARE CANAL.

*Loading.*—The live loads used for design were as follows:

For the floor system of the Chesapeake City, St. Georges, and Summit Bridges, two 15-ton trucks abreast, or uniform load, as shown in Fig. 4(*a*), or one 40-ton tank.

For the floor system of the Reedy Point Bridge, two 15-ton trucks abreast, or uniform load as shown in Fig. 4(*b*).

For all sidewalks, 100 lb. per sq. ft.

For all trusses, uniform live load, as shown in Fig. 4, over the entire roadway plus one-half this uniform load on the sidewalks, or the loadings specified for the floor system.

An impact allowance of 30% was made for all live loads.

Canal traffic was required to be maintained uninterrupted during the construction of any bridge; hence, the specifications called for a vertical clearance of 55 ft. for a width of 25 ft. to be maintained in all falsework over the channel.

Since the ultimate canal will have a depth below low water of possibly 35 ft. and since no rock was found in any exploration borings, the least depth to which pier bases might safely be carried was considered to be Elevation —40. The plans in each case stipulated that caissons be sunk either by

open dredging or by the pneumatic process at the option of the contractor, and that in either case they must be unwatered for examination of the foundation material before sealing. The contractor elected to use a caisson of his own design on all contracts and to sink it by open dredging until such time as this method became impracticable, and then to resort to the pneumatic method.

Except at Summit, where the so-called abutments are really buried piers, the abutments are of conventional type with wing-walls parallel to the center line of the roadway and supported on piling.

*Operating Machinery.*—These vertical lift bridges are simple spans suspended at each corner by wire ropes which pass over sheaves on towers and connect to counterweights about equal to the weight of the span. The span is arranged to move up and down vertically in such a manner as to be always parallel to its lowest position. The counterweights move in a similar manner inside the towers. The operating machinery comprises four spirally grooved drums connected through trains of gears to a direct-current electric motor (or gasoline engine auxiliary unit), all of which are mounted on a housed-in platform at the center of the lift span and just above the roadway clearance. Each drum is wound with and controls two pairs of operating ropes which lead from them horizontally to a corner of the span, pass either over or under deflector sheaves, and thence, vertically, one upward the other downward, to connections on the tower columns. Revolution of the drums in one direction winds on all up-haul ropes, "pays off" all down-haul ropes, and raises the span. Reversal of the direction of rotation of the drums pulls the span down.

The operating ropes connect to take-up devices for adjustment of length and tension. The electric motor is governed by a drum controller and is equipped with a solenoid brake, with a hand-brake as auxiliary equipment. Thus, the span is moved, held level during operation, and may be stopped and held at any point by stopping the machinery.

When a span is raised, say, 90 ft., there is transferred from the span side of the tower sheaves to the counterweight side, 90 lin. ft. of suspending ropes at each corner of the span. This is no inconsequential weight and would materially affect the balance of the span were it not compensated. For the short lift at Summit (68 ft.) this change in balance is not dangerous; nor does it cause excessive power consumption. Compensation is obtained on the other three bridges by balance chains hung between each counterweight and its tower so that as the span rises and is lightened by the loss of suspending ropes on its side of the sheave, double this weight of the chains is removed from the counterweights. The balance thus remains unchanged for any position of the span.

*Use of Concrete.*—Each counterweight is a block of concrete with pockets or wells at the top for balance blocks. A structural steel girder is used to carry the weight of the forms and the first, or girder, layer of the counterweight itself. This girder is a heavily reinforced concrete beam designed to carry the superimposed concrete of the completed counterweight and, therefore, it was allowed to cure thoroughly before any further concreting was done on the counterweight. The forms used were of $\frac{1}{4}$-in. and $\frac{5}{16}$-in. steel plates held to proper width and length by $\frac{3}{4}$-in. tie-rods. Difficulty was experienced

in obtaining plane faces because no wales or continuous stiffeners were used and the sheets were too thin to have the necessary stiffness.

*Materials and Concreting.*—All materials were delivered by barge. Sand and gravel were stored on plank platforms. Water for the concrete was taken from the upper level of the canal for all jobs except that at Reedy Point, where wells were sunk to avoid the use of brackish tide water. The specifications called for the concrete to be proportioned by volume of materials, but to contain not less then 6 sacks of cement for 1 yd. of 1:2:4 concrete, nor 5 sacks for 1:2.5:5 concrete.

Some variation occurred in the gravel and there were natural variations in the sand due to moisture content. It was the practice to vary the proportions of the aggregates for workability and to keep within a 0.1 sack of cement of the prescribed minimum, always keeping the water ratio as low as possible. Except at Summit, measurement was by wheel-barrow. However, by calibrating the bucket into which the mixer discharged, a constant check was available on the cement content. After each day's run the sack count was checked against the concrete yardage placed in the forms. At Summit Bridge, conditions permitted two whirlers to operate within reach of one mixer, and a batcher was built which permitted the use of a method that proved superior to the antiquated one used on the other jobs; one whirler handled concrete and the other fed the batcher. Water regulation and control were rigidly enforced, and the concrete never showed a slump test exceeding 2 in.

When the temperature was below 40° Fahr., the water was heated by turning the mixer exhaust into the tank and steam jets were placed in the aggregate piles. Fresh mass concrete was covered by tarpaulins and heated by steam. All materials were unloaded to stock by whirlers which also handled the concrete between the mixer and the forms.

*Tower Straightening.*—In bridges of this type the entire load of the span and counterweights is carried by the front legs of the towers, the rear legs acting only as bracing members to carry dead and wind loads. When the load is applied to the front legs or columns of the towers, there is an appreciable shortening due to the elasticity of the metal; consequently, these legs are fabricated longer than normal in order to compensate for this shortening under load. As this shortening takes place there is a progressive forward rotation of the tower about each rear-leg panel-point, which extends to the bottom. In order to have these tower columns plumb in the completed bridge they are erected in a cambered position. The towers must be plumb in the transverse direction so that the span will hang free of its guides and thus operate with a minimum power demand. Furthermore, both columns of the tower at the fixed end of the lift span must be in the same vertical plane to prevent binding of the jaw-guides which hold the span against longitudinal movement. The heights of the towers from the top of the masonry to the center line of the sheaves and the extreme span lifts are as given in Table 2.

The towers of the St. Georges and Chesapeake City Bridges were plumbed by using plumb-bobs and those of the Summit and Reedy Point Bridges, by transit. Each method has its advantages and either will give accurate results under proper working conditions.

*Electrical Equipment.*—The electrical units installed on the various jobs are as listed in Table 3.

*Illumination.*—All illumination is by electric power from the storage battery. There are lights in the battery house and in the operating room, on the stairs to the operating room, on the towers at the foot and top, for roadway illumination, as required by law for navigation, warning signals on the barrier gates, and flashing signals at the portals. As these lights are on wiring circuits regularly carrying the normal battery voltage and as the voltage is much higher during the time when the battery is being charged, variable resistances are installed in all lighting circuits to permit reducing the voltage to a safe maximum.

TABLE 2.

| Bridge. | Height of tower, in feet. | Height of lift, in feet. |
|---|---|---|
| St. Georges, Del. | 168.1 | 123 |
| Chesapeake City, Md. | 186.0 | 131 |
| Summit Bridge, Del. | 115.6 | 71 |
| Reedy Point, Del. | 174.1 | 131 |

*Telephone.*—All bridge operating rooms are connected by telephone to commercial exchanges regardless of the position of the span. This is accomplished by means of a flexible cable between the span and one tower. The suspension point on the tower is slightly above the mid-height. A small sheave riding in the loop of the cable and held by a vertical guide-wire restrains the cable from blowing against the side of the tower, or under the span.

TABLE 3.—List of Electrical Units at the Various Bridges.

| Units. | St. Georges, Del. | Chesapeake City, Md. | Summit, Del. | Reedy Point, Del. |
|---|---|---|---|---|
| Total moving load, in tons. | 1 425 | 2 040 | 1 400 | 1 138 |
| Operating motor (horsepower) | 70 | 100 | 70 | 70 |
| Rates of speed in rising, in feet per minute | 65 | 75 | 80 | 70 |
| Time for full opening, in minutes | 2 | 2 | 2 | 2 |
| Number of cells in battery | 250 | 250 | 110 | 250 |
| Type of cells | F 9 | F 13 | F 13 | F 9 |
| Voltage of battery | 520 | 520 | 230 | 520 |
| Capacity of battery | 40 amperes for 8 hours; final voltage, 437; 160 amperes for 1 hour; final voltage, 405. | 60 amperes for 8 hours; final voltage, 437; 240 amperes for 1 hour; final voltage, 405. | 60 amperes for 8 hours; final voltage, 192; 240 amperes for 1 hour; final voltage, 178. | 40 amperes for 8 hours; final voltage, 437; 160 amperes for 1 hour; final voltage, 405. |

*Warning Signals to Highway Traffic.*—For signaling to highway traffic that the bridge is being raised there is a warning bell and a pair of flashing red lights on the oncoming side of each approach. These are put in action before the opening is begun, by turning a snap switch in the operating house. The switch must be on before power is available for operating the motor.

*Storage Batteries.*—The storage batteries are housed in well-ventilated brick buildings near the north end of each bridge. On all bridges except that at Reedy Point an ampere-hour meter in the battery leads registers the approximate quantity of stored power at all times. The indicator hand moves in one direction as power is withdrawn and returns as it is replaced by charging. An automatic trip on this meter shuts the generator set down as soon as the battery reaches the fully charged state.

*Details of Construction, St. Georges Bridge.*—The plans for this bridge required a symmetrical layout of the two piers and two abutments, as shown in Fig. 5. The contractor worked the north side of the canal with a 10-ton "whirler" derrick equipped with a 75-ft. boom and the south side with a steel stiff-leg derrick. The caissons were 15 ft. by 41 ft. in plan. The north one was to be driven to Elevation — 43.0 and the south one to Elevation — 41.0; in each case the top of the base was at Elevation 0.0, at which point the neat work begins. An attached coffer-dam was required because this bridge crossed the canal in the upper level where the water was held at Elevation +17.5. The cutting-edge of the north caisson was set at Elevation + 9.0. The first concrete poured was allowed to set six days before the forms were stripped and the sinking was begun.

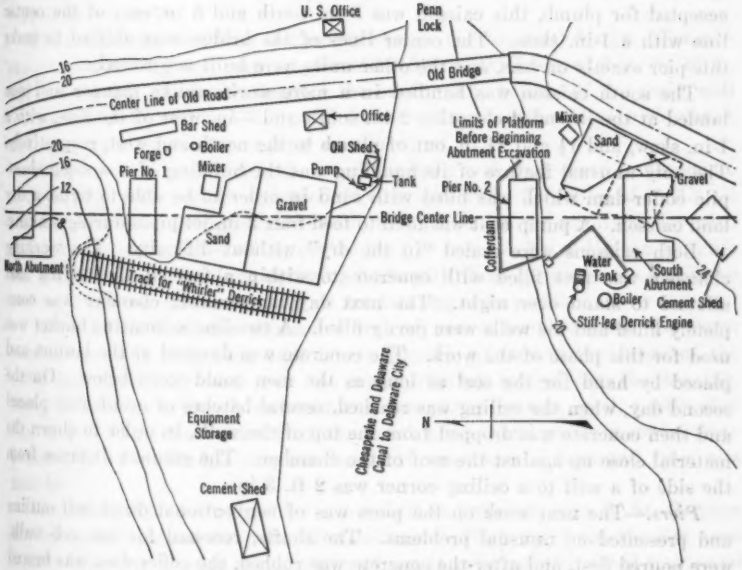

FIG. 5.—PLANT LAYOUT OF SUBSTRUCTURE, ST. GEORGES BRIDGE.

Sinking was halted when the top of the concrete was about 2½ ft. above the ground surface, forms were set, and another lift of concrete was poured. These lifts averaged about 6 ft. in height. Forms were removed in not less than 48

hours and sinking was resumed. No unusual sinking difficulties were encountered in either of these caissons except that in the beginning the contractor's organization was indifferent to the need of checking the location adequately and directing the mucking properly. The inspection force was determined to make the pioneer job a standard for the following ones, however, and the contractor was required to plumb the north caisson which was leaning 12½ in. north and 11½ in. west, with only 4 ft. to sink before the landing elevation was reached. The cutting-edge at this point was 48 ft. below the ground surface and the material had been quite firm for the 27 ft. of sinking. The center of gravity was well below the ground line and mucking under the high edge combined with blocking under the low edge was ineffectual to right the caisson, even when two water jets were worked along the high side. All this time the caisson was sinking and was soon below the intended landing point and in acceptable material for sealing. Finally, a bridle was rigged on needle-beams and twice daily a strain was taken and clamped off, and the jetting was continued. By this method in 13 days the caisson was brought to within 2 in. of plumb in this direction. In the transverse direction the high end was loaded with earth by covering the east well and sheathing the east row of struts, thus forming a pocket inside the coffer-dam. Two jets were worked around the high end and the leaning was corrected from 12 to 1½ in. in 11 days. When accepted for plumb, this caisson was 3 in. south and 5 in. east of the center line with a 1-in. skew. The center lines of the bridge were shifted to make this pier exactly on line, and the other units were built accordingly.

The south caisson was handled in a more workmanlike manner and was landed at the intended elevation 2 in. south and 3 in. west of the line, with a 1-in. skew, and 1½ and 2½ in. out of plumb to the north and west, respectively. The only unusual feature of its handling was the building of a wooden sheet-pile coffer-dam which was filled with sand in order to be able to build a dry land caisson. A pump boat was used to feed four 2-in. jet pipes during sinking.

Both caissons were sealed "in the dry" without difficulty. The working chamber was first filled with concrete to within a foot of the ceiling and allowed to stand over night. The next day the working chamber was completely filled and the wells were partly filled. A two-line submarine bucket was used for this phase of the work. The concrete was dumped at the bottom and placed by hand for the seal as long as the men could work below. On the second day, when the ceiling was reached, several batches of grout were placed and then concrete was dropped from the top of the wells, in order to churn the material close up against the roof of the chamber. The greatest distance from the side of a well to a ceiling corner was 2 ft. 3 in.

*Piers.*—The neat work on the piers was of conventional dumb-bell outline and presented no unusual problems. The shafts, recessed for the web walls, were poured first, and after the concrete was rubbed, the coffer-dam was braced against the shafts to permit the removal of the cross-braces so that the web wall might be poured without boxing out the bracing timbers. After this work was finished, the bolts holding the sheeting of the attached coffer-dam to the caisson were backed out, the timber bracing was removed just ahead of the back-filling, and the sheeting pulled.

*Abutments.*—The abutments are supported on concrete piles 14 in. square and varying in length from 16 to 26 ft. The lengths necessary were determined by driving a timber test pile of the same cross-section (14 in. by 14 in.) as the concrete piles, and 30 ft. long; these test piles were driven when the abutment excavation was at such a depth that the little additional material penetrated might be disregarded. Seven of these piles were driven for the north abutment and a contour sketch was made of the elevations of the tips when the requisite bearing of 20 tons per pile was reached. On this basis lengths were determined for pre-casting the piles. The first piles driven stopped at the depths anticipated, but those driven later, after the soil became more compacted, met with greater resistance. It was impossible to drive test piles even to the minimum penetration required in the coffer-dam at the south abutment. A 1¼-in. jet was rigged up and five holes jetted over the area disclosed the presence of a thick layer of fine tight blue sand through which the piles would have to be jetted. Consequently, 20 ft. 3-in. piles were cast with a 2-in. pipe in the center. In driving, a hole was first made with a free jet and the pile placed therein with its inside jet flowing. At times, the outside jet was required during driving. In all cases the water was shut off when the pile was within a foot of the required depth and the remaining penetration was secured by the hammer alone, in order to have a figure for computing its supporting capacity.

The coffer-dams for these abutments were of conventional design. Tongue-and-groove sheeting was used on one and a double thickness of 2-in. by 10-in. and 2-in. by 12-in. oak sheeting for the other. The bottom of the main wall footing was at Elevation + 0.5, or 17 ft. below the water level in the old canal, and, therefore, constant pumping was required.

The piles were cast during the winter months and were cured under steam at about 120° Fahr. They withstood driving very well. Two piles of 1 : 1.5 : 3 concrete, cured for 19 days under steam, were driven on the twentieth day with only a small amount of spalling on the head of one. A No. 2 Vulcan hammer was used for all the driving; swinging leads with three guys were used and the bottom of the pile was accurately set for locating it in position.

The neat work of the abutments was of conventional design. By some overhead bracing and tying back it was possible to remove the struts of the coffer-dam timbering and pour the walls without boxing out the bracing. Material for the approach embankment was partly caisson spoil, partly clay dug by an orange-peel bucket from the canal bottom, and partly material from borrow-pits at the bridge site, but mostly it was material borrowed from pits near-by.

*Erection of Steel Work.*—The two towers and the lift span of St. Georges Bridge contain about 250 tons of metal each. With the floor, the lift span weighs 700 tons. Due to the necessity of not interfering with canal traffic and the fact that five panels of the lift span were over dry land prior to the final dredging operations, it was necessary to erect the span on falsework high enough to provide 55 ft. of vertical clearance over the water. All steel for this contract was transported by water and unloaded at the site by a stiff-leg derrick on the north side, which was mounted to travel on rails parallel to

the bridge (see Fig. 6). This derrick had an 85-ft. boom. Steel for the south tower was then carried across the canal on a scow to within reach of the derrick.

The bottom section of the north tower was erected by means of the stiff-leg derrick which then was used to erect the falsework for the north five panels of the lift span. A steel guy derrick with a 75-ft. mast and a 70-ft. boom, supported on falsework 117 ft. high, was then rigged to complete the erection of the north tower (see Fig. 6) and, after being moved to a lower

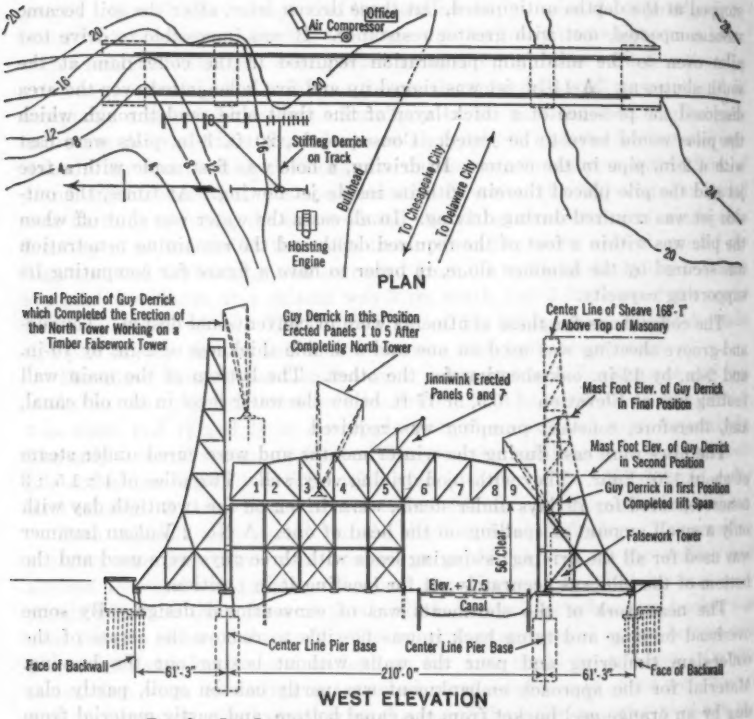

FIG. 6.—JOB LAYOUT, ST. GEORGES BRIDGE SUPERSTRUCTURE.

position, was used to erect the north five panels of the lift span. This derrick was then moved to the south side of the canal for setting the steel in the bottom section of the south tower. Its next position was on falsework inside the tower, where the bottom of the mast was about 36 ft. above the top of the masonry. From this point a falsework bent was built to carry the south end of the lift span. During this time a "jinniwink" working from the top chord of the lift span, and fed by the stiff-leg derrick, placed the steel of the two panels south of the center panel, cantilevering over the channel. The guy derrick then completed the lift span and south tower in two moves.

Steel-plate counterweight forms were assembled on the floor of the approach spans with the reinforcing and counterweight girders inside. Two counterweight ropes were passed over each sheave, by a gin-pole mounted on top the tower, and connected through the equalizers and eye-bars to the counterweight girder. The opposite ends of these ropes were then connected to two sets of blocks reeved for two lines to a hoisting engine, and the counterweight box with the girder was raised until the ropes could be attached to the lifting girder. The gin-pole then placed the remaining ropes over the sheaves. After all the counterweight ropes had been connected and allowed to carry the full load of the empty counterweight box (about 20 tons) some variation in length was observed, due to unequal untwisting of the ropes in erecting. These long ropes were disconnected at one end and were reconnected with from one-half to one and one-half turns more twist in them, depending on the shortening desired. Tests made later at the rope factory on 1¾-in. ropes, 176 ft. long, showed that a half turn changed the length nearly ½ in. The balance chains were erected in short sections after the counterweight ropes, using a line from the hoisting engine.

The towers were plumbed in the position of computed camber before riveting was begun. The lift span was swung clear of the falsework before it was riveted.

*Concreting.*—Concreting of the floor-slabs and counterweights was done in the following sequence, in order not to overload the two falsework bents which were then the sole support of the lift span: (1) North span slabs; (2) 7-ft. pour at the north counterweight; (3) 7-ft. pour at the south counterweight; (4) lift-span slabs; (5) counterweights completed; and (6) south span slabs.

Due to cold weather, a special quick-setting cement was used for the sidewalk slabs of the south span. All concrete, of course, was heated prior to placing in the forms. The metal counterweight forms were draped with tarpaulins extending well below the bottoms and were heated by steam jets. Concrete for the counterweights and the lift span slabs was elevated by means of a bucket running up a mast. Such a mast was set up on the floor of each tower span.

*Adjustments.*—The bridge is paved with 5-in. by 12-in. asphalt blocks laid on a ½-in. mortar cushion. By the time the paving was completed, all machinery, other than electrical, was installed, and the counterweights were loaded with balance blocks until the span could be raised by the gasoline engine. The falsework bents were then removed and the span was lowered to the down position; the shoes were grouted to proper elevation; the expansion plates on the fixed spans were set to match those on the lift span; and the span and the counterweight guide casting were set and attached. One of the castings had been attached prior to the pouring of any counterweight concrete. After beginning operation, it developed that that method was improper because the counterweight did not hang exactly as had been expected and the guide casting wore quite rapidly. It had to be replaced by one properly set.

Traffic was turned on the bridge on March 1, 1926, to permit the removal of an old lock, and the bridge was operated by the auxiliary power unit pending the completion of electrical installation. Since the movement was only 10 ft.

of travel per min., much adverse comment was forthcoming from the traveling public.

The installation of electrical equipment was completed before commercial power was made available for operating the motor generator set for charging the battery. After the battery (250 cells of 9 plates each) was set up and the electrolyte poured, an attempt was made to make the initial charge by driving the generator by the gasoline motor, but to charge the entire battery as a unit was impossible, because the belt drive, from engine to generator, was too short and was in the wrong direction to transmit full load. Consequently, the battery was split in half for charging purposes and each half was charged for twelve hours each day continuously except for time required for making lifts. Ten days were required to raise the specific gravity to a point high enough to make it safe to leave the battery inactive. When commercial electric power was made available, operation was begun with the use of regular equipment. The speed of travel in lifting was increased to 60 ft. per min., with a satisfactory shortening of delay to traffic. The cost of this bridge was $354 000.

## Substructure of the Chesapeake City Bridge

At Chesapeake City the bridge crossing was over Back Creek, which is tide water. Both pier locations were in the stream and both abutment locations were covered at high tide. The contractor elected to work each side with his favorite bit of equipment, a 10-ton "whirler" derrick with a 75-ft. boom. (See Fig. 7.)

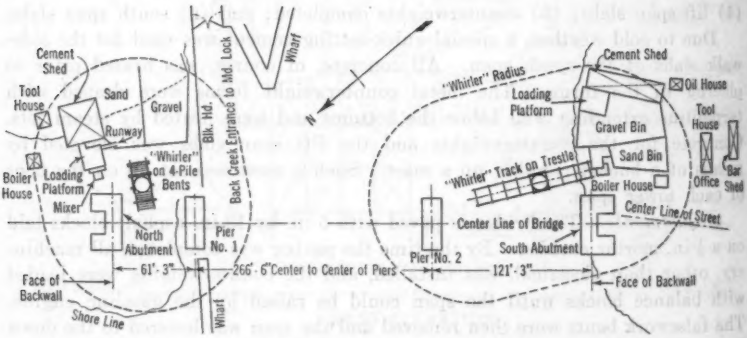

Fig. 7.—Plant and Job Layout, Chesapeake City Bridge Substructure.

*Caissons.*—The pier bases were 16 by 43 ft. in plan and were built 42 ft. and 49 ft. high for the north and south piers, respectively. The planned elevation of the tops was —15 (mean low water at Chesapeake City is Elevation +2.3 and mean high water is Elevation +4.5). Floating caissons 26 ft. high were built on land ways and launched at high tide. A composite steel and timber construction was used; the cutting-edge, walls, and roof of the working chamber and wells for a height of 20 ft. were of steel-plate and angle construction as was some bracing in the bottom 6 ft. The outside faces

above the cutting-edge were of 3 by 12-in. tongue-and-groove oak sheeting supported by 12 by 12-in. timber bracing.

Both caissons were adequately caulked and no difficulty was encountered in towing them to position. The work of sinking the floating caisson to the creek bottom was begun on an ebbing tide until 6 ft. of concrete had been poured. At first, difficulty was experienced in keeping the caissons plumb because the 1-yd. concrete bucket was too large for the narrow caisson openings. Open-well dredging was then begun and concrete was poured as required. Coffer-dams, similar in detail to those used at St. Georges, were attached above the tops of the caissons.

The south caisson was sunk by open-well dredging until it became apparent that proper control was impossible because of buried logs. The equipment for pneumatic work was then installed. There were three wells, 7 ft. in diameter, and one man-lock, one muck-lock, and one concrete lock. This caisson was sunk under air from Elevation —28 to Elevation —42, when it was necessary to shift the pneumatic equipment to the north caisson. Open dredging was again attempted and abandoned as unsatisfactory. After the north caisson was sealed, the air equipment was returned to the south caisson, which was uneventfully driven to Elevation —57 and sealed in a hard blue clay. For the sealing, both the concrete lock and the muck-lock were used; the working chamber was filled to within 1 ft. of the ceiling and allowed to set under pressure for 60 hours before removing the locks and concreting the wells.

The north caisson was sunk to Elevation —42 by open dredging, where strata of sandstone prevented further sinking by this method and the pumps could not keep the water down sufficiently for men to enter the working chamber. The air plant was installed and the sinking was continued to Elevation —64. The material at this elevation was not as good as was desired and, after making a series of explorations by auger borings, it was decided to stop the caisson where it was, but to excavate to Elevation —69 before sealing.

*Erection of Steel.*—The site of the Chesapeake City Bridge and the suitable plan of erection differed radically from those of the other jobs. All three spans were over water and within reach of the boom of a derrick-boat. Furthermore, the span was too long to erect, economically, on falsework, and, at the same time, provide the required clearances.

The towers, above the bottom section, were erected by a creeper which traveled up the front legs. A small stiff-leg derrick (equipped with a jib) was mounted on a trussed frame that rested on brackets bolted to the tower columns. The entire unit was hoisted by cables reeved through blocks attached to the tops of the last erected column sections. The sheaves were set and the ropes hung by this creeper.

The counterweight forms, of the same metal arrangement as those at St. Georges, were assembled resting on a grillage supported by temporary brackets attached to the tower front and rear legs. In this position the counterweight was about 1½ ft. below its position with the span seated. After the towers were riveted, the counterweight concrete was poured sufficiently high in the forms so as not quite to balance the metal and machinery of the lift span.

The balance chains could not be attached until after the supporting grillage had been removed.

The lift span was erected on three scows anchored in front of the south pier and was protected by a system of pile clusters. The operating machinery was installed and the down-haul ropes run on the drums. The up-haul ropes had been attached to the tower tops. The falsework on the scows had been detailed so that, at high tide, the span would be high enough to permit attaching the ropes, already fastened to the counterweights, to the lifting girder and, by partly flooding them at low tide, the scows would lower the span to its position on the shoes and be low enough to pull out from under.

On January 23, 1926, canal traffic at this point was suspended and the lift span was floated into a position where it should have been possible to move it sidewise into place over its shoes. An interference developed which required the removal of four deflector sheaves and a steel member in the roadway floor system at the north end before the span was coaxed into position. The counterweight ropes (sixty-four in all) were connected and after the scows were taken from under the span, the supports upon which the counterweights had been built were removed, and the installation of operating ropes was completed. Thereupon, an effort was made to raise the span by means of the 40-h.p. gasoline engine. The first effort was unsuccessful, due to extra weight that had been placed on the span to insure its picking the counterweights off their supports. After the removal of some of this weight, the span was picked on the second attempt with the engine fully loaded. As the span was raised and the weight of the counterweight ropes was transferred from the span to the counterweight side of the sheaves the engine found the load easier and easier to pull until after having lifted the span 86 ft. the balance was nearly even. The span was lashed at this point and was not moved again until all the concrete and paving work was completed.

The approach spans were riveted as soon as they were swung and the towers as soon as they were plumbed and before the counterweights were poured. On the lift span the lifting posts, lifting girders, floor-beam connections, and stringer connections at alternate floor-beams were riveted while the scows were carrying the load; all other riveting was done after the span was swung.

After the span had been raised and canal navigation had been resumed, an investigation as to the cause of the lack of end clearance during the "floating in" was made. It was discovered that through an error in the drafting-room, four members in the eleven-panel trusses, had been fabricated 2⅝ in. too long. To replace them was impracticable and it was necessary to shift all the deflector sheaves 2⅝ in. and to reinforce all top chord splices (many of which were partly open) so that the stresses might be computed as being carried entirely by rivets.

On April 24, 1926, all metal work, concrete, paving, and machinery installation had been completed, and the bridge was opened to traffic to allow the removal of the old bridge. On the next day, while operating in a heavy wind, a balance chain fouled on a horizontal brace of the north tower, and broke. The falling chain and the tower were severely damaged. The bridge was

closed to traffic and replacement parts and material for a revision of details of the chains and towers were ordered. The approaches to this bridge were constructed by the State of Maryland. The cost of the bridge was $476 000.

## Substructure of Summit Bridge

Summit Bridge is located 5 miles east of Chesapeake City, in what is known as the "Deep Cut". The banks at this point are 80 ft. high and it was necessary to excavate 56 000 yd. of dry material so that the substructure could be put in and the approaches made. This was an extra contract item and was performed by steam shovel and trucks in a period of four months, before actual work on the regular contract could begin. The bridge rests on four piers as shown in Fig. 8. Piers Nos. 1 and 4 are spill-through abutments, and Piers Nos. 2 and 3 are essentially of the dumb-bell type, resting on solid concrete bases.

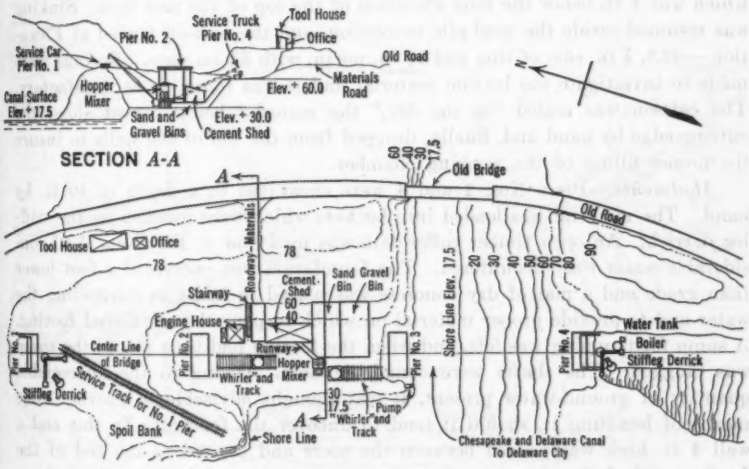

Fig. 8.—Plant and Job Layout, Summit Bridge Substructure.

The contractor used two 10-ton "whirlers" with 75-ft. booms for Piers Nos. 2 and 3, and two stiff-leg derricks for Piers Nos. 1 and 4. A central mixing plant was used for concreting. The two "whirlers" handled materials and placed the concrete for Piers Nos. 2 and 3, but trucking was necessary to convey the concrete to Piers Nos. 1 and 4.

*Caissons.*—The pier bases were built by sinking concrete caissons, 20 by 46 ft. in plan, with three 7-ft. wells. These wells are of the same type as those described for the bridge at St. Georges. The base for the south pier was planned for a height of 49 ft., but was built 55 ft. high. The base for the north pier was planned and built with a height of 43 ft. The attached cofferdams were similar in detail to those at St. Georges Bridge.

The shoe for Pier No. 2 was set at Elevation +41 and the first pour made. After the usual 6-day curing time, the work of sinking the caisson was begun. At Elevation —27 it became necessary to extend the attached coffer-dam (which was already 24 ft. high) by an additional 20-ft. section. The sinking of the caisson was resumed, but friction on the sides of the attached coffer-dams became so great that three days of jetting and jarring with dynamite were necessary to start the caisson moving. Steel drums 7 ft. in diameter were placed around the wells, and the caisson was loaded with mud for added weight to aid sinking. At Elevation —37 the west end of the attached coffer-dam was seen to be pulling free from the caisson and sinking was stopped. At this point the top of the pier base was at Elevation +6 and the ground surface at Elevation +41, which gave a vertical height of 35 ft. of attached coffer-dam subject to skin friction. Thirty days were lost while 45-ft. steel sheet-piling was secured and driven around the caisson. This sheeting was driven quite close to the attached coffer-dam and penetrated to Elevation —4, which was 4 ft. below the final elevation of the top of the pier base. Sinking was resumed inside the steel-pile protection, and the caisson landed at Elevation —42.8, ⅞ in. east of line and 1½ in. north, with 3½-in. skew. Borings were made to investigate the bottom material and it was found to be satisfactory. The caisson was sealed "in the dry," the material being placed along the cutting-edge by hand and, finally, dropped from the top of the wells to insure the proper filling of the working chamber.

*Abutments.*—Piers Nos. 1 and 4 were excavated to a depth of 40 ft. by hand. The material was loaded into buckets which were handled by the stiff-leg derrick. An open timber coffer-dam was used and at Elevation +40 considerable water was encountered. The foundation was excavated a foot lower than grade and a mat of dry concrete was placed to assist in controlling the water and to provide proper material on which to pour the reinforced footing. A sump for pumping was left, and when the footing had been placed the sump was plugged. The shafts were completed next. Owing to the appreciable quantity of ground-water present, it was thought advisable to provide some means of handling it, should it tend to uncover the footing. To this end a wall 4 ft. high was poured between the piers and beyond to the end of the footing, with drain pipes placed so that a connection might be made to them. Thus, the water might be carried away without the possibility of erosion close to the pier.

*Erection of Steel Work.*—The erection plan called for the use of falsework bents under the entire structure, the lift span being erected in the down position. This plan left a clear height of 56 ft. through the then existing canal channel which passed under the south approach span. One bent of falsework was omitted under the fifth panel, leaving a clear width of 25 ft. between bents. Timber fenders were built to protect the pile bents in the narrow channel.

The steel and machinery were delivered by rail at Mount Pleasant, Del., two miles from the bridge site, by a concrete road, and were trucked to the job where the traveler unloaded and sorted them in the yard.

A 10-ton traveler with 50-ft. boom was used to set the falsework as well as the steel in the floor system and the trusses of the three spans. When the spans were completed a guy derrick was set on falsework on top of the north end of the lift span and by the use of a 100-ft. boom all the north tower steel was placed. The derrick was shifted from the north to the south end of the lift span in 8 days, and the south tower was erected in 14 days thereafter. The cost of this bridge was $475 000.

### Substructure of Reedy Point Bridge

The Reedy Point Bridge was built over the already dredged, but not then used, new entrance south of Delaware City. The abutment and pier details were quite similar to those at St. Georges, except that timber piles were used under the abutments instead of concrete. (See Fig. 9.) The site was level and entirely free from obstruction of any nature. Abutment excavation was in a light sand and jetting of the piles was not necessary; 26-ft. piles reached the required bearing value of 20 tons.

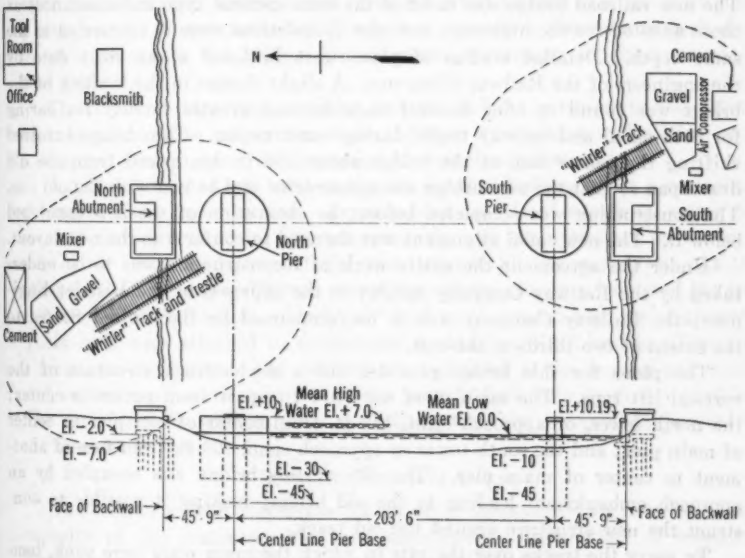

Fig. 9.—Plant Layout, Reedy Point Substructure.

*Caissons.*—In order to avoid the building of floating caissons, circular coffer-dams, 43 ft. in diameter, were driven in 40-ft. lengths of 13½-in., straight-web steel sheet-piling to Elevation —30 and filled up to above high water with sand dredged from the canal. The caissons were built on these islands. Excavation was done partly by orange-peel bucket and partly by hand.

*Erection of Steel Work.*—The shore lines, at high tide, were against the abutment faces; the channel was closed to all traffic and the Government loaned the contractor a 10-ton derrick-boat; these last named features per-

mitted simple falsework erection (3-pile bent) and the building of the lift span complete, including concreting and paving, in the down position.

Some steel was delivered by barge from the rail-head at Delaware City, but mostly it was trucked from Wilmington, Del., and unloaded by the traveler brought from Summit for the purpose.

The bottom sections of the towers were erected by the derrick-boat on the south side and by the traveler on the north side. The same creeper that was used at Chesapeake City, revised for the narrower width, was used to erect the remaining tower steel and no difficulty was encountered. The sheaves and the counterweight ropes were set by means of the creeper before it was finally lowered to the ground. The lift span was erected in part by the derrick-boat and in part by the traveler. The cost of this bridge was $318 000.

### Bridge of the Pennsylvania Railroad Company

By agreement with the Chief of Engineers, United States Army, the Pennsylvania Railroad Company arranged to rebuild its bridge across the canal. The new railroad bridge was to be of the same general type and clearances as those adopted for the highways, and pier foundations were to be carried to the same depth. Detailed studies of plans were initiated at an early date by the engineers of the Railway Company. A slight change in the location of the bridge was found to offer decided economy and greater facility for caring for both canal and railway traffic during construction. The change involved shifting the center line of the bridge about 250 ft. southward from the old draw-span so that the new bridge was constructed end to end with the old one. The construction was completed before the excavation of the new canal bed below it. The new canal alignment was changed to conform to the new layout.

Under the agreement the entire work of reconstruction was to be undertaken by the Railway Company subject to the approval of the District Engineer; the Railway Company was to be reimbursed by the United States to the extent of two-thirds of the cost.

The plans for this bridge provided for a double-track structure of the vertical lift type. The main piers were 211 ft. apart from center to center; the north tower, or approach span, 172 ft. from center of rest pier to center of main pier; and the south tower or approach span, 106 ft. from face of abutment to center of main pier. The site of this bridge was occupied by an approach embankment leading to the old bridge, making it possible to construct the new structure around the old track.

To carry the tracks over the pits in which the main piers were sunk, temporary girders, supported on pile abutments, were installed, and switches were provided to shunt all regular railway traffic to the northbound track on the bridge. The southbound track was left free for use of the necessary construction plant engaged on the new work.

In all essential elements, the design of this bridge was the same as that of the highway bridges, except for the heavier loading. The main piers were sunk by the same process and to the same depths as those for the highway bridges. The foundation material was not as satisfactory as could have been desired (especially that in the north main caisson) and, later, gave rise to

troublesome pier movements. There was, however, no promise of finding better material by going deeper, so it was necessary to make the best of the material encountered. The share of the cost of this bridge paid by the United States was $552 000.

### Pier Movements

The St. Georges, Summit, and the Pennsylvania Railroad Bridges were constructed prior to the excavation of the new canal prism past their sites, and subsequent to or during such excavation, movements of the main piers occurred in all three cases. The principal movement in each case occurred on the north pier, and in the latter two cases it was sufficient to interfere with the operation of the bridge. The maximum movement seems to have been about 3 in. horizontally, that is, the piers moved toward the channel that much, while the railroad bridge pier not only moved horizontally about the same amount, but also settled about 3 in. This movement in each case appears to have been due to a slight tipping of the pier due to a re-adjustment of earth pressures after the foundation material had been disturbed by the excavation of such a large prism. It was necessary to resort to corrective measures in each case in order to render the bridge operative without danger to either canal or land traffic.

The railway bridge was raised by jacking, and the north tower was moved back enough to give proper clearances. Shims were placed under it to raise it to proper grade. After this operation it worked satisfactorily.

A different method was used on the St. Georges Bridge, where a horizontal movement alone had occurred. A pump-boat capable of supplying water for seven or eight jets of 1½-in. pipe was available, and jets were sunk on the land side of the piers until the material was loosened all the way down. At the same time a 3-in. steel cable was passed around the pier in a loop, and the two ends were brought back to substantial "dead men" located near the abutments. These ends were attached to screw-jacks working on the "dead men" to give a strain on the cables. The cables were tightened as the jetting proceeded, and, in this manner, the pier was slowly brought back into its proper position. The same method, with suitable variations, was then successfully applied to the Summit Bridge.

### Economic Value of Canal

The soundness of a prediction for an early demand for an increase in the capacity of this waterway has been questioned. Antagonists of waterway improvements have declared it a waste of public funds. This is not the case in the instance of the Chesapeake and Delaware Canal. Assuming that a public work like this is for public good, for public convenience, and for public economy, this canal makes an excellent showing for the funds expended on it. Omitting all consideration of pleasure boats, passengers, and empty vessels, it gives passage to from 600 000 to 700 000 tons of freight annually. Knowing the classification of this freight, its points of origin and destination, and the proper carriers rates, it is possible to compute the actual cost of transporting that freight by water, and to compute what it would have cost if shipped by rail, thus giving the direct saving, if any, due to the existence of the canal.

This computation was made in 1926 for the canal for the entire period since it was taken over by the United States in 1919. From the annual savings thus computed there was deducted all actual operating costs of the canal, an assumed sinking fund of 2% to amortize the total cost in fifty years, and interest at 4% on all appropriations. After making these deductions, the net savings in freight transportation costs (which is thus added to the National wealth) is in round numbers $1 000 000 per year, or, say, $1.25 for every ton of freight passing through the canal.

## Hydraulics

Prior to the completion of the canal, considerable interest from technical and practical standpoints attached to the question of the tides and currents that might be expected after the completion of the projects. The question involved a study of the result of the interference of two unequal opposed waves in a canal of limited length and of practically constant cross-section. There is little knowledge in the engineering world of the resultant phenomena in such cases. Navigators are interested in them from a practical standpoint, since they will have a bearing on the passage of vessels through the canal. Early attention, therefore, was given to studies of phenomena to be expected with a view to predicting them beforehand, and subsequently checking the predicted results by observing the actual phenomena.

The canal was to be 90 ft. wide on the bottom, with side slopes of 1 on 2. It was to be somewhat wider at the two ends, but this extra width was neglected in studying the problem. The depth was to be 12 ft. at mean low water, referred to the Sandy Hook datum plane; that is, its bottom was to be level. It has only a few curves, which are of long radius, and these were also neglected. Its length from Delaware River to Back Creek is 13.5 miles, and it extends down Back Creek (a slowly widening stream) for 4.5 miles. Back Creek was omitted from consideration in the computations for the sake of simplicity. This omission undoubtedly involved some error, but how much is not known. It is thought to be small. The major tide entering the canal (an average amplitude of 6 ft.) comes from the Delaware River. The minor tide entering from Chesapeake Bay has an average amplitude of 2.4 ft. at Chesapeake City. Mean tide level is at substantially the same elevation at each end. The smaller tide reaches Chesapeake City two hours earlier than the major tide passes the jetties in Delaware River. The bottom of the canal is 15 ft. below mean sea level.

There are many localities where unequal and opposed tides meet in natural channels, but in most such cases the phenomena peculiar to this problem are so masked by others due to purely local conditions (such as varying widths and depths) that very little progress has been made in their study, and but few studies are available in the English language.

Canals of fairly constant depth and cross-sectional area are usually artificial; and it is to this class that engineers must look principally for a solution of the problem proposed.

The Cape Cod Canal, which is an artificial cut connecting Cape Cod Bay with Buzzards Bay, in Massachusetts, presents the problem in a manner very similar to the Chesapeake and Delaware Canal. It has been described by William Barclay Parsons,[5] M. Am. Soc. C. E., who based his study on the writings of Airy, de St. Venant, and Maurice Levy. The equations he gives are substantially those of Levy.

Probably the best study of the problem in a natural channel is that of the English Channel by M. Bourdelles,[6] who does not attempt to solve the problem mathematically; but his explanation of the theory is excellent. By following the theory of M. Levy as given by Mr. Parsons, the writer has computed the tides and currents to be expected in the Chesapeake and Delaware Canal. The predicted tides as given by this computation are shown graphically in Fig. 10 (*a*), and the predicted currents are shown in Fig. 10 (*b*).

A study of the assumptions made in the deduction of the Levy equations, however, led the writer to doubt their validity, especially in the case of such a shallow canal as the one under consideration. He concluded that: (1) The wave propagated from each end should be considered merely as a wave of translation, with a positive phase during high water and a negative phase during low water; (2) its height at any point in the canal should vary sinusoidally as did the generating waves in the respective bays; (3) each of these waves of translation contained a certain quantity of energy; and (4) one-half the energy was potential and was represented by the height of the wave above mean sea level, and the other half was kinetic, represented by the velocity of the water at a given point; (5) this energy was expended in overcoming friction in accordance with a law which was deduced, resulting in a consequent falling off of height of wave and of velocity as the wave was propagated farther into the canal; (6) the resultant height at any point in the canal at any instant was the algebraic sum of the instantaneous heights due to each wave at that point; and, (7) the resultant velocity at any point was the algebraic difference between the instantaneous velocities due to each wave at that point. Fig. 11 shows the resultant heights and velocities as computed under these assumptions.

There are no striking differences in the results. Both indicate that (*a*) tidal propagation is not instantaneous; (*b*) in general, the canal surface between the two ends will be concave on a rising tide and convex on a falling tide; (*c*) the larger tidal oscillation at the Delaware River progressively decreases in amplitude to a point about 2½ miles from Chesapeake City; (*d*) the resultant wave is propagated in the direction of west to east, or against the direction of propagation of the major component wave; and (*e*) the speed, or rate of travel of the wave, is very small at the western end but extremely rapid at the eastern end.

Some discrepancies are found between the two results. The Levy formula gives symmetrical curves for high and low water, while the wave-of-translation formula does not. It gives amplitudes of greater magnitude for the positive

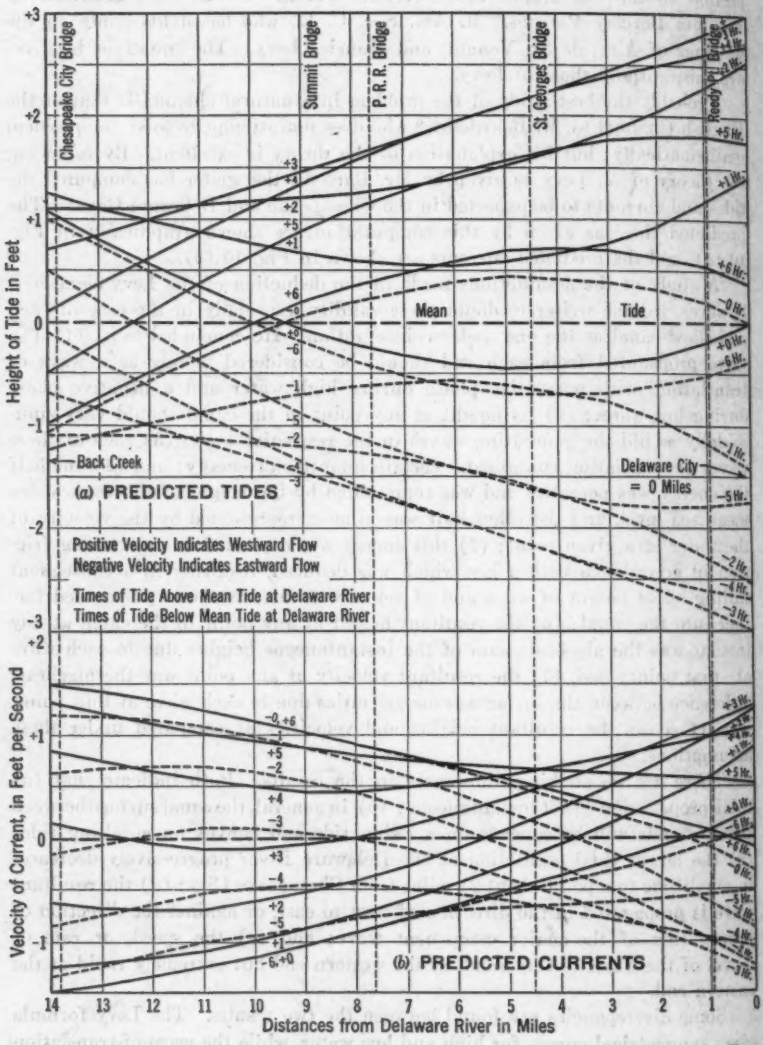

FIG. 10.—COMPUTED INSTANTANEOUS VELOCITIES OF TIDAL FLOW FOR EACH HOUR OF TIDE (BY PARSONS' METHOD).

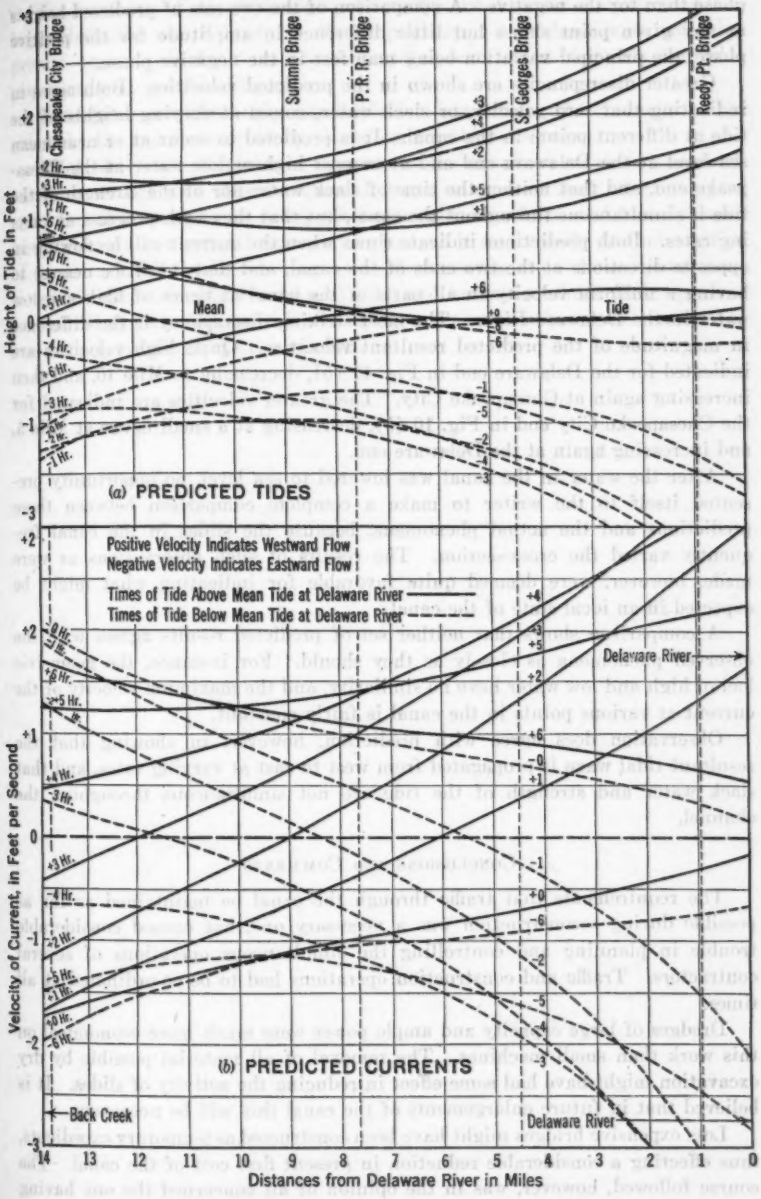

FIG. 11.—INSTANTANEOUS VELOCITIES OF TIDAL FLOW COMPUTED BY THE WAVE-OF-TRANSLATION FORMULA.

phase than for the negative. A comparison of the two sets of predicted heights at any given point shows but little difference in amplitude for the positive phase, the principal variation being manifest in the negative phase.

Greater discrepancies are shown in the predicted velocities. Both agree in indicating that zero velocity, or slack water, comes at varying heights of the tide at different points in the canal. It is predicted to occur at or near mean sea level at the Delaware end and at or near high or low water at the Chesapeake end, and that neither the time of slack water nor of the strength of the tide is simultaneous throughout the canal, but that they both progress at varying rates. Both predictions indicate times when the current will be flowing in opposite directions at the two ends of the canal, and that it will be nearest to having a uniform velocity in all parts of the canal at times of high and low water in the Delaware River. The most striking discrepancy is the difference in magnitude of the predicted resultant velocities. Quite high velocities are indicated for the Delaware end in Fig. 11 (*b*), decreasing to Mile 10, and then increasing again at Chesapeake City. The greater velocities are indicated for the Chesapeake City end in Fig. 10 (*b*), decreasing at a small figure at Mile 5, and increasing again at the Delaware end.

After the water in the canal was lowered to sea level, no opportunity presented itself to the writer to make a complete comparison between these predictions and the actual phenomena, because the slides in the canal frequently varied the cross-section. The results of such observations as were made, however, were deemed quite favorable for indicating what might be expected in an ideal state of the canal.

A comparison shows that neither set of predicted results agrees with the observed phenomena as closely as they should. For instance, the geometric loci of high and low water have no similarity, and the maximum velocity of the current at various points in the canal is fairly constant.

Observation does agree with prediction, however, in showing that the resultant tidal wave is propagated from west to east at varying rates, and that slack water and strength of the tide are not simultaneous throughout the channel.

## Conclusions and Comments

The requirements that traffic through the canal be maintained as far as possible during reconstruction was a necessary one, but caused considerable trouble in planning and controlling the simultaneous operations of several contractors. Traffic and construction operations had to be co-ordinated at all times.

Dredges of large capacity and ample power were much more economical on this work than small machines. The removal of all material possible by dry excavation might have had some effect in reducing the activity of slides. It is believed that in future enlargements of the canal this will be necessary.

Less expensive bridges might have been constructed as temporary expedients, thus effecting a considerable reduction in present first cost of the canal. The course followed, however, was in the opinion of all concerned the one having the greater ultimate economy.

The provision of an ample right of way for the disposal of spoil is exceedingly desirable where land is relatively cheap. Any damage to adjacent private property leads to vexatious disputes, exorbitant demands for compensation, and possible litigation.

Wet borings are absolutely unreliable for determining the character of the sub-soil. Dependence should be placed on core borings only.

Tidal variations of level and currents in the canal are on the whole detrimental to navigation. The detriment lies not so much in their effect on speed and time of transit, as on safety to the vessel. If a large and heavily laden vessel grounds and gets athwart the channel, as it may readily do under action of currents, a fall in the tide may break the vessel in two. Tows approaching closed bridges with a fair wind and tide, and having to check their speed on account of failure of the bridge to open, are particularly exposed to having one or more vessels of the tow ground.

## DISCUSSION

F. T. CHAMBERS,[7] M. AM. SOC. C. E. (by letter).—In recording the construction stages of the Chesapeake and Delaware Canal and in giving quantities, yardage, costs, and methods in connection with the dredging operations of the conversion from lock-level to sea-level, the author has done a useful service. The description of the deposit of spoil in the high-level disposal areas by means of modern hydraulic dredges of standard construction and the record of costs of this part of the work are in themselves sufficient justification of the paper without its many other features. The dredge performance is the more creditable by reason of the condition of the material as encountered.

While the history given is sufficient as to the physical aspects and the Canal Company finances, a bibliography of all publications concerning this canal and the many projects in general for canals across the Delaware Peninsula should be attached to this paper. Several public documents treat of this subject. A single report[8] relates much of this effort and records other reports with borings along this and other routes.

Public Joint Resolution No. 37, approved June 28, 1906, authorized the President of the United States to appoint a commission consisting of an officer of the Engineer Corps of the Army, an officer of the Navy, and one person from civil life,

"* * * to examine and appraise the value of the works and franchises of the Chesapeake and Delaware Canal, connecting the waters of the Chesapeake and Delaware bays, with reference to the desirability of purchasing the said canal by the United States and the construction over the route of the said canal of a free and open waterway having a depth and capacity sufficient to accommodate the largest vessel afloat at mean low water;" and, also, "to the extent that the same can be done from the surveys heretofore made under the direction of the War Department and within the limits of the appropriation herein made" to "examine and investigate the feasibility, for the purpose of such a waterway, of the route known as the Sassafras route."

The Commission was ordered to:

"Make a report of its work, together with its conclusions upon the probable cost and the commercial advantages and the military and naval uses of each of the said routes, to the Secretary of War, who shall transmit the same to Congress at its next session."

The late Gen. Felix Agnus, of Baltimore, Md., was the Chairman and Maj. (late Maj. Gen.) C. A. F. Flagler, Corps of Engineers, U. S. A., M. Am. Soc. C. E., and the writer were the other members of that Commission. From the very nature of its precept, the Agnus Commission was obliged to use past reports and other available data, and thus Senate Document No. 215 contains, in addition to survey and boring figures resulting from the field work of its own personnel, much that appears in previous reports.

Although it was the apparent belief of many interested people that the Chesapeake and Delaware Canal should be taken over by the National Govern-

[7] Rear-Admiral (C. E. C.), U. S. N.; Director, U. S. Naval Petroleum Reserves and Oil Shale Reserves, Washington, D. C.

[8] Senate Doc. No. 215, 59th Cong., 2d Sess.

ment and converted to sea-level operation by stages as the traffic demand might require, it will be seen from the text of the Congressional Resolution that the Agnus Commission started with a considerable handicap to full investigation. It was limited not only in time and money, but more particularly in the requirement of a canal to accommodate the largest vessel afloat. Although the Commission took considerable liberty in its interpretation of that expression it was still obliged to consider a depth of 35 ft. at mean low water. True, it took further liberties and figured a 30-ft. depth also but, because of its instructions, it could not estimate on barge depths. It did, however, go so far as to recommend the purchase of the Chesapeake and Delaware Canal for a sum not to exceed $2 514 289.70 and to record the public pressure for gradual deepening. It may be stated here that the Commission assumed that much of the high-elevation excavation would be steam-shovel work.

Although the Commission reported upon the Sassafras route, it found in favor of the Chesapeake and Delaware route, recommending a sea-level canal following much the same lines as that described by the author, but debouching upon the Delaware several thousand feet below Reedy Point. It also found for jetties at the Delaware entrance "for at least 1 000 ft. from shore".

The author's study of the canal hydraulics is interesting. It is to be hoped that observations of actual tidal heights and currents will be made and published. The Angus Commission gave consideration to the matter of currents and to a difference of tidal heights between the Chesapeake and the Delaware ends of 6 to 10 ft. It also gave consideration to the tidal lag at the Chesapeake end. It compared the physical conditions at the Chesapeake and Delaware Canal with those at Suez, where M. Quellenec reported an extreme tidal difference of 9.02 ft. and a resultant current of 2.6 knots. Furthermore, it cited the lockless sea-level canals of Corinth and Tasmania, which are easily traversed by vessels, together with computations made for a tide-level Panama Canal. It did not attempt, on account of its limited time and funds, to make complex computations based on any recognized formula, but it did make rough over-all estimates. It concluded that a tide lock was not indicated as part of the cost.

The writer has nothing to criticize in this able paper. He agrees with the author in the conclusion that in future enlargement of the canal it may be a saving of expense in the lessening of landslides to remove some part of the overburden by dry methods.

His only disagreement is with regard to wet borings. Such borings are not absolutely unreliable for determining the character of the subsoil. The writer has made or supervised the making, first to last, of many borings at numerous places. He does not choose wash-rod borings where time and money will procure borings of a more positive type. A small percentage of his borings have been exclusively wash borings. Many wash borings are worthless, or nearly so; but the wash rod with casing can be applied with considerable satisfaction for the determination of some subsoil conditions, especially of conditions for dredging and where due care is had in the use of sampling devices, ancillary to the methods of the wash rod.

# EFFECT OF TURBULENCE ON THE REGISTRATION OF CURRENT METERS[1]

BY DAVID L. YARNELL[2] AND FLOYD A. NAGLER,[3] MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. CHARLES S. BENNETT, CARL ROHWER, BREHON B. SOMERVELL, N. C. GROVER, BURKE L. BIGWOOD, G. H. NETTLETON, C. LINDEN, H. R. LEACH, LUDWIG A. OTT, B. F. GROAT, FORREST NAGLER, ROBERT E. HORTON, RICHARD VAN VLIET, AND DAVID L. YARNELL AND FLOYD A. NAGLER.

## SYNOPSIS

This paper describes a series of experiments which were conducted on several types of current meters for the purpose of determining the effect of turbulence, or variations in direction, and rapid changes in speed of flow, on their registration. In contrast with experiments hitherto made by moving the meter in still water, these tests were made by holding the meter stationary in a controlled stream of water.

The results of the tests are shown in diagrams and the conclusions are given at the end of the paper.

## INTRODUCTION

The current meter is an instrument commonly used to obtain water velocities as a part of the process of making discharge measurements on natural streams, and is also frequently used similarly in open artificial channels. The meter is usually rated or calibrated by pulling it at definite speeds through quiet water. Although such a rating may be performed with extreme accuracy, it is obvious that the stream-line condition is generally quite different from the more or less turbulent flow encountered by the meter when held stationary in a moving current. In fact, parallel filaments of flow, such as are duplicated in ordinary rating methods, are seldom seen in water

[3] Prof. of Hydr. Eng., Univ. of Iowa, Iowa City, Iowa.

flowing in either natural or artificial channels. On the contrary, the main stream current often appears to be the resultant of numerous cross-currents, rotating vortices, and eddies. This is particularly true in natural channels. Less turbulent conditions exist in canals, and gauging stations may usually be located at the lower ends of long tangents where the degree of turbulence is a minimum. Current-meter measurements demanding maximum accuracy often must be made in the head and tail-races of power plants where there is likely to be considerable turbulence.

Eddies encountered in flowing streams may be considered as circling or whirling masses of water moving within the whole mass of the stream. In other words, each eddy is, in effect, a separate body of water having a momentum of its own entirely different both in direction and magnitude from that of the main current. When the impact of such a body is transmitted to the moving wheel of a current meter, its registration, for the moment, will be different from that obtained in the uniformly flowing stream.

With these eddies passing irregularly in both time and magnitude, individual velocity measurements made at a given point by a current meter may be subject to considerable variation for no other reason than that the meter was not held long enough at the point to obtain an integrated mean representing the true average current. Believing that such departures may be of a compensating nature in combining all the observed points in a given stream measurement, engineers seldom spend more than 90 sec. in securing an individual reading. Nevertheless, even in mildly eddying water, considerable variation will be obtained in two consecutive readings of the ordinary duration, and the possible departure increases with increasing turbulence.

Current meters are made in various styles, but all have a rotating element, called the wheel or propeller, actuated by the moving stream. The instrument is generally designed so that the moving wheel forms, through the proper mechanism, a contact in a compartment where the electrical terminals for registering its revolutions are placed. Thus, the number of revolutions of the wheel may be obtained by connecting the meter with an electric counter, bell, or buzzer. Some meters are constructed so that the contact is made after the wheel has turned a certain number of revolutions as 1, 5, 10, 25, or 50. Thus, from the speed of rotation as measured over a definite period of time, the velocity of the flowing water is determined.

The current meters in common use may be classified as of two types: The cup type in which the wheel rotates about a vertical axis; and the screw type in which the wheel or propeller rotates about a horizontal axis, ordinarily intended to be held parallel to the direction of flow of the stream. When a meter is held at a definite point in a turbulent stream, it may be acted upon during successive instants by different stream filaments which may be flowing in various directions and may have various speeds. Even if the current meter is held rigidly at one place, the wheel will then be acted upon, not only by stream filaments which strike the rotating element at various angles, but also by filaments with appreciable variations in speed. The combination will cause the speed of the wheel to be alternately accelerated and retarded. There has existed hitherto a dearth of information regarding the effect of turbulence in

flow on the registration of different types of current meters, and it was to throw light on this question that the present investigation was made.

Some experimental studies have been made in the past to determine the characteristics of different types of meters under circumstances departing from the good velocity conditions usually found at most gauging stations; but hitherto few data have been published showing the specific deviation to be expected under abnormal conditions in using either of the common types of meter. Nearly all canal gauging stations and many river stations have conditions that yield readings to an accuracy that is within 1 to 4 per cent. Exceptions to these stations occur where gaugings must be made: (1) From a bridge with pier obstructions disturbing the flow; (2) in mountain streams and canals with bottoms strewn with rocks of various sizes; (3) on streams in which whirls and boils with mud and sand travel slowly with the stream; and (4) where gaugings must be made along narrow crests that develop vertical angularity to the flow. At such stations the hydrographer desires particularly a meter that will be actuated by the forward components of velocity only, provided the meter equipment is such that he can hold the instrument directly up stream. If they are free to turn and face the local current, all meters, of course, will reflect the direct velocities which are greater than the down-stream components perpendicular to the gauging section. The ideal situation, with parallel filaments of flow, would usually involve velocities too low to turn a meter with acceptable accuracy.

A summary of the comments of American experimenters in this field is given in the Appendix. The experience of these investigators seems to indicate that, under normal conditions such as exist at the majority of gauging stations, the current meter is to be regarded as a reliable instrument for measuring water velocity. Obviously, the best available conditions for stream gauging should always be sought. When eddies do exist, some meters have been found to register more, and others less, than the true forward component of the turbulent water. This forward component is equal to $V \cos \alpha$, in which, $V$ is the velocity of the water, and $\alpha$, the angle between the direction of local flow and the axis of the stream. Hereafter, this component will be referred to as the "cosine component".

When these experiments on current meters were begun it was expected that it would be a simple matter to put a given meter into a smooth, straight, uniform channel, carrying a known, constant, parallel-filament flow, and observe the meter reading; then produce violent turbulence by artificial means and measure the changes produced in the meter readings. Upon making the trial, however, it was found impossible to obtain consistent results that could be interpreted to any useful purpose. Therefore, it became necessary to change and expand the entire plan of experimental procedure. One step led to another until finally experiments which, at the outset, it had been intended to complete in 2 or 3 weeks, were carried on at intervals for 1½ years.

The experiments were made at the Hydraulic Laboratory of the State University of Iowa, during December, 1924, May and June, 1925, and May, 1926, by D. L. Yarnell, M. Am. Soc. C. E., Senior Drainage Engineer, under

the direction of S. H. McCrory, M. Am. Soc. C. E., Chief, Division of Agricultural Engineering, U. S. Bureau of Public Roads. S. M. Woodward and F. A. Nagler, Members, Am. Soc. C. E., of the State University of Iowa, acted as advisers, making suggestions during the conduct of the experiments and collaborating in the preparation of the data and the report.

## Types of Current Meters Used in the Experiments

Tests were made on the eleven current meters illustrated in Figs. 1 to 8, inclusive. Several of the meters have adjustable contact points so that the meter may record various numbers of revolutions per contact. In these tests, with certain exceptions that are noted where used, the maximum number of revolutions per contact was used for each meter.

It should be noted that the Hoff meter has a rubber propeller. Since rubber, with a specific gravity of 1.3, is but little heavier than water, presumably this meter has less bearing friction and responds more readily to changes in the velocity of water than the all-metel meters. Obviously, also, the flexible rubber propeller is unlikely to be injured by contact with floating débris that might break or bend the metal propeller.

## Description of Experimental Installation

The water used in the current-meter experiments was drawn from the Iowa River above the University Dam into the Laboratory Testing Canal which is 190 ft. long, and 10 ft. wide. In the canal, below a water-tight bulkhead, was constructed a smooth concrete box-flume (see Fig. 9), 4 ft. wide, 4 ft. deep, and 36 ft. long, in which all the experiments were made. The meters were held by rigid rod suspension in the water, 10 ft. up stream from the lower end of the flume. The entrance to the flume was rounded with a 6-in. radius. For all the experiments the water flowing in the flume was kept exactly 3 ft. deep so that the cross-section of the stream was 12 sq. ft. The constant depth was maintained by means of a check-gate across the canal below the flume. This gate was a loosely fitting rectangular panel, hinged at the bottom, so that its crest could be easily adjusted to the height necessary to maintain the water surface above at exactly the desired elevation.

All the water flowing down the canal passed through the flume and was measured by a 10-ft. suppressed weir near the lower end of the canal. The weir was 8.03 ft. high and had been constructed with great care to secure maximum precision for other laboratory research, during which the computed discharge was checked by volumetric measurements of the flow. Since the cross-section of the canal above the flume was several times as great as that of the water in the flume, the velocity of flow in the canal was low, and, in effect, the flume was drawing water from a quiet pond. The smooth rounded entrance of the flume thus produced a stream of remarkably uniform velocity, much like a jet flowing from an orifice. When there was no obstruction in the flume, measurements with a current meter at eight different points in the cross-section showed almost no measurable variation in velocity. The locations of the points and the measured values of the velocity are shown in Fig. 10.

The quantity of water entering the canal from the river was controlled by a large head-gate. Just below the head-gate is a small submerged sluice-gate which may be opened to allow water to escape from the canal back into the river just below the dam. This sluice-gate was used to make the finer adjustments in regulating the flow through the canal and flume.

### Constancy of Experimental Conditions

Experiments were made with velocities of 1, 2, 3, and 5 ft. per sec. in the experimental flume. When, for example, it was desired to run a series at 2 ft. per sec., the head-gate would be opened and the relief sluice-gate would be adjusted until 24 cu. ft. per sec. was flowing over the standard weir at the lower end of the canal. Then, the hinged gate below the flume would be raised until the depth in the flume was exactly 3 ft., thus producing a velocity of exactly 2 ft. per sec. Throughout the experiments the river fluctuated but slowly, so that, when the head-gate had been once set, it was easy during any experiment to keep the variation in quantity of water flowing to a small fraction of 1 per cent.

Since all the meters tested had not been rated recently, and since the study was concerned with the change in the reading of the meter for a certain definite change of conditions and not the absolute value of the meter readings, it was decided at the beginning of the investigation to compare each meter with itself only; that is, in each test the meter reading under what might be called normal or standard conditions was compared with the reading of the same meter when some abnormality of condition had been introduced. Under this plan the investigation could have been confined to one type of meter, or it could have included any number.

At the end of each day it was necessary to close the big head-gate. This gate could not easily be set with precision, the range of regulation by means of the sluice-gate was limited, and the storage in the canal was so large that after the head-gate was opened in the morning considerable time was required for the hook-gauge at the measuring weir to come to a steady constant value. This made it desirable to conserve time. Therefore, an error of 1 or 2% in any particular quantity of flow was considered close enough, and the first setting was held constant throughout the series of experiments with the meter under test. Consequently, where results are shown, for example, for a velocity of 2 ft. per sec., the figures given for one meter may have been obtained with an actual velocity flow of 1 or 2% less than 2 ft. per sec. and with another meter with an actual velocity of 1 or 2% greater than 2 ft. per sec. This procedure was considered justifiable since, whatever actual velocity of flow obtained, it was maintained constant throughout all the experiments on one meter, and the readings obtained with one meter were compared with themselves only and not with the readings of any other meter.

### Effect of Turbulence in Producing Errors in Current-Meter Registration

In the first or preliminary series of experiments, in a flume carrying a constant quantity of water, varying degrees of turbulence were purposely

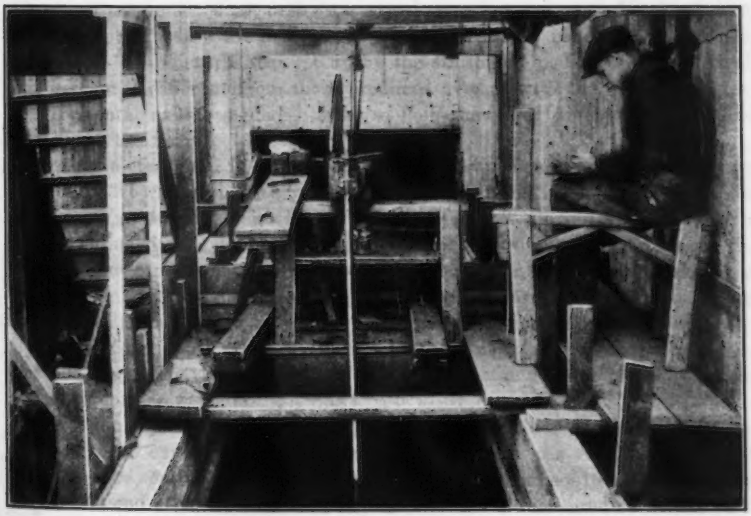

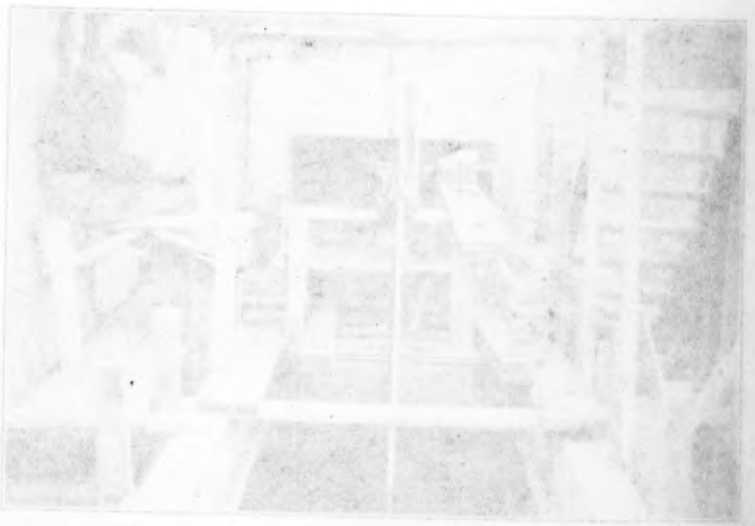

FIG. 9.—APPARATUS USED TO GIVE METERS VARIABLE HORIZONTAL MOTION.

created by the insertion of different types of baffles and obstructions. These obstructions were designed to create a definite and fixed constant disturbance in the flowing stream of water. Each meter was then held in turn at eight fixed points in the flume down stream from the obstruction, the points indicated in Fig. 10.

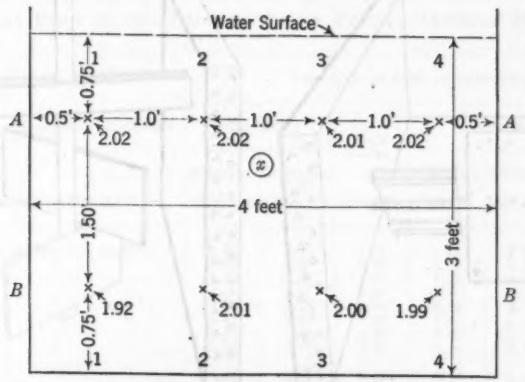

FIG. 10.—CROSS-SECTION OF CHANNEL LOOKING UP STREAM. CROSSES INDICATE METER POSITIONS USED IN EXPERIMENTS THAT FORM FIRST SERIES.

The fixed obstructions creating the turbulence were placed in the flume 6 ft. up stream from the testing section. In some experiments the eddies were produced by either vertical or lateral obstructions in the flume made by a submerged triangular dam, or by a vertical pier, but the most disturbed condition was obtained by the devices resembling stationary paddle-wheels, shown in Fig. 11. The disturbances set up by the stationary paddle with a vertical axis were quite different from those produced by that with the horizontal axis. The horizontal axis was placed so as to hold the lower edges of the paddles 3 in. above the floor.

The six meters used in this preliminary series of experiments are shown in Figs. 1, 2, 3(*b*), 4, and 5(*b*). Eight definite locations in the testing section shown in Fig. 10 were selected for the readings. Tests were run first with no obstructions in the flume. The testing flume had rounded entrance corners, and the flow conditions were more nearly ideal than ordinarily would have been encountered in natural streams, or even in artificial channels. The tests were then duplicated with the fixed obstructions in the flume.

The uniformity of velocity distribution with no obstruction in the flume may be seen in Fig. 10. The velocities shown are the average of the readings taken by four screw meters.

Since the object of this series of experiments was to determine what variation might be expected in the actual use of meters, the revolutions of the propeller were counted for a period no longer than is commonly used (generally between 40 and 90 sec.), and the time was accurately measured by means of a stop-watch. Undue smoothing of a local reading by an excessively long period

of time was purposely avoided as impractical in field practice. In Experiments Nos. 8 and 9, duplicate readings as shown in Table 1 were taken at each point in the cross-section in order to determine the possibility of error by taking observations for too short a time in turbulent water.

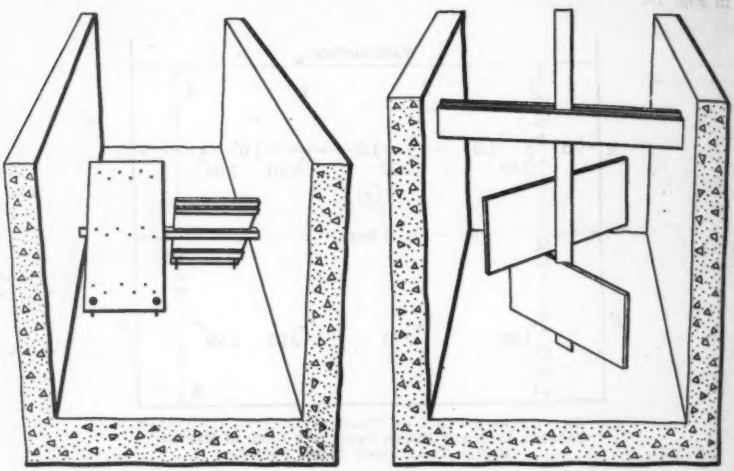

FIG. 11.—STATIONARY PADDLE-WHEELS USED FOR CREATING TURBULENCE.

At the conclusion of Test No. 9, an additional series was run to ascertain whether the meters performed in a radically different manner when the center of the propeller of each meter was located accurately in the plane of the testing section in contrast to the earlier procedure of locating the supporting rods themselves in this section. Although the distance from rod to meter propeller varied somewhat for the different instruments, the relative performance of the meters was altered but little by the change.

The entire series of observations for four tests are presented in Table 1. These include, for a velocity of 2 ft. per sec., experiments with the stationary paddle-like obstructions shown in Fig. 11.

When readings for the various meters are compared for the same point in the channel, it may be seen from Table 1 that in case of turbulent flow there is considerable difference. For example, at Point $A_2$ in Test No. 8, the Price meters over-registered, whereas the screw meters under-registered. In many cases the registration of the cup type of meter is more than 200% that of the propeller type for certain points in the tests with turbulent flow.

The check observations in Tests No. 8(*a*) and No. 9(*a*) indicate that individual observations of velocity in this turbulent water, taken for the usual length of time, may vary as much as 10 to 20%, but even this difference (which may be compensating in an average of the many observations taken in a discharge measurement), is not nearly so significant as the error of uniform sign due to the continual over-registration or under-registration of the meter in eddies and turbulent water.

While the data of Table 1 do not disclose the correct values of the average velocity of the current, it became evident from the angularity tests made later that the Price meter recorded too high a value and that the values obtained with the other meters are in varying degrees below the true amount.

Comparisons such as those presented in Table 1 demonstrate that meters may give vastly different registrations in turbulent water, but do not necessarily furnish the basis for an absolute comparison under like conditions, since the projected area of the propellers of the different types of meters was different in both size and shape. Although the utmost care may have been exercised to locate the center of the meter wheels in identical positions, and the regimen of the turbulent condition at any point may have been uniform, it cannot be assumed that the vanes themselves encountered exactly the same kind of stream filaments since the degree of turbulence varied throughout the cross-section of the channel. These conditions prompted further methods of investigations.

Since velocity measurements were taken at each measuring point (Fig. 10) with all six meters, a comparison was made of the mean of the velocities determined at the eight points by the various meters with the mean velocity computed from the weir discharge. These data are shown in Table 2. Although a greater number of observation points would have been used if actual discharge measurements had been made, the data show certain tendencies which were verified by later tests. It will be noted that the velocities as measured by the screw meters are usually less than their weir velocities, whereas those measured by the cup meters are generally greater.

### Effect of Fluctuations in Speed of Flowing Water

The series of experiments described, served to show that a considerable degree of turbulence in the flowing water introduced large errors into the current-meter readings; but the results did not appear to be favorable for determining what modifications of type or design in the meter itself would give most promise of reducing these errors to a minimum. Furthermore, multiplying the number of such experiments did not seem to be a worthy procedure, largely because there is no existing method of measuring degree of turbulence and no standards or units in which turbulence may be expressed. Rather than leave the matter in this incomplete and unsatisfactory state, it appeared desirable to attempt to resolve the problem into simpler elements and to attack them separately.

When a current meter is held in a turbulent stream, the action of the water against the rotating wheel may differ in two respects, and only two, from the action in straight stream-line flow: First, the velocity of successive portions of the stream coming into contact with the wheel may vary rapidly in amount; and, second, there may be similar rapid changes in the direction or obliquity with which the water encounters the wheel. This leads to the following two kinds of errors in the results: (1) Error in registration due to the

failure of the meter propeller to respond accurately by rapid changes in speed to the rapidly changing momentum of the water as the eddy passes; and (2) error in registration due to the fact that the stream lines of the eddy, as it moves down stream, strike the propeller blade at rapidly varying angles. The latter is a condition far different from the parallel filaments, flowing normal to the meter section, which propel the rotor during its rating test in still water.

Referring to the errors in the first class, a heavy propeller would be slow in acceleration and possibly equally slow in retardation. It is considered desirable that a meter shall record the correct average velocity of the passing water irrespective of its instantaneous behavior under the varying impulses of the eddy. If the meter is held at each point a reasonably long period of time, it should record this correct average.

The second series of experiments was designed to evaluate the first of these two possible sources of error in registration. Each meter, mounted on a rod supported in a frame, was immersed at a definite point (Point $x$ in Fig. 10), in a stream moving with a steady uniform straight-line velocity. The entire frame was then moved back and forth in a horizontal direction, parallel to the direction of flow at various speeds, by means of a crank and connecting rod operating through a stroke of 2 ft. Thus, instead of attempting to superimpose upon the stream of water definite and rapid changes in speed, an equivalent result was more easily accomplished by moving the meter itself, thereby producing, in the course of a test, many rapid fluctuations in the relative velocity of the water with respect to the meter. The determination of the accuracy of meters in registering the velocity of the filaments of an eddy which strike the meter at an angle, was reserved for the third and last part of this investigation.

The apparatus designed to create rapid changes in the relative velocity of the water with respect to the meter is shown in Fig. 9. The large wheel could be rotated at any desired speed, so as to cause the cross-head holding the meter rod to move back and forth through a stroke of 2 ft. in a definite manner approaching a simple harmonic motion. The connecting rod, however, was only 2 ft. long; hence, the motion of the piston was unsymmetrical and the piston attained a maximum velocity somewhat greater than that of the crank-pin. Although the operator attempted to rotate the wheel at a uniform speed, probably the down-stream stroke was completed in a slightly shorter period than the up-stream stroke, since greater resistance was encountered in moving the meter against the current, and there was very little fly-wheel effect in the mechanism.

All the meters illustrated in this paper except that in Fig. 1 were attached in turn to the apparatus and tested in four different quantities of flow, giving average velocities in the channel of 1, 2, 3, and 5 ft. per sec. Under each of these flow conditions, the meters were held 1 ft. below the surface of the water in the center of the channel, and the mechanism was rotated at speeds of 5, 10, 15, 20, 25, 30, 40, and 50 rev. per min.

Each period during which the propeller revolutions were counted lasted for at least 5 min. The times of intermediate contacts were also recorded, in order to make sure that the conditions were uniform and that the meter was functioning properly.

A complete set of observations on each meter under each condition of uniform velocity was made in five steps, as follows:

1.—The desired velocity in the flume was obtained by means of the weir.
2.—An observation was made with the meter held stationary.
3.—Observations were made at each of the rotating speeds mentioned, with occasional intermediate readings with the meter held stationary in order to check the uniformity of the local velocity at the fixed point in the channel.
4.—A final observation was made with the meter held stationary.
5.—Readings on the weir hook-gauge were taken before and after each observation to check the uniformity of the discharge through the channel.

The ratio of the average revolutions per second of the meter when oscillated to the corresponding speed of rotation when the meter is held stationary in the same current, is a measure of the degree to which the changes in relative water velocity affect the meter. The percentage of error in the registration of each of the meters thus obtained, plotted against the ratio of the crank-pin velocity to the uniform stream velocity, is shown in Fig. 12. The ordinates, "Relation of Meter Reading When Moving to Reading When Stationary", were computed from the number of revolutions, which approximately equals the ratio of stream velocities. The points plotted are the weighted averages for stream velocities of 2, 3, and 5 ft. per sec. When any points coincide, the symbols are moved to one side of the point.

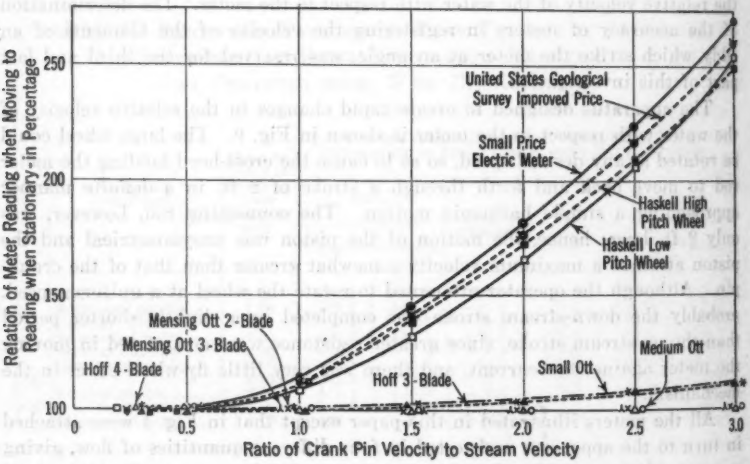

FIG. 12.—VARIATION IN RATIO OF READINGS WHEN METER IS MOVING TO READINGS WHEN METER IS STATIONARY. (WEIGHTED AVERAGE FOR STREAM VELOCITIES OF 2, 3, AND 5 FEET PER SECOND.)

Since the crank-pin velocity is almost equal to the maximum velocity of the cross-head operating the meter, the latter ratio is not only proportional to, but almost expresses, the ratio of the maximum internal velocity of the assumed eddy to the uniform velocity of the stream.

Fig. 12 indicates that the two Price meters and the two Haskell meters registered excessive velocities after the crank-pin velocity had approached the stream velocity in value, whereas the remaining screw meters showed little or no effect due to the oscillation of the meter. Below this point, where no reversal occurred in direction of the velocity of the water with respect to the meter, and thus the meters, at all times, were propelled by positive currents, the changes in relative water velocities produced less error in the registration of the meters. When the velocity of the meter did not exceed one-half the velocity of the water, they all behaved alike in integrating to obtain the direct average current velocity, regardless of the weight, shape, and size of the propeller. These tests show in reality that an eddy striking the meter "head on" does not affect the total counts of revolutions, provided the time of reading is not too short. According to the work of Hoff (cited in the Appendix), the weight of the propeller had an appreciable influence on the rating of the meter. Any practical difference did not become apparent in the Iowa tests.

When the maximum velocity of the backward stroke of the piston exceeded the stream velocity, a reverse current propelled the meters, during a part of the time. Under the impact of this current, the propellers of the Price meters continued to turn in a positive direction, thus over-registering; but the screw meters reversed their direction of rotation and, if no meter contacts were made while rotating in the backward direction, the reverse current was automatically subtracted from the excessive forward current measured during the up-stream stroke. With the proper contact mechanism there was practically no over-registration of this type of meter at any eddy speed.

Fig. 12 indicates some slight over-registration of the small Ott meter and the three-bladed Hoff meter when the maximum backward velocity exceeded twice the forward stream current. This was probably due in these two meters to the larger amount of interference to the reverse flow caused by the frames of the meters making the rotor move much more slowly in a reverse current than in a forward current of the same magnitude.

The two Haskell meters registered every single revolution of the propeller, which represented a travel of water past the meter of only 3.02 or 1.23 lin. ft., respectively. Moreover, the contact continued for more than one-half revolution; hence, in the back stroke of 2 ft., the reverse current made additional contacts which could not be distinguished from those made while rotating in the proper direction. The Haskell meters would have behaved the same as the other screw meters if they had been provided with registering devices which contacted every five revolutions or more. In fact, the other screw meters, which could be so adapted, behaved in a manner similar to the Haskell meter when operated on their single revolution contacts, registering a reverse current by contacts made in a distance less than the length of the back stroke of the piston. Tests under these conditions with the next to the smallest quantity of flow are shown in Fig. 13.

It is apparent, therefore, that the meters tested will not be influenced by successive variations in the speed of the flowing water as long as they are practically stationary and up-stream currents are not encountered. However, in case these backward currents do exist, the Price meters will invariably over-

register and the screw meters will apparently do the same, unless some means of detecting the contact made in the reverse direction of rotation is adopted, or a contacting period is used, which is longer than the time in which the meter is under the influence of the backward current. If such a long interval between contacts is used, all the screw meters will perform with reasonable accuracy under ordinary changes in velocity.

### Effect on Current-Meter Registration of Stream Filaments Striking the Propeller at Various Angles

The determination of the accuracy of meters in registering the velocity of the filaments of an eddy striking the meter at an angle was the object of the third part of this investigation. As in the previous experiments, the meters mounted on rods were held at the center line of the testing section. A pointer fastened to the rod and parallel to the axis of the meter enabled the operator to set the instrument so that the current in the testing canal struck the propeller at any desired horizontal angle (Fig. 9). In testing the Price meters with the current striking the propeller at various vertical angles, the meter rod was secured to the side of the cross-head of the machine as shown in Fig. 9. It could thus be turned to make the desired angle with the vertical.

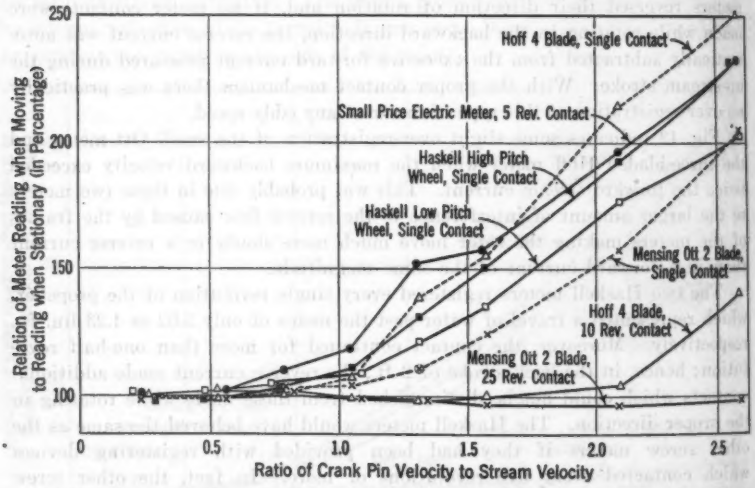

Fig. 13.—Variation in Ratio of Readings When Meter Is Moving to Readings When Meter Is Stationary, with a Stream Velocity of 2 Feet per Second.

All the meters illustrated in Figs. 1 to 8, inclusive, were tested in turn in four different quantities of flow giving average velocities in the channel of 1, 2, 3, and 5 ft. per sec. Under each of these conditions of flow, the meters were held rigidly on a rod 1 ft. below the surface of the water, with the rod at the center of the channel. The velocity at the point at which each meter was held, was quite uniform as shown in Fig. 10. The tests were made first with the propeller of the meter turned to the right when looking up stream so

that the meter axis made angles of 10°, 20°, 25°, 30°, 35°, 40°, and 45° with the normal position parallel to the filaments of flow.

The meters were then tested with their propellers turned to the left through the same series of angles with the maximum quantity of flow. These readings indicated that the performance of the three Price meters (Figs. 1, 2, and 8) and the medium Ott meter (Fig. 4(*b*)) departed farther from the ideal, with their propellers turned to the left than during the previous tests with their propellers turned to the right. Consequently, these four meters were tested through the entire series of angles when turned to the left in the same quantities of flow as those used in the tests with propellers turned to the right.

Apparently, the screw meters should perform practically the same in a current striking the propeller at a given angle regardless of whether the variation in angle is in a horizontal or a vertical direction, since a symmetrical face appears to be presented to the flow. This is not true of the cup meter. Hence, the three Price meters were tested in the same quantities of flow as those used in the horizontal angle tests, but with the meter axis tilted upward 5°, 10°, 15°, 20°, 25°, and 30° and also downward through the same series of angles.

Each observation during which the propeller revolutions were counted, lasted for at least 5 min. The times of all intermediate contacts were recorded in order to make certain that conditions were uniform and that the meter was functioning properly.

A complete set of observations on each meter under each condition of velocity included the following:

1.—A velocity reading was taken 1 ft. on each side of the center of the channel in order to check the uniformity of the horizontal velocity distribution.
2.—A reading was taken in the center of the channel with the meter in the normal position.
3.—Observations were made at each of the angles previously mentioned with occasional intermediate readings in the normal position to check the uniformity of the flow.
4.—A reading was finally taken with the meter in the normal position at the center of the channel.
5.—Readings of the weir hook-gauge were taken before and after each observation to check the uniformity of the discharge through the channel.

The tail-pieces of all the meters were removed when operated in the two maximum quantities of flow, because of the obstruction that they caused. The readings on a series of piezometers located near the bottom of one side of the channel were carefully observed when the large meters were turned at angles of 45° from the normal position in order to detect any appreciable change in channel depth caused by the obstruction of the meter. The maximum difference in depth under any condition did not exceed 0.002 ft.

The removal of the 4 by 4-ft. concrete flume at the conclusion of these tests afforded an opportunity to test the meters in a channel, 10 ft. wide, at a distance 120 ft. down stream from the head-gate. Tests duplicating those previously described in which the meters were displaced through horizontal angles, were made on several of the meters at various depths of submergence. No difference in behavior from that obtained in the smaller channel was noted.

When a current strikes the wheel of a meter in a diagonal direction, the ideal meter, if prevented from turning to face the oblique flow, should register in amount only the component of the velocity of the current which is parallel to the axis of the meter and normal to the gauging section. This component is equal to the actual velocity of the water multiplied by the cosine of the angle between the meter axis and the stream line of the current.

TABLE 3.—READINGS RECORDED BY ELEVEN DIFFERENT CURRENT METERS, HELD AT VARIOUS HORIZONTAL ANGLES WITH THE CURRENT. DEPARTURES OF THE RATIOS OF VELOCITY RECORDED BY METER AT VARIOUS ANGLES SHOWN AS A PERCENTAGE OF THE COSINE VALUE OF VELOCITY RECORDED BY METER, WITH AXIS PARALLEL TO THE CURRENT.

In making the tests with the water striking the propeller at various horizontal angles, most of the meters showed a slightly different performance when the water approached the meter from the left than when it approached at the same angle from the right. The results of the tests made on all the meters using the maximum velocity of flow (the water approaching the meter from the left and then from the right) are shown in Table 3. The Price meters over-registered every current that approached from any appreciable angle in a horizontal direction. The performance of the screw meters varied somewhat, all of them under-registering currents approaching at large angles.

When tested in the four different velocities of flow, the same meter generally showed a slight variation in performance for the same angles. The extent of the difference is indicated in Fig. 14 for one of the cup and one of the screw meters. While the variation is not large, repeated checks demonstrated that the difference observed was not accidental, but that there was a significant variation in the performance of the meters under the influence of currents of different velocities.

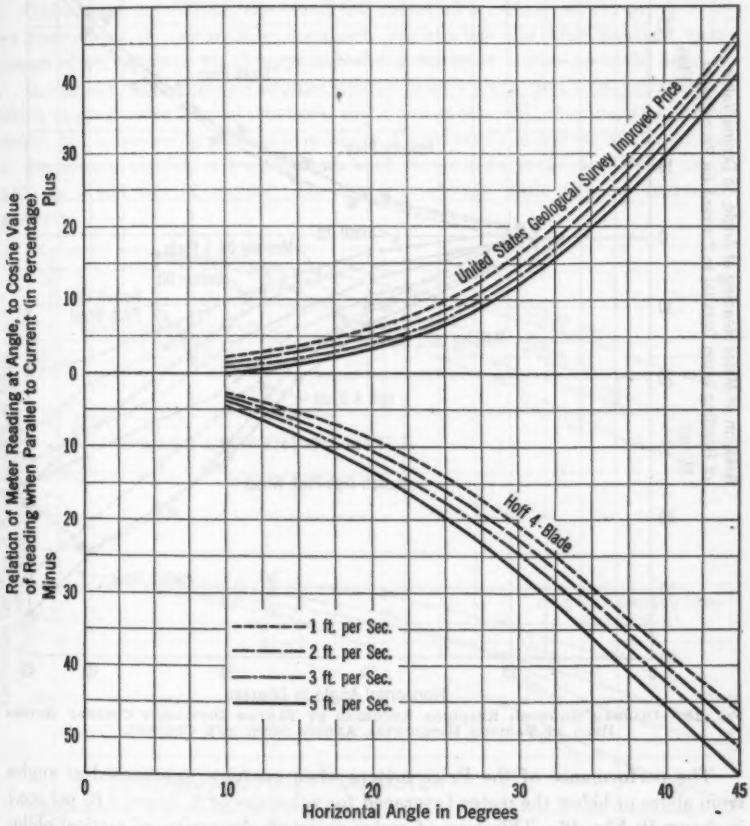

FIG. 14.—DIAGRAM SHOWING EFFECT OF HOLDING TWO TYPES OF METERS AT VARIOUS HORIZONTAL ANGLES WITH THE DIRECTION OF THE CURRENT.

A weighted average of the results secured from each meter when using velocities of 2, 3, and 5 ft. per sec., was computed by giving each separate result a weight proportional to the velocity under which it was obtained, and taking the water approaching the meter from either side gave the greater divergence from the ideal. The maximum erroneous effect of oblique currents thus revealed is plotted in Fig. 15.

At large current angles, the Price meters over-registered, and all screw types registered less than the forward component of velocity.

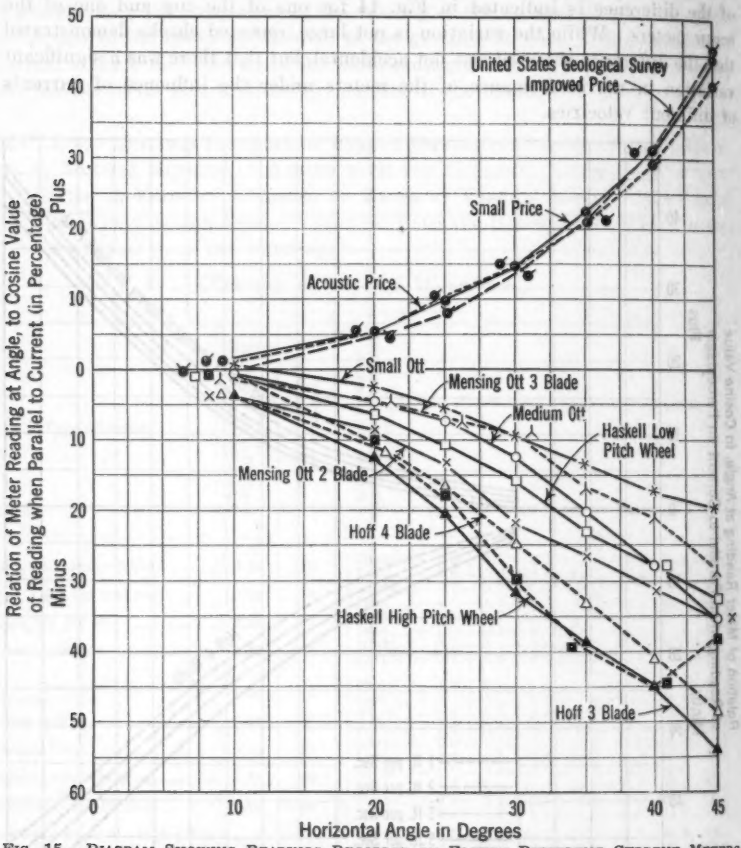

FIG. 15.—DIAGRAM SHOWING READINGS RECORDED BY ELEVEN DIFFERENT CURRENT METERS HELD AT VARIOUS HORIZONTAL ANGLES WITH THE CURRENT.

The performance of the Price meters when currents approached at angles from above or below the meter (averaged for velocities of 2, 3, and 5 ft. per sec.) is shown in Fig. 16. This type of meter registers the cosine of vertical obliquities with much better accuracy than the horizontal, showing a slight tendency toward under-registration of these currents. The degree of under-registration of the component vertical to the gauging section in vertical currents, however, is not nearly as great as the amount which this meter over-registers these components in measuring horizontal disturbances.

No important difference was observed in the performance of the three types of Price meters in these tests, and probably no other type of meter will register more accurately under conditions of vertical obliquities.

In a turbulent stream, where filaments strike the meter with equal frequency from all angles, the meters would perform on the average as shown in Fig. 17. Where such a condition exists, it should be remembered that vertical and horizontal angles develop compensating effects in the cup meter. The curves shown are obtained by averaging the performance of the meter in the four directions measured in these tests. Under this condition of turbulence, the Price meter compares more favorably with the others than it did in Fig. 15.

Under these conditions, the small Ott meter (Fig. 4(*a*)) would prove to be an instrument of remarkable accuracy, registering the true average component of all currents which approached the meter at angles up to 20 degrees.

In making measurements around débris, bridge piers, and side contractions which cause horizontal disturbances, the Price meter will over-register appreciably; but in metering in channels where disturbances originate at the bottom of the stream, causing a preponderance of vertical currents, the Price meter held on a rod should register the desired velocity with a good degree of accuracy.

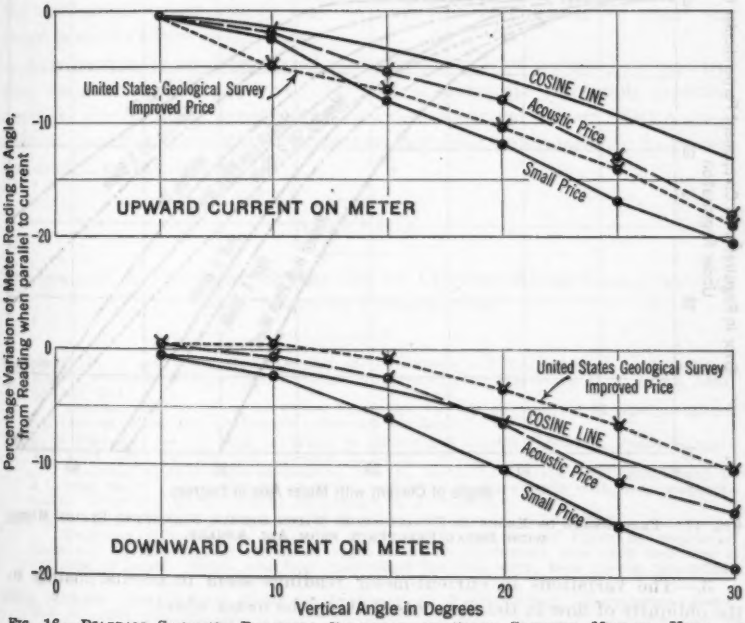

FIG. 16.—DIAGRAM SHOWING READINGS RECORDED BY PRICE CURRENT METERS, HELD AT VARIOUS VERTICAL ANGLES WITH THE CURRENT. WEIGHTED AVERAGE FOR STREAM VELOCITIES OF 2, 3, AND 5 FEET PER SECOND.

## CONCLUSIONS AND LIMITATIONS

The following general conclusions seem to be justified:

1.—A flowing stream may be so turbulent as to change very noticeably the readings obtained by a current meter.

2.—The disturbances in the current-meter readings are not caused to any noticeable degree by the fact that the flow is unsteady; that is, they are not influenced by the inertia of the current-meter wheel, nor are they produced necessarily when there are pulsations or any unsteadiness in the stream.

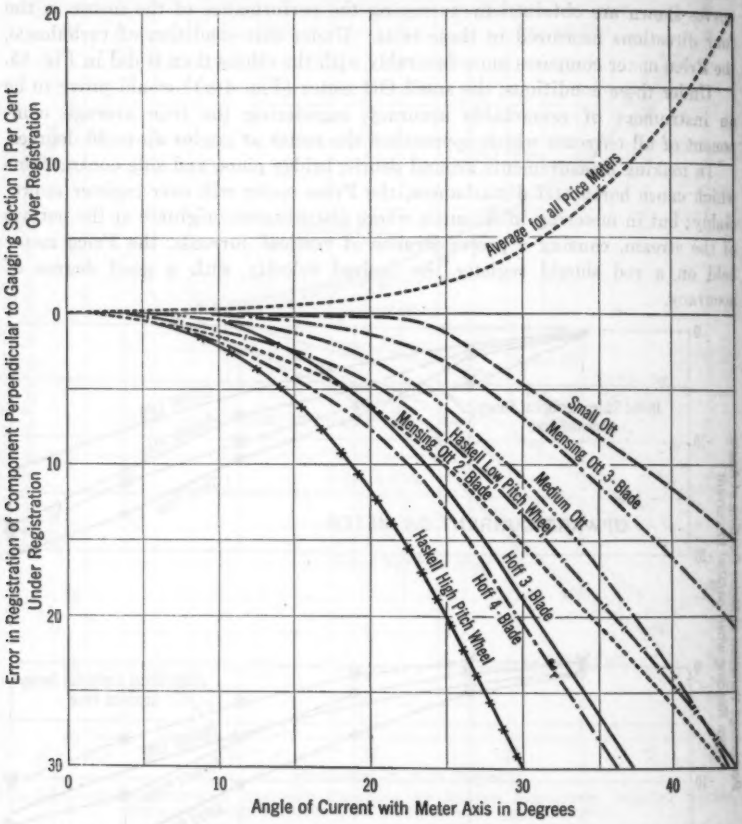

FIG. 17.—PERCENTAGE OF ERROR IN REGISTRATION WHEN STREAM FILAMENTS STRIKE METER WITH EQUAL FREQUENCY FROM ALL ANGLES.

3.—The variations in current-meter readings seem to be due mainly to the obliquity of flow in the filaments striking the meter wheel.

4.—When meters are held on a rod in a rigid position, with the meter axis parallel to the general axis of the stream, turbulent flow invariably causes the cup meter to over-register and the screw type to under-register.

5.—The cup meter registers the true velocity of currents approaching the meter from almost every horizontal direction; hence it over-registers the component perpendicular to the gauging section of horizontally oblique flow. Obliquity of flow in a vertical direction has a slight tendency to cause under-

registration and thus may compensate to some degree for the over-registration caused by horizontal obliquity.

Certain limitations should be mentioned. This study was not an attempt to make a careful or sweeping comparison of meters produced by different manufacturers, and the figures shown should not be used for this purpose.

It should be remembered also that rod support was used in all these experiments, and the conclusions must not be applied without modification to cable-suspended meters. In a majority of cases, stream gauging is done with cable-suspended meters. In such suspension the tail-vanes tend to keep the meter squarely facing the current regardless of any local or temporary obliquity of flow. In some places, however, such as close to the sharp corners of piers or obstructions, the curvature of the filaments may be so sharp that the direction of flow at the meter wheel is appreciably different from that at the vane. In such case oblique flow must necessarily strike the current wheel. Furthermore, the dynamic center of some meters does not coincide with the mechanical center. Since the suspension by cable comes in a line with the mechanical center, there may be sufficient eccentricity to cause the meter to swirl unduly in the water.

Finally, it is to be remembered that the question of accuracy of registration, discussed in this paper, is only one of numerous important practical questions arising in the construction and use of current meters. Other questions of importance are cost, convenience, portability, durability, consistency, uniformity, reliability, etc.

## APPENDIX

### Bibliography of Published References on Current-Meter Characteristics by American Investigators

**Humphreys, A. A., and Abbot, H. L.** Report on the Physics and Hydraulics of the Mississippi River. *Professional Paper No. 4*, Corps of Topographical Engineers, U. S. Army, 1861, pp. 203, 224.

Mentions current meter as a possible device for use on study of Mississippi River, but rejected same with preference expressed for floats.

**Henry, D. Farrand.** On the Flow of Water in Rivers and Canals. *Journal*, Franklin Inst., Vol. XCII, 1871, pp. 167-173, 257-262, 322-328, 383-389.

Describes various water-measuring devices, including his electrical attachment to a current meter. Gives results of meter ratings and comparisons with float measurements. Discusses many natural phenomena of stream flow.

**Ellis, T. G.** Report, Chief of Engineers, U. S. Army, 1878, Pt. I, pp. 305-350.

Describes measurements made on discharge of Connecticut River by means of floats and current meters. A screw type of meter (Woltman) was used and also a cup type of meter (Ellis) was first constructed for this work, both giving concordant results with the float measurements.

**Blum, Richard.** The Current Meter of Professor A. R. Harlacher. *Engineering News*, Vol. IX, 1882, pp. 141-142.

Describes the Harlacher screw type of electric current meter.

**Fteley, A., and Stearns, F. P.** Description of Some Experiments on the Flow of Water Made During the Construction of Works Conveying the Water of Sudbury River to Boston. *Transactions*, Am. Soc. C. E., Vol. XII (1883), pp. 117-118.

Describes current meter used in making comparative measurements with weir, and states the agreement was within 1% unless the velocity was very irregular. Extreme agitation of the current meter during rating caused an error of 9 per cent.

**Stearns, F. P.** On the Current-Meter, Together with a Reason Why the Maximum Velocity of Water Flowing in Open Channels Is Below the Surface. *Transactions*, Am. Soc. C. E., Vol. XII (1883), pp. 301-338.

Illustrates and describes the Fteley and Stearns screw type of current meter. Gives results of rating experiments in which an irregular and variable velocity was

created by oscillating the meter; and experiments during which the axis of the meter was turned at various angles with the direction of motion of the rating car up to a maximum of 41°, in which position the meters under-registered about 10 per cent. Results of twenty-seven experiments are given in which the discharge of the Sudbury Conduit was measured both by current meter and weir with varying degrees of agreement depending mostly on the method used in taking the velocity observations by current meter.

**The Price Current Meter.** *Engineering News,* Vol. XXIX, 1893, pp. 196-197.
Describes large Price meter invented by the late W. G. Price, M. Am. Soc. C. E., and patented August 25, 1885. Follows article describing current-meter measurements on Niagara River.

**Price, W. G.** A New Current Meter and a New Method of Rating Current Meters. *Engineering News,* Vol. XXXIII, 1895, p. 27.
Describes Price acoustic current meter and method of rating from skiff in still pond.

**The Ritchie-Haskell Direction-Current Meter.** *Engineering News,* Vol. XXXIII, 1895, pp. 27-28.
Describes the Haskell current meter and also direction-recording apparatus by which the direction of the current may be observed.

**Noble, Theron A.** Gauging of Cedar River, Washington. *Transactions,* Am. Soc. C. E., Vol. XLI (1899), pp. 1–26.
Describes the use of a Haskell meter in measuring stream flow, and compares same with measurements by floats. The discussion as to the accuracy of the measurements has historical interest.

**U. S. Geological Survey.** Annual Report, 21st, 1899-1900, Pt. 4, Hydrography, pp. 28-29.
Describes and illustrates by two diagrams a screw type of current meter known as the Moulinet, Type H.

**Haskell, E. E., Shenehon, F. C., and Sabin, L. C.** Report of the Chief of Engineers, U. S. Army, 1900, pp. 5322-5401.
Describes measurements of Niagara and St. Clair Rivers in which Haskell meters were rated and used, with various comments as to their reliability.

**White, W. M.** The Pitot Tube, Its Formula. *Journal,* Assoc. of Eng. Societies, Vol. 27, 1901, pp. 64-66.
Uses Price current meter to compare with Pitot tube in rating experiments by towing through still water, showing excellent agreement between the two instruments.

**Horton, Theodore.** Flow in the Sewers of the North Metropolitan Sewerage System of Massachusetts. *Transactions,* Am. Soc. C. E., Vol. XLVI (1901), pp. 78-92.
Describes the use of an Ellis (cup type) meter in measuring the discharge in a sewer. Mr. Horton's closing discussion mentions the possibility of erroneous registration where stream filaments of different velocities act on the two sides of the propeller.

**Murphy, E. C.** Tests to Determine the Accuracy of Discharge Measurements of New York State Canals and Feeders. *Water Supply and Irrigation Paper No. 47,* 1901, U. S. Geological Survey, pp. 18-29.
Describes comparative measurements by rods and meter on New York State canals and also experiments made in 1900 with rods, small Price meters, and weir at Cornell University Hydraulics Laboratory.

**U. S. Geological Survey.** Methods of Stream Measurement. *Water Supply and Irrigation Paper No. 56,* 1901.
Describes various methods of stream measurement, including use of the current meter. The Price meter is described in detail.

**Murphy, E. C.** Accuracy of Stream Measurements. *Water Supply and Irrigation Paper No. 64,* 1902, U. S. Geological Survey, pp. 11-95.
Discusses difficulties, and instruments used in measuring stream velocities, giving history of current meter, describing various types, and stating their advantages and disadvantages. Discusses the effect of pulsation of velocities of moving water on measurements. Extracts results of Ellis, Marr, Henry, Gordon, New York State Canal Survey, Fteley and Stearns, comparing float measurements with weir. Describes in detail his own experiments at Cornell University and Chevy Chase, Md., in 1900-1901. Compares measurements with Price, Haskell, and Fteley meters with weir measurements. Concludes that small Price current meters under ideal conditions can measure discharge within 1 or 2%; is more accurate when held rigidly on a rod rotating faster under this condition; will under-register current velocities closer to the water surface than 0.5 ft., etc. Some experiments under abnormal conditions showed results departing as much as 40% from the weir discharge. Haskell meter registered velocities near the surface more accurately than Price meter, not as accurate in low velocities.

**Williams, G. S., Hubbell, C. W., and Fenkell, G. H.** Experiments on Flow of Water in Pipes. *Transactions,* Am. Soc. C. E., Vol. XLVII (1902), pp. 337-341.
Occasional reference to meter ratings in flowing water as compared with still water, with particular reference to its accuracy as compared with Pitot tube. In discussion, E. C. Murphy (pp. 202-203) gives results of eighteen measurements with Price meters in moving water at Cornell University showing agreement with standard weir within 2.8% in every case; D. Farrand Henry (pp. 224-226) describes early experiments comparing velocities obtained by floats with that registered by meters; George Y. Wisner, (pp. 231-233) discusses error in registration of meters in flowing water; E. E. Haskell (pp. 283-289) describes rating tests in flowing water which gave favorable comparison between a Haskell meter and floats; and Robert E. Horton (pp. 289-291) discusses nature of eddies and the performance of current meters.

**Murphy, E. C.** Current Meter and Weir Discharge Comparisons. *Transactions*, Am. Soc. C. E., Vol. XLVII (1902), pp. 370-391.

Describes fifty discharge measurements with Haskell and Price meters in testing canal at Cornell University with agreement between meters closer than with weir, but in every case variations were less than 4.8%; twenty of the tests showed differences less than 1 per cent. In discussions: Charles H. Miller (pp. 379-380) discusses comparative results with different current meters, describing experiments with Haskell and Price meters mounted on a skiff which was rocked, producing over-registration of the Price meter and under-registration of the Haskell meter; J. B. Lippincott (pp. 383-387) describes eleven experiments comparing Price and Haskell measurements, also, in some cases, with weir; mentions possible error involved in integration method using Price meter; and E. E. Haskell (pp. 387-388) expresses his opinion of the relative merits of screw type and cup type of meters.

**Murphy, E. C., Hoyt, J. C., and Hollister, G. B.** Hydrographic Manual of the United States Geology Survey. *Water Supply and Irrigation Paper No. 94*, 1904, U. S. Geological Survey, pp. 19-31.

Discusses use of meters in obtaining discharge measurements, and describes Price meters in detail.

**Murphy, E. C.** Accuracy of Stream Measurements. *Water Supply and Irrigation Paper No. 95*, 1904, U. S. Geological Survey, pp. 1-169.

Revision of *Water Supply Paper No. 64* with additional experimental data comparing Price and Fteley meters in shallow streams of varying roughness with weir measurements. The part giving data on vertical velocity curves has been augmented by additional data.

**Barrows, H. K.** Work of Hydrographic Branch, United States Geological Survey, in New England, and Discussion of Methods for Estimating Stream Flow. *Journal*, Assoc. of Eng. Societies, July, 1905, pp. 19-20.

Describes work of the U. S. Geological Survey on surface water resources in New England, including current practice in securing discharge measurements with Price meter.

**Senate Document 105**, 62d Congress, 1st Session, pp. 72-74.

Describes an experiment by F. C. Shenehon, M. Am. Soc. C. E., with a Haskell meter in the Detroit River in 1906, comparing the velocity registered by this meter with that observed from the rate of travel of liquid blueing. Good experiment was obtained.

**Gregory, W. B.** Test of a Rotary Pump. *Transactions*, Am. Soc. Mech. Engrs., Vol. 28 (1907), pp. 745-769.

Gives results of pump discharges measured in a flume by both Price electric current meter and a Tulane Pitot tube. Individual measurements showed a maximum variation of 2% between the results obtained in measuring about 153 cu. ft. per sec. with the two different instruments and an average variation of but 0.1 per cent.

**Hoyt, John C.** A Universal Current Meter. *Engineering News*, Vol. 57, 1907, p. 263.

Describes adaptability of small Price meter to stream gauging, and gives rating curves for Fteley, Warren, Haskell, small Price, large Price, and Lallie current meters.

**Stevens, J. C.** Comparison of Formulas for Computation of Stream Discharge. *Engineering News*, Vol. 59, 1908, pp. 682-684.

Discusses errors involved in various methods of using current-meter data in obtaining the discharge of a stream. Recommends the method adopted by the U. S. Geological Survey, and also multiplying each depth by its corresponding velocity.

**Hoyt, John C.** Recent Changes of Methods and Equipment in the Water Resources Work of United States Geological Survey. *Engineering News*, Vol. 60, 1908, pp. 15-16.

Describes refinements which were made in construction and use of Price meter, referring to pentacount registering device, torpedo weights, rods, etc.

**Hoyt, John C.** The Use and Care of the Current Meter as Practiced by the United States Geological Survey. *Transactions*, Am. Soc. C. E., Vol. LXVI (1910), pp. 70-105.

Gives history of current-meter development, plates showing Price, Haskell, Fteley, Ellis, Richards, Woltman, Ott, and Amster meters. The use, care, and rating of the Price meter is thoroughly discussed. In discussion, A. H. Dramont (pp. 106-107) describes gaugings and ratings of Fteley meter in measuring the discharge of Croton Aqueduct; E. C. Murphy (pp. 107-108) mentions the possibility of the different behavior of a meter near the sides and bottom of a channel; H. K. Barrows (pp. 108-110) stresses certain precautions in use of the Price meter; C. E. Grunsky (pp. 110-126) discusses the difference in results obtained in computing discharges from average of velocity observations taken at the end of sections as practiced by the U. S. Geological Survey in contrast to the method proposed by W. H. Hall, M. Am. Soc. C. E., in 1878 of multiplying velocity measurements by depth at the point of the measurement. Mentions possibility of error in meters of various types and other gauging problems; E. Kuichling (pp. 126-128) suggests various possibilities of error in the rating and registration of meters; G. H. Matthes (pp. 128-129) concludes that the precision of the current meter is far ahead of other observations made in obtaining discharge data on natural streams; Walter Pearl (p. 130) agrees with the conclusion of Mr. Matthes; and C. M. Allen (pp. 130-132) expresses confidence in measurements with the current meter, based on experiments at the Hydraulic Laboratory of the Worcester Polytechnic Institute and elsewhere.

**Van Winkle, Franklin.** Stream Flow at Single Cross-Section. *Power*, Vol. XXXII, Pt. 2, 1910, pp. 1553-1557.

Describes pressure plate, Pitot tube, float wheel, and current meters. Gives detailed discussion of Price and Ott meters. Use and advantages of each.

**Stevens, J. C.** Hydrometry as an Aid to the Successful Operation of an Irrigation System. *Transactions*, Am. Soc. C. E., Vol. LXXI (1911), p. 323.

Gives results of twelve measurements made for the purpose of comparing the small Price pentacount head with the single count head. The maximum difference was 1.8 per cent.

**Williams, Gardner S.** Measurement of Water. *Journal*, Western Soc. of Engrs., Vol. XVII, 1912, pp. 22-48.

Discusses various devices, including current meters, mentioning comparison with float measurements at Cornell University and work of U. S. Lake Survey.

**Hoskes, R. M.** Measurement of the Flow of Water in Large Pipe Lines. *Journal*, Western Soc. of Engrs., Vol. XVII, 1912, pp. 34-39.

Describes special Price meter of electrical and mechanical type used on rods inside 28-in. wood-stave pipe. Rating curves for same are shown.

**Groat, B. F.** Characteristics of Cup and Screw Current Meters. *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), pp. 819-840, 852-870.

Describes tests made with Haskell and Price current meters and Pitot tube at Massena, N. Y., concluding that cup meters over-register (on the average 6%) more than screw meters under-register (the average for Haskell was about 1 per cent.). States that current-meter measurements in perturbed water should be made with caution. Results of experiments given in which meters were oscillated longitudinally and transversely through a small amplitude in a still-water rating, and also some ratings from a skiff with oscillations caused by rocking the boat. An addendum states that experience on some mountain streams indicates that cup meters will over-register three to six times the amount which the screw meter under-registers. In discussion, W. G. Price (pp. 841-844) defends the Price meter and states its merits; E. E. Haskell (pp. 844-846) states merits of screw meter and gives eight comparative measurements between the velocities obtained by meters and floats; C. H. Miller (pp. 846-848) stresses accuracy in rating meters; and J. C. Hoyt (pp. 848-852) gives reasons for the U. S. Geological Survey adopting the Price meter and concludes that it will give reliable results at all but the most exceptional stations.

**Rumpf, Charles P.** An Investigation of the Use and Rating of the Current Meter. *Engineering News*, Vol. 71, 1914, pp. 1083-1084.

Gives results of tests on cup and screw meters holding meters at various angles with the current.

**Groat, B. F.** Pitot Tube Formulas, Facts and Fallacies. *Proceedings*, Engrs.' Soc. of Western Pennsylvania, Vol. 30, 1914-15, pp. 323-383.

Paper devoted mostly to Pitot tube, but on pages 351-366 gives results of ratings of large Price and Haskell current meters from boats under ideal conditions and with boat rocking; describes use of these meters in turbine tests at Massena, N. Y. Concludes that cup meter was accelerated by rocking and screw meter retarded.

**Moody, Lewis F.** The Measurement of the Velocity of Flowing Water. *Proceedings*, Engrs.' Soc. of Western Pennsylvania, Vol. 30, 1914-15, pp. 280-323.

Paper devoted mostly to Pitot tube, but on pages 320-322, the results of comparative ratings of a Pitot tube, Price meter, and Fteley and Stearns meter are compared with the meters turned through various horizontal angles up to 70 degrees. Also gives results of an experimental screw meter with good characteristics. Concludes cup meter over-registers and registers velocities from right differently from those from left; screw meter under-registers. In discussion, Gardner S. Williams (p. 386) describes results of rating of Haskell meter by weir in turbulent water in which Haskell under-registered more than 3%; N. C. Grover (pp. 391-397) discusses work of the U. S. Geological Survey and adaptability of Price meter to this work; efforts to develop screw meter; and general history of Price meter; Thomas P. Roberts (pp. 397-400) remarks generally on some difficulties encountered with current meters; Charles M. Allen (pp. 401-402) describes Worcester Polytechnic Institute circular rating station; Clemens Herschel (p. 410) remarks generally to the effect that current-meter gauging is only adapted to the measurement of large open channels; E. H. Brown and F. Nagler (pp. 415-424) give account of tests made on large and small Price current meters operated at center of 42-in. main, rotated at various angles with the thread of the current, through 360° in horizontal plane and 180° in vertical plane. Curves for small Price meter show different registration to left from that of right, over-registration at all angles in horizontal plane, and satisfactory or under-registration for angles in vertical plane. Curves for large Price meter show its inferiority to small Price meter; Lewis F. Moody (pp. 454-455) gives results from Rensselaer Polytechnic Institute thesis on Price meter inclined at various horizontal and vertical angles up to 12°, confirming Brown and Nagler tests; and B. F. Groat (pp. 460-473) further discusses the Massena current-meter work, design of ideal meter, and mentions same having been produced at Rensselaer Polytechnic Institute. Comments on Haskell meter, and effect of bearing friction in current meters, possible inertia effect of heavy propellers.

**Scobey, Fred C.** Behavior of Cup Meters Under Conditions not Covered by Standard Ratings. *Journal of Agricultural Research*, May 25, 1914, pp. 77-83.

Gives results of experiments on Price current meter rated in still water on rod and cable, tipped varying amounts to 30° upward and downward, also near water surface, bottom, and channel sides, with dull pivot, and vertical oscillation of meter. Concludes meter should be held horizontal, channel sides have little effect, but bottom and surface readings are in error; dull pivot has inappreciable effect for velocities greater than 1 ft. per sec.; vertical meter movement rotates the meter in the same direction as moving water.

**Harding, S. T.** Experiments in the Use of Current Meters in Irrigation Canals. *Journal of Agricultural Research*, November 8, 1915, pp. 217-232.

Comparisons of the relative accuracy of discharge measurements made in irrigation canals with current meters using different methods of measuring velocities in the verticals are discussed. No type of meter is mentioned.

**Groat, B. F.** Chemi-Hydrometry and Its Application to the Precise Testing of Hydro-Electric Generators. *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), pp. 1231-1271.

Describes still-water rating experiments on Haskell, Ott, and Price meters at University of Michigan, in which the meters were oscillated at various periods through arcs of various lengths in a horizontal, vertical, and longitudinal direction. Longitudinal oscillations showed that water pulsations affect meters but little, while lateral disturbances made the Price meter over-register, whereas the Ott and Haskell meters under-registered, the under-registration of the Haskell meters exceeding that of the Ott type. In discussion, Robert E. Horton (pp. 1283-1285) discusses accuracy of current-meter measurements; and W. S. Richmond (p. 1287) mentions several comparative measurements between current meters and other methods, and instances of erroneous registration of both types of meters.

**Hoyt, J. C., and Grover, N. C.** River Discharge. Fourth Edition, 1916, pp. 6-22.

Discusses history of and use and care of current meter with particular reference to the Price meter, duplicating article by J. C. Hoyt, *Transactions*, Am. Soc. C. E., Vol. LXVI (1910), p. 70.

**Blanchard, Murray.** Hydraulics of the Chicago Sanitary District's Main Channel. *Journal*, Western Soc. of Engrs., Vol. XXV, 1920, pp. 483-506.

Describes measurements with Haskell and Price meters under a variety of field conditions with data from occasional still-water ratings made during the progress of the work. Concludes that the Haskell meters appeared more accurate and reliable than the cup meters.

**Fortier, S., and Hoff, E. J.** Defects in Current Meters and a New Design. *Engineering News-Record*, Vol. 85, 1920, pp. 923-924.

Discusses the inaccuracies of meters under field conditions and describes the new Hoff meter giving curves comparing the effect of friction in various types of meters.

**Gutmann, O.** Glorifying the Current Meter. *Engineering News-Record*, Vol. 97, 1926, p. 840.

Review of "Der Genauigkeitsgrad von Flügelmessungen bei Wasserkraftanlagen", by Dr. Ing. A. Staus, in which the propeller type of meter is shown to be more reliable than the cup type.

**Hoyt, K. K.** Defense of the Price Current Meter. *Engineering News-Record*, Vol. 97, 1926, p. 1010.

Letter defends the use of Price meter by the U. S. Geological Survey, comparing the behavior of same with screw meters advocated by Dr. Ing. A. Staus.

**Matthes, G. H.** Price Current Meter: Serviceability *vs.* Scientific Design. *Engineering News-Record*, Vol. 98, 1927, p. 126.

Letter stresses the fact that the hydrographers of the U. S. Geological Survey during the early existence of the Bureau found the Price meter to be more serviceable than other types.

**Groat, B. F.** In Defense of Current Meters. *Engineering News-Record*, Vol. 98, 1927, p. 370.

Letter defends current meter as a valuable measuring device, and mentions characteristics of different types.

**Liddell, William A.** Stream Gauging. First Edition, 1927, p. 9 and pp. 136-150.

Discusses experimental work done in the United States, the effects of turbulent flow, and the behavior of cup-shaped and screw-shaped meters when subjected to various tests.

## DISCUSSION

CHARLES S. BENNETT,[4] M. AM. SOC. C. E. (by letter).—The data presented in this paper are of particular interest to hydrographers because they make possible a quantitative comparison of the effects of turbulence in streams on the various types of meters. For many years there has been considerable discussion among hydraulic engineers regarding the relative merits of the different types of meters, and the data obtained in these experiments should give conclusive evidence with respect to some of the various contentions. While a few similar experiments have been made heretofore, it appears that the work done in this series more nearly approaches actual field conditions than any previous attempts.

It has long been recognized that meters of the cup type will over-register when exposed to transverse or reverse currents and that the screw-type meters tend to under-register under similar conditions. It is interesting to note that the percentage of over-registration of the Price or cup type of meters for various horizontal angles does not greatly exceed that of under-registration in the screw-type of instruments. It would appear that, disregarding all other considerations, all types of meters now in general use (with the exception of the Haskell, high-pitch wheel, and the Hoff) are subject to about the same degree of inaccuracy under these conditions, to horizontal angles of about 30 degrees. However, meters of the cup type tend to under-register under the influence of obliquity of flow in a vertical direction. Since turbulence causes obliquity vertically as well as horizontally, it follows that the cup meter will probably show less actual over-registration in a turbulent stream than is indicated by the data in Fig. 15.

Stream-flow measurements with current meters are made ordinarily from cables or bridges at selected points, and the proportion of the total cross-section in which turbulence occurs due to piers or obstructions is relatively small. When measurements are carefully made at such sections, the results should be reasonably accurate, no matter what type of standard meter is used. However, there are so many practical advantages in the improved Price meter used by the U. S. Geological Survey, that it seems to be the most satisfactory for general purposes.

It might be suggested that, where it is necessary to make measurements in races or other streams in a turbulent condition, readings be obtained with a cup meter as well as with a screw meter, such as the small Ott. Comparisons of the readings should give an idea of the approximate compensation to allow for inaccuracy due to angular approach of the stream filaments. It might also be well to make longer observations than usual when turbulent conditions exist; that is, make each reading of velocity cover a period of about 180 sec. instead of the customary 60 to 70 sec.

The data in Tables 1 and 2 result from experiments made at velocities of 2 ft. per sec., and less. From Fig. 14 it appears that an increase of velocity up to 5 ft. per sec. makes a considerable difference in the percentage of variation

[4] Engr., The Miami Conservancy Dist., Dayton, Ohio.

for two types of meters at various horizontal angles. This comparison raises the question of the effect of higher velocities, such as occur in ordinary streams in flood, on the variation. It is hoped that further studies may be made, using experiments at velocities somewhat higher than those of this series.

The writer believes that these experiments bear out the general opinion of hydrographers that current meters cannot be expected to register correctly in turbulent water; but it should be remembered that the greatest practical value of the current meter lies in its use for the measurement of the flow of average streams, in which it is usually possible to select a measuring section where there is a minimum of disturbing conditions.

CARL ROHWER,[5] ASSOC. M. AM. SOC. C. E. (by letter).—The current meter is frequently the only available means of measuring the discharge of natural streams or artificial channels, and any information that bears on this subject is always welcomed by those who are concerned with the measurement of water. The authors have carried on extensive experiments that show the action of current meters under extreme conditions, as well as the conditions ordinarily met with in practice, and are to be commended for their work. Their summary of the comment of other investigators on the behavior of various types of current meters under different conditions, is also valuable.

The authors mention that the meters used in the experiments were not rated at the time of the tests because only the relative values of the observations when compared among themselves were to be considered in the experiments. In Table 2, however, the velocities indicated by the meters are compared with the velocity computed from the weir discharges. Obviously, in this case, any error in the meter rating will be included in the deviation due to the obstruction in the channel. The error due to the inaccuracy in the rating of the meter is probably small in comparison with the differences observed; nevertheless, there is a definite change in the rating of meters as is shown by Table 4[6] which gives the ratings of a small Price electric meter extending over the period from 1919 to 1929. All these ratings were made under the same conditions at the station of the Hydraulic Laboratory at Fort Collins, Colo. It will be noted that, in general, the changes are small from year to year, but occasionally there is a definite change. This is not due to inaccuracies inherent in rating, because the check ratings in 1921 and 1929 are almost identical.

Almost without exception the variation in mean velocity caused by different obstructions in Table 2 is greater at the low velocity than at the high velocity. This seems unusual. Ordinarily, the faster the water flows, the greater is the disturbance caused by the obstruction. In the data shown in Table 2 this seems to hold true only in the case of the submerged weir.

The data plotted in Fig. 12 and Fig. 13 show that under some of the extreme conditions of the test, single-count meters give very erroneous results. This does not mean that errors of this magnitude are to be expected under

[5] Assoc. Irrig. Engr., Colorado Experiment Station, Fort Collins, Colo.

[6] Unpublished records of the Irrigation Investigations of the Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, co-operating with the Colorado Experiment Station.

conditions met with in practice. It is doubtful if the velocity would ever reverse at a point in any section that would be chosen for a current-meter measurement. It is true that, at some rating stations, the water may flow backward near the banks at certain stages, but as long as it remains at the same stage, it will continue to flow in the same direction. The records of all the meters show that a variation of 50% in the velocity has practically no effect on the accuracy of registration.

TABLE 4.—RATING OF A SMALL PRICE ELECTRIC METER MADE DURING THE PERIOD FROM 1919 TO 1929, AT THE HYDRAULIC LABORATORY, FORT COLLINS, COLO.

| Date. | Equation. | Remarks. |
|---|---|---|
| June 7, 1919 | $V = 2.201\ R + 0.025$ | |
| November 24, 1919 | $V = 2.214\ R + 0.020$ | |
| November 26, 1920 | $V = 2.199\ R + 0.052$ | |
| July 5, 1921 | $V = 2.185\ R + 0.022$ | Check ratings. |
| July 5, 1921 | $V = 2.185\ R + 0.026$ | |
| September 27, 1921 | $V = 2.176\ R + 0.027$ | |
| March 3, 1922 | $V = 2.183\ R + 0.040$ | |
| March 31, 1923 | $V = 2.196\ R + 0.035$ | |
| June 16, 1924 | $V = 2.198\ R + 0.020$ | New shaft installed. |
| May 28, 1926 | $V = 2.330\ R + 0.050$ | Velocities less than 2.4 ft. per sec. |
| May 28, 1927 | $V = 2.172\ R + 0.023$ | New pivot and shaft installed. |
| April 16, 1928 | $V = 2.166\ R + 0.048$ | |
| July 15, 1929 | $V = 2.172\ R + 0.031$ | Check ratings. |
| October 18, 1929 | $V = 2.173\ R + 0.030$ | |

As shown in Table 3 none of the meters, except the small Ott, gives very satisfactory results when measuring the axial component of the velocity if the water approaches the meter at an angle to the horizonal plane. All the Price meters over-register, because they measure the velocity in the direction that the water is moving and not along the axis of the meter. The errors in the Price meters shown in Table 3 are the deviations due to multiplying the axial velocity by the cosines of the angle at which the water approaches the meter.

TABLE 5.—EFFECT OF MULTIPLYING THE AXIAL VELOCITY BY THE COSINES OF THE ANGLES AT WHICH THE WATER APPROACHES THE METER.

| Description. | Type of meter. | Horizontal Angles, in Degrees. | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | | 10 | 20 | 25 | 30 | 35 | 40 | 45 |
| Reduction in velocity, in percentage, due to multiplying by cosine of angle. | (Computation) | 1.5 | 6.0 | 9.4 | 13.4 | 10.1 | 23.4 | 29.3 |
| Over-registration of meter, in percentage, when compared with axial component of velocity. | Price Meter, No. 211 880 | 1.4 | 4.3 | 8.7 | 12.8 | 19.5 | 26.6 | 36.9 |
| | Price Acoustic | 0.7 | 4.7 | 8.0 | 13.4 | 18.2 | 25.2 | 34.8 |
| | U. S. Geological Survey Improved Price | 1.0 | 5.0 | 6.8 | 11.7 | 18.0 | 25.4 | 36.2 |

This is proved by Table 5 which was derived from Table 3, and shows for each angle and each Price meter the reduction of the velocity caused by multiplying by the cosine of the angle and the over-registration of the meter

when compared with the axial component of the velocity. In the comparison, the means of the right and the left deviations are used.

As shown by Table 5, the horizontal angle at which the water strikes the meter apparently has very little effect on the accuracy of registration of the velocity in the direction of flow by the Price meters until it exceeds 40 degrees.

TABLE 6.—COMPARISON OF CURRENT METER MEASUREMENTS BY DIFFERENT METERS AND METHODS WITH WEIR DISCHARGE WHEN CURRENT METER IS TURNED 10° TO THE RIGHT BOTH BEFORE AND AFTER WEIR DISCHARGE WAS REDUCED BY MULTIPLYING BY THE COSINE OF 10 DEGREES.

This characteristic of the Price meters has its advantages, as well as its disadvantages, because for this reason it is not necessary to hold the meter exactly parallel to the axis of the stream in order to make it register accurately. This is not true of the propeller meters.

When the water approaches the meters at a small horizontal angle, all the meters register the axial component of the velocity with a fair degree of accuracy, as shown by Table 3. This is also shown by Table 6 which gives the results of some experiments[7] on cup and propeller meters using different methods of measurement made at the Bellvue Hydraulic Laboratory in 1921. In making these tests, the water was measured by the current meters in an 8-ft. rectangular channel and checked by a standard 10-ft. Francis weir constructed according to the plans of the weir used in the Lowell hydraulic experiments. Each meter was held so that its horizontal axis made an angle of 10° with the axis of the channel. The results given in Table 6 show the deviation in the measured discharge by each meter when compared with weir discharge, both with and without the cosine correction. The table shows that the results

[7] Unpublished records of the Irrigation Investgations of the Div. of Agricultural Eng., Bureau of Public Roads, U. S. Dept. of Agriculture, co-operating with the Colorado Experiment Station.

of the measurements with the small Price electric with tail and the small Ott with tail are closer without the cosine correction; the results for the Hoff meter are bettered by introducing the cosine correction, and the results for the small Price electric without tail are divided.

All the tests reported by the authors show that small changes from the normal cause relatively small errors in the registration of the meters. The large errors occur when the meters are subjected to unusual conditions. The tests indicate that, if the rating station is chosen properly, both the cup and the propeller meters will indicate the velocity with a satisfactory degree of accuracy.

BREHON B. SOMERVELL,[8] M. AM. SOC. C. E. (by letter).—The authors have added some valuable and interesting information to the data available as to the behavior of certain types of current meters under conditions differing from the regular and normal flow of the water measured. The Board on Sand Movement and Beach Erosion appointed by the Chief of Engineers of the Army to investigate conditions at points along the Atlantic and Gulf Coasts, was faced at the beginning of its investigation with the necessity for finding a meter which would not only give reasonably satisfactory measurements with varied flow, but one which would record reversals in flow and currents of very low velocity. In the investigation of wave action on the coast it was necessary to determine certain characteristics of the waves themselves and to ascertain the combined effect of the currents caused by waves, winds, and tides.

After a canvass of the experience of the members of the Board and its Consultants, and after conferences with other Government agencies having extensive experience with current meters, the conclusions were reached that (1) there was no meter on the market that would record reversals of current every few seconds; and (2) none that would record the extremely small velocities which were expected to be found when all forces acting on the water except those of the tides were negligible. The service which the meter was required to perform evidently demanded an horizontal-axis apparatus because one with a vertical axis was not adapted to measure the direction of flow of the water near the ocean beach. Various types of horizontal-axis meters manufactured in the United States as well as a French and a German meter were considered; some of them were actually put in use, to determine to what extent they might serve to measure the currents encountered. In the Ott current meter, reversals in current were shown by the alternate occurrences of long and short rings of a buzzer, denoting three and two revolutions, respectively. Inasmuch as these revolutions sometimes were very rapid and sometimes extremely slow, it was impossible to tell from the recording device whether the rings were short or long. For this reason the direction of rotation could not be established definitely, except in shallow water where the motion of the propeller could be observed. All were found to be inadequate by reason of the fact that they could not record reversals in the currents for this and other defects.

The essential parts of the meter, as designed by Dean G. B. Pegram, of Columbia University, are shown in Figs. 18, 19, and 20. The inertia of the

[8] Maj., Corps of Engrs., U. S. A., Memphis, Tenn.

FIG. 19.—MOUNTING OF PEGRAM CURRENT METER.

FIG. 18.—DETAILS OF PEGRAM CURRENT METER.

moving parts is overcome to a great extent by mounting the propeller in glass bearings and by making it as light as possible. The propeller was made to have approximately the same specific gravity as salt water. This was done by making the hub hollow and sealing it so as to give it some buoyancy which overcame its weight and the weight of the propellers themselves. The complication of additional gears, shafts, and other devices was eliminated by recording the revolutions of the propeller electrically. As will be noted from Fig. 20, the meter is fitted with two poles insulated from the frame. The propeller has four blades. In the one-tip meter, a single blade is fitted with a rubber tip which

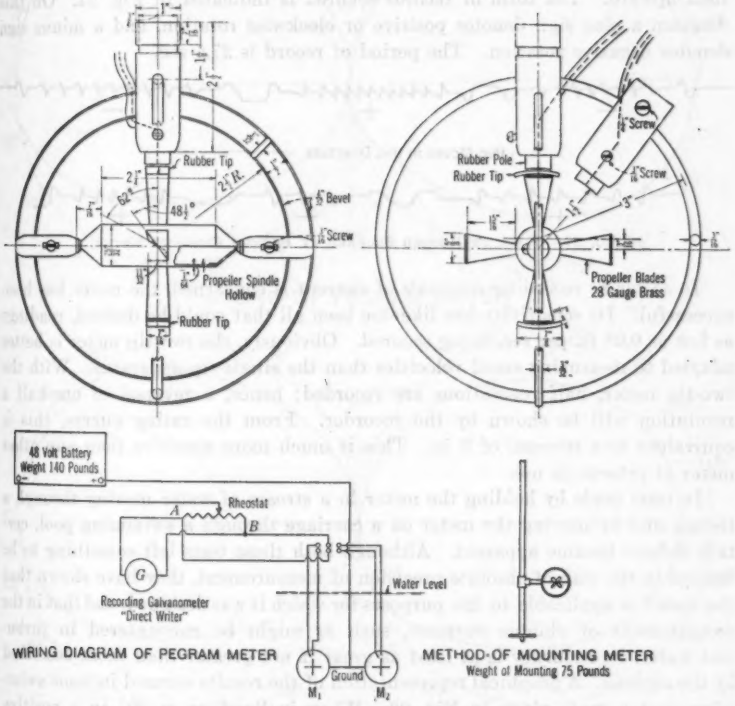

FIG. 20.—PEGRAM CURRENT METER.

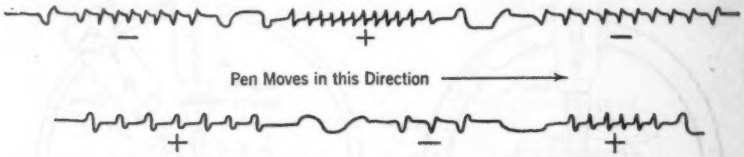
is counterbalanced by an opposed weight on the opposite tip. In the two-tip meter, two opposed propeller blades are fitted with rubber tips. As the propeller revolves, these tips pass the poles of the meter which are connected to a recording galvanometer; the resistance of the sea water is cut down as the insulated tips pass the poles, and, with the increase in conductivity, a characteristic mark is obtained on the record of the galvanometer.

In the original meter, only one pole was used. The shape of the rubber tips on the ends of the propellers was triangular and, in the laboratory, a characteristic notch was secured on the recorder when the blunt end of the tip

passed the pole first; when the sharp end of the tip passed first a different notch was recorded. However, when this meter was used in the field, it became very difficult to distinguish between the notches caused by rotations in one direction and those caused by reversal of direction. To obviate this uncertainty, an additional pole was placed on the frame of the meter. The result of adding this pole was to cause a double deflection as the tip passed the two poles. If the direction of rotation of the propeller was positive, the recorder was first deflected upward and then immediately downward, whereas, were the direction of rotation negative, the deflection was first downward and then upward. The form of records secured is indicated in Fig. 21. On this diagram a plus sign denotes positive or clockwise rotation, and a minus sign denotes negative rotation. The period of record is 27.5 sec.



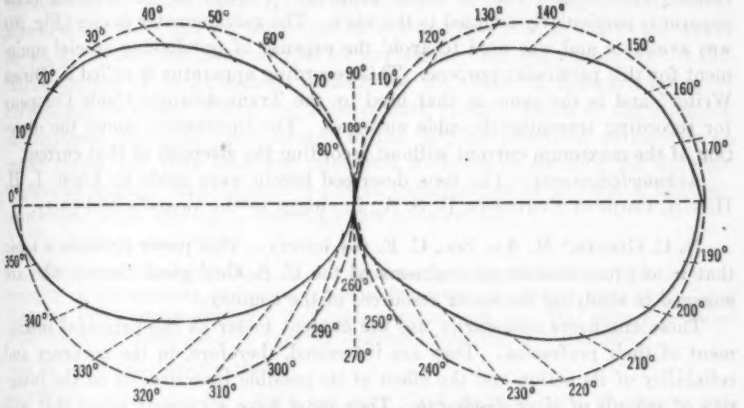


FIG. 21.—FORM OF RECORD SECURED BY PEGRAM CURRENT METER.

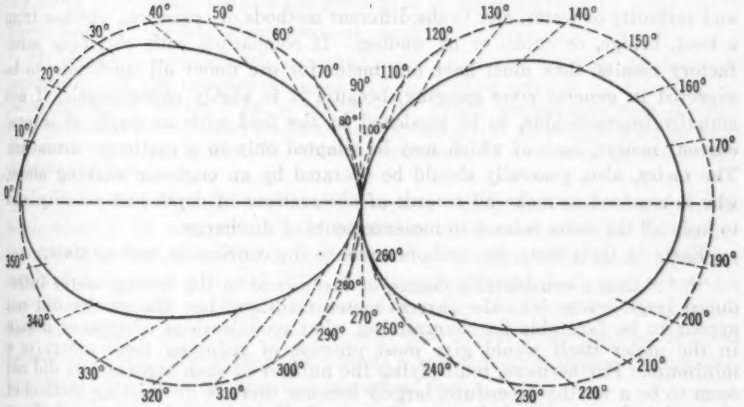

In so far as recording reversals of current is concerned, the meter has been successful. Its sensitivity has likewise been all that could be desired, readings as low as 0.08 ft. per sec. being secured. Obviously, the two-tip meter is better adapted to measuring small velocities than the single-tip apparatus. With the two-tip meter, half revolutions are recorded; hence, a reversal of one-half a revolution will be shown by the recorder. From the rating curves, this is equivalent to a reversal of 3 in. This is much more sensitive than any other meter at present in use.

In tests made by holding the meter in a stream of water moving through a trough and by moving the meter on a carriage through a swimming pool, certain defects became apparent. Although both these tests left something to be desired in the way of absolute precision of measurement, they have shown that the meter is applicable to the purposes for which it was designed, and that in the measurement of oblique currents, such as might be encountered in turbulent water, its accuracy is at least as great if not greater than those described by the authors. A graphical representation of the results secured in some swimming pool tests is given in Fig. 22. When inclined up to 20° in a positive direction, the Pegram meter gave little or no variation from the cosine curve; at 20° in a negative direction from 5 to 15% variation; at 40°, the meter under-registered in a positive direction about 15%, and at 40° in a negative direction, it under-registered 20 to 30 per cent. Considering the motion in a positive direction only, the results appear to be more satisfactory than those obtained with the meters used in the authors' experiments. These tests seem to indicate further that some change in the shape of the blades of the propeller would be desirable, in which case equally accurate readings in both positive and negative directions could be secured. In the tests made by the Board on Sand Movement and Beach Erosion, two meters were mounted on a staff, at right angles

to each other, and the components in the two directions were measured. In this way, the final result becomes an error in direction and a still smaller error in velocity, since the combined velocity becomes the square root of the sum of the squares of the individual velocities.

(a) ONE-TIP PEGRAM METER

(b) TWO-TIP PEGRAM METER

FIG. 22.—RESULTS SECURED IN THE SWIMMING POOL TESTS.

The passage of the water through the meters was retarded to some extent by the mounting adopted. To reduce the size of the mounting, however, would probably result in a loss of strength which would prevent the use of the meter in any but the very mildest seas. The accuracy of the meter can also be somewhat improved by a better balancing of the propellers. This must be done under water, as the difference in the specific gravity of the rubber and brass in

the propeller causes the rotating parts to become unbalanced when they are placed in the water. With these improvements the meter should be of considerable value in salt water, or in liquids having some conductivity. At present, it is somewhat cumbersome because of the weight of the recording apparatus. This weight can be easily reduced, however, by substituting other apparatus particularly adapted to the work. The galvanometer device (Fig. 20) was available and was used to avoid the expense of purchasing special equipment for this particular purpose. This recording apparatus is called a "Direct Writer" and is the same as that used by the Trans-Atlantic Cable Company for recording transatlantic cable messages. The instrument shows the direction of the maximum current without recording the strength of that current.

*Acknowledgments.*—The tests described herein were made by Lieut. L. H. Hewitt, Corps of Engineers, U. S. A., in charge of the Board's field party.

N. C. GROVER,[9] M. AM. SOC. C. E. (by letter).—This paper presents a topic that is of great interest to engineers of the U. S. Geological Survey who are engaged in studying the water resources of the country.

These engineers necessarily use the current meter as the principal instrument of their profession. They are interested, therefore, in the accuracy and reliability of its action and the effect of its possible inaccuracies on the integrity of records of river discharge. They must have a current meter that will give reliable results under a wide range of conditions related to velocity, depth, and turbidity of water, and to the different methods of operation, whether from a boat, bridge, or cable, or by wading. If compatible with obtaining satisfactory results, they must have one meter for use under all conditions to be expected in general river gauging, because it is highly objectionable, if not actually impracticable, to be burdened in the field with an outfit of several current meters, each of which may be adapted only to a particular situation. The meter, also, generally should be operated by an engineer working alone, who is required to make all records of observations of depth and velocity and to keep all the notes related to measurements of discharge.

Early in their tests, the authors came to the conclusion, and so state,

"* * * that a considerable degree of turbulence in the flowing water introduced large errors into the current-meter readings; but the results did not appear to be favorable for determining what modifications of type or design in the meter itself would give most promise of reducing these errors to a minimum. Furthermore, multiplying the number of such experiments did not seem to be a worthy procedure, largely because there is no existing method of measuring degree of turbulence and no standards or units in which turbulence may be expressed."

The conclusion thus reached is indicative of the difficulties experienced by field engineers as well as by laboratory investigators in connection with the measurement of turbulent water and the development of a current meter that will reliably measure such water.

Just as engineers have recognized that good leveling work can not be done in unsteady air, so they have recognized that good current-meter work can not be done in turbulent water, and as they have learned to refrain from attempting

[9] Chf. Hydr. Engr., U. S. Geological Survey, Washington, D. C.

to run precise levels under conditions of unsteadiness, so they should learn that they can not do first-class current-meter work in turbulent water by using any type of current meter yet devised. The greater the unsteadiness or turbulence of either air or water the greater will be the possible inaccuracies in the measurements. Unfortunately, it is impossible to define the degree of unsteadiness of either the vibrating air or the turbulent water and, as far as the writer knows, no method has been devised for expressing even approximately the different degrees of turbulence as a basis for the study of inaccuracies or of corrections for them. Thus, the authors have brought again to the attention of engineers the basic facts related to the varying effects of turbulence on meter action, but they have not attempted to define or describe the different degrees of natural turbulence of water in such manner as to form a basis for corrections to be applied to current-meter observations.

The authors state that,

"While the data of Table 1 do not disclose the correct values of the average velocity of the current, it became evident from the angularity tests made later that the Price meter recorded too high a value and that the values obtained with the other meters are in varying degrees below the true amount."

and in their conclusions that,

"When meters are held on a rod in a rigid position, with the meter axis parallel to the general axis of the stream, turbulent flow invariably causes the cup meter to over-register and the screw type to under-register."

Then, they add the following words of caution:

"It should be remembered also that rod support was used in all these experiments, and the conclusions must not be applied without modification to cable-suspended meters. In a majority of cases, stream gauging is done with cable-suspended meters. In such suspension the tail-vanes tend to keep the meter squarely facing the current regardless of any local or temporary obliquity of flow."

In these statements, the authors bring out clearly the kind of suspension used, whether by rod or cable (a condition often overlooked by laboratory investigators) and, in addition, they state what is perhaps the most important result of their tests. Although it has long been recognized that cup-type current meters over-register under conditions of considerable turbulence, it has not been so generally recognized that propeller-type meters under-register by comparable amounts. The authors have made a valuable contribution to engineering literature in making clear this important fact.

As engineers of the U. S. Geological Survey must use cable suspension in connection with a large proportion of their measurements, a comparison between the behavior of propeller-type meters and cup-type meters on cable suspension would be very desirable. However, this comparison remains now, as before, entirely unknown. It may be reasonable to suppose, as the authors have inferred, that, with all types of meter, obliquity of current may not be so important a factor with cable suspension as with rod suspension.

There is a belief apparently widely prevalent, especially among engineers of limited field experience and laboratory workers who are likely to overlook the important aspects affecting field serviceability of the meter, that the pro-

peller (horizontal-axis) type of meter is superior in every way to the cup (vertical-axis) type of meter. Whatever the theoretical advantages of the former, however, the latter seems to have certain practical aspects of superiority that have been controlling. These are related to delicacy of action, essential accuracy, adaptability to use under a variety of conditions, sturdiness, lightness, and reliability. The authors limit their discussion to accuracy of registration. They have referred to these other aspects in a pertinent way in the final paragraph of the paper.

The development of a current meter so that it may serve with even reasonable satisfaction under the wide variety of conditions to be found in general river measurement work is difficult. The small Price meter has perhaps been used more extensively and has received more expert study than any other current meter. As a result, in part, of this situation and, in part, of the natural advantages of the cup type, the small Price meter is now better adapted to general use than any other meter that has been developed. It is light and yet strong; sensitive and yet durable; it will measure, without great error, velocities ranging from less than $\frac{1}{4}$ ft. per sec. to velocities sixty times as great. It can be used readily whether suspended by a cable or supported on a rod. It will hold its rating under rough usage; it is easily repaired, is quickly taken apart from cleaning and oiling, and is re-assembled just as quickly without change in rating. It is sensitive, although it is not equipped with ball bearings. It can be used by an engineer working without an assistant. No other current meter known to engineers of the U. S. Geological Survey satisfies these conditions.

On the other hand, this meter generally over-registers in turbulent water. Its lack of adaptability to such conditions should be recognized, and it should not be used in eddying or seething water or from a boat that, by a rolling motion or by rising and falling on waves, gives the meter a churning motion.

Many attempts have been made to develop a propeller type of meter for general use, and engineers look forward with hope to such a meter in the future. The writer is informally advised that engineers of the Dominion Water Power and Reclamation Service of Canada, starting with an Ott meter, are about to produce their fourth trial meter of the propeller type to meet their needs in situations where there were difficulties with frazil ice which filled the cups of the small Price meter. They are to be congratulated in their attempts and should be encouraged to continue until they have produced a satisfactory propeller type of meter.

There are, however, many difficulties to be overcome before the equal of the small Price meter can be produced. The practically frictionless pivot bearing of the vertical-axis type of meter can not be used with the propeller type; cylindrical bearings must be substituted, if the advantages to be obtained from the overhung propeller are to be realized. Ball bearings are immediately suggested, but it is still an open question whether such bearings can be made as nearly frictionless as pivot bearings of the vertical-axis type. This will be apparent especially when it is recognized: (1) That the meters must be used in silt-laden rivers at depths greater than 50 ft.; (2) that exclusion of water

from the bearings under these conditions is probably impossible; (3) that silt, often gritty, will be forced into them to interfere with the action of, and to increase the friction in, the bearings; and (4) that such bearings are not easily cleaned. In addition, the propeller must be overhung if there is to be no obstruction in front of it. This, of course, entails the use of a shaft of considerable strength and size, thereby increasing the friction and decreasing the sensitiveness of operation of the meter. The wheel must also be perfectly balanced and must remain so under ordinary usage, or it will not operate evenly in water that moves at small velocity, but will tend to stop when the heavy part of the propeller is below the axis. By contrast, a meter of the cup type, equally eccentric on its axis, would continue to revolve in water moving at the same velocity. Even a minor injury to the vanes of a propeller type of meter will change the rating, whereas experience has shown that injured cups of the small Price meter can be pressed into approximate shape in the field and the use of the meter continued without change of rating.

Because of inaccuracies in the operation of current meters in turbulent water, engineers for many years have specified that sites for river-gauging stations must be so selected that current-meter measurements will be made in water that is free from cross-currents, boils, and eddies; and, ordinarily, river measurement work is performed under selected conditions that are known to give reliable results. This situation is recognized by the authors in their reference to "the good velocity conditions usually found at most gauging stations." That the results obtained by engineers of the U. S. Geological Survey are generally reliable has been shown many times by comparisons with measurements of discharge made by other current meters and in other ways.

The latest comparisons of this kind that have come to the attention of the writer are the following:

A comparison between measurements by means of the salt-velocity method and the small Price current meter was made in a canal at Bellows Falls, Vt., on August 16 and 17, 1929. The salt-velocity determinations were made by C. M. Allen, M. Am. Soc. C. E., and the current-meter measurements, by H. B. Kinnison, Assoc. M. Am. Soc. C. E. This statement relative to the comparison has been abstracted from an unpublished report by Mr. Kinnison. The width of the canal at the surface is 100 ft., and at the bottom, 35 ft.; the side slopes are 1 : 1¼; and the depth of water was about 28 ft. The maximum velocity of water observed during the tests was 6.56 ft. per sec. The current-meter measurements were made within the stretch in which the salt-velocity determination was made and about 35 ft. down stream from the pipes used to inject the salt water. There was, therefore, some turbulence in the section where the current-meter measurements were made, due to the pipes. Two salt-velocity determinations were made by Professor Allen in connection with each current-meter measurement of discharge, one at the beginning and one at the end of each measurement. The discharge by the salt-velocity determination is the average of the two determinations thus made. The first comparison was made on August 16 when 1 hour and 41 min. were required

for the current-meter measurement. The average of the two salt-velocity determinations was 9 780 sec-ft.; the discharge as determined by current meter was 9 896 sec-ft.; the excess shown by the current meter over the salt-velocity method was 1.19 per cent.

The second comparison was made on August 17 when 1 hour and 18 min. was used in making the current-meter measurement. The mean of the two determinations by the salt-velocity method was 8 587 sec-ft., and the discharge as determined by the current meter was 8 612 sec-ft. The excess shown by the current-meter over the salt-velocity method was 0.29 per cent.

A comparison of measurements by the salt-velocity method and by the small Price current meter was made in 1924 by S. B. Soule, District Engineer, U. S. Geological Survey, Madison, Wis. This comparison was made in the Mississippi River at St. Paul, Minn., between gate-openings of the Ford Power Plant. The gate-openings were rated by Professor Allen by the salt-velocity method. Current-meter measurements were made by Mr. Soule in the river about 1 200 ft. down stream from the power plant. The mean depth of water in the measuring section was about 6.5 ft. Two comparisons were made on December 19, and two on December 20, 1924. In the first comparison the discharge obtained from the gate-openings was 1 927 cu. ft. per sec., and by the current meter, 1 975 cu. ft. per sec.; the excess by current meter was 2.5 per cent. In the second comparison, the discharge from gate-openings was 2 290 cu. ft. per sec., and by current meter, 2 342 cu. ft. per sec., an excess by current meter of 2.3 per cent. In the third comparison, the discharge by gate-openings was 1 990 cu. ft. per sec., and by current meter, 2 033 cu. ft. per sec., an excess by current meter of 2.2 per cent. In the fourth comparison, the discharge by gate-openings was 1 668 cu. ft. per sec., and by current meter, 1 666 cu. ft. per sec., an excess by current meter of 0.1 per cent. The report of these comparisons has been abstracted from an unpublished report by Mr. Soule.

Comparisons have been made by Mr. Kinnison between calibrated weir measurements at the Alden Laboratory, Worcester, Mass., and the small Price current meter as follows:

(1) Discharge by weir, 1.74 cu. ft. per sec.; by current meter, 1.75 cu. ft. per sec.; an excess for the current meter of 0.57 per cent.

(2) Discharge by weir, 25.05 cu. ft. per sec.; by current meter, 24.83 cu. ft. per sec.; a deficiency for the current meter of 0.88 per cent.

(3) Discharge by weir, 31.469 cu. ft. per sec.; and by current meter, 30.83 cu. ft. per sec.; a deficiency for the current meter of 2.0 per cent.

It would be unfortunate if engineers were led by this paper to lose confidence in the reliability of the current meter because, in the writer's opinion, there is no occasion for loss of confidence. The authors have created artificial turbulence in order to show clearly the dangers resulting from the use of current meters in turbulent water and to compare the behavior of meters of different types. They should perhaps place greater emphasis than they have on the fact that their observations of meter operation in water that is not turbulent confirm the essential accuracy of the action of current meters of both standard types when operated under proper conditions.

Moreover, there is no other method for obtaining reliable records of discharge as expeditiously or as cheaply as by use of the current meter. Other methods, which may be used in tests of water-wheels, or otherwise, where accuracy is essential and where a stretch of smooth-flowing water is not available for current-meter work, are not adapted to general river measurement because they are often more difficult to apply and always much more costly in their application.

BURKE L. BIGWOOD,[10] ESQ. (by letter).—The experimental data presented in this paper apparently prove conclusively that, under certain conditions of flow, results of stream measurements that are obtained by use of the current meter may be grossly in error. Even without such experimental proof, trained users of the current meter would be cognizant of the existence of such inaccuracies in its operation. The concrete evidence submitted by the authors confirms beliefs heretofore based on general observation and reasoning only.

The current meter is in widespread use at present (1930), as it has been for many years. In the United States and in Canada the cup-type meter is generally preferred. The U. S. Geological Survey uses the small Price meter almost exclusively in its vastly extensive activities in the field of general stream-gauging work.

It is the general opinion that at a first-class river-gauging station this type of meter produces an accurate record of the flow of the stream. This is assuredly the opinion of the personnel of the U. S. Geological Survey. Practical tests have been made which bear out this belief. This meter has been tested against accurate weirs of all kinds, against volumetric methods of measurement, against Venturi meters, and against salt-velocity and other so-called chemical methods of measurement. An imposing array of evidence could undoubtedly be assembled to prove that this meter, properly operated, gives results well within required limits of accuracy. This precision in results has been brought about and maintained by the practical elimination of those conditions of flow which produce the errors in operation of the meter.

First-class river-gauging stations contain as a most essential element a "smooth" measuring section. By this is meant a section of the stream channel through which the water flows with a minimum of turbulence and horizontal angularity. It would be expected that any type of meter would produce good results at such a station, but it is the writer's opinion that the Price meter has one great advantage, indicated by the results of the authors' experiments.

Through the selection of "smooth" measuring sections the adverse effect of turbulence and of lines of flow approaching the meter at angles from the right or left has been practically eliminated; but owing to the character of river beds in general, it is impossible to eliminate the effect of roughness of the bed of the stream on an observation to determine the velocity near the bottom. It is the writer's opinion that the usual rocky or boulder-strewn bed creates waves in the lines of flow near the bottom of the stream. This does not amount to turbulence since lines of flow above, toward the surface, are not disturbed by this action. A meter suspended in water flowing in this

[10] Dist. Engr., U. S. Geological Survey, Hartford, Conn.

manner is acted upon by lines of flow approaching at angles from above or below. Under this condition, the experiments outlined in the paper (Fig. 16) prove that the Price meter gives the best results.

All meters give least reliable results under conditions of turbulence and horizontal angularity. Having eliminated these conditions by the proper selection of gauging sections, the remaining conditions are such that, in the writer's opinion, the Price meter gives the most reliable results, mainly owing to its ability to measure accurately the wave flow near the bottom of the section.

G. H. NETTLETON,[11] ESQ. (by letter).—This paper covers important ground from the meter user's point of view. The experimenters are to be complimented on the thorough manner in which the tests were carried out, but the writer cannot agree entirely with their findings for reasons here given.

The fact that the bucket type of current-meters has a tendency to over-register and those of the screw pattern to under-register when they are acted upon by very turbulent streams of water, has been long recognized. In this paper much interesting work has been described that bears out this contention; but it appears that, during the actual tests, meters were subjected only to turbulence of a most violent nature. Such conditions may be exaggerated with the definite purpose in view of ascertaining some weakness in the behavior of an instrument, but the fact must be borne in mind that conditions may be exaggerated to such an extent that they bear little or no relation to actual stream conditions at average measuring sections. This latter contention would appear to be the case in the experiments described by the authors. The turbulence was of such a degree that meters were forced to operate under conditions for which they were not designed and which would not be encountered at what may be described as even the more poorly selected measuring sections. Further, the artificially produced turbulence was of such a high magnitude that it was out of proportion to the mean velocity of the stream, namely, from 1 ft. to 5 ft. per sec.

It is difficult to conceive any conditions which might exist in the open channel of a river having much greater velocities than those used in the tests, which would produce such abnormal turbulence, and it would be even less true of a selected measuring section. Rapids or water-falls might be responsible for such violent agitation and they would cause vortices, etc., but no engineer would ever consider attempting a measurement in a stream at such locations. In support of the writer's contention that the artificially produced turbulence and the conditions under which the meters were used in the tests were not applicable to actual field measurements, he would draw attention to the following points.

The fixed paddle-wheels (Fig. 11) were apparently only 6 ft. up stream from the meter and were of such a size that they actually masked it to a considerable extent, and must have almost, if not entirely, prevented the natural tendency of an unobstructed flow to smooth out deviating threads of current.

[11] In Chg., Dominion Govt. Current Meter Rating Station, Dominion Water Power and Reclamation Service, Calgary, Alberta, Canada.

In this case the angle at which the water was caused to impinge on the meters was very much in excess of that encountered in any river, and unobstructed flow could hardly have existed anywhere in the cross-section of the experimental flume at the meter section. Further, in the test with the vertical paddles (Table 1), there was a gap of 3 in. between their bottom edges and the bed of the flume. In the case of one paddle this would have the effect of creating a high velocity undershot current which would turn sharply upward from the flume bed owing to the low pressure area at the back of that paddle. From the viewpoint of producing violent turbulence, the arrangement was excellent, but it would appear impossible to believe that such conditions existed at measuring sections.

Again, rolling vortices appear to be treated as though they were moving along and resting on the bed of a river in the same manner in which a wheel rolls over a road. In fact, in some tests, what may be described as the negative or low velocity side of such a rolling body of water was apparently given a value approximately equal to the mean velocity with which the water was flowing down the flume. This is anything but true of river conditions because such a body of water as a whole is moving down stream and the negative or low velocity side has a forward and not an up-stream velocity in an open channel. These changes in velocity affect the meter in a river as current pulsations and, as is conceded by the authors, pulsations in the flow of a stream do not cause a meter to register incorrectly. It is true that in the experiments pulsating currents did cause some difference in the recording of instruments of the cup and screw type, but the difference was accounted for by the artificially produced effect of the current changing from a positive to a negative value, or from flowing down stream to up stream.

If a meter was freely suspended by cable in a river-measuring section where such conditions existed, the instrument would naturally face the direction of flow and, consequently, at times, would be pointing up stream and at others, down stream. Such conditions have never been encountered by the writer even in turbulent mountain rivers, but the flowing water always had a down-stream or positive value, even though the velocity might vary from time to time. Experiments carried out by the writer showed that what may be described as pulsating currents, that is, currents the velocity of which rose and fell above and below a mean velocity, did not cause either a meter of the screw or cup type to register incorrectly. The value of the pulsations was exaggerated purposely so that the difference in rise and fall of the velocity was considerably in excess of anything of the nature that had been experienced in field work, but at no time was the velocity given a negative or up-stream value. Furthermore, numerous measurements of different rivers have been made, using a cup and screw type of meter at the same time. These rivers were representative of those found in the Province of Alberta, Canada, in the foot-hills of the Rocky Mountains. In all cases the difference between the mean velocity recorded by each type of instrument was of such small value that it was negligible, and, further, the cup meter did not always show the greater velocity; frequently the screw meter gave the higher figure.

Although it is agreed that violent disturbance of a stream will usually cause a cup type of meter to over-register and a screw pattern to underestimate true velocity values, yet it is considered that at the average selected measuring sections, instruments of either pattern will give reliable data to within the accepted degree of accuracy for stream-measurement work. Furthermore, the experiments, as described in the paper, were conducted under abnormal conditions of flow and turbulence which made it impossible for the current meters to function either as they would in the field, or under the conditions for which they were designed.

C. LINDEN,[12] ESQ. (by letter).—The investigations described by the authors have added valuable data to the information pertaining to current meters and current-meter action; but like all previous tests these have failed to bring definite results or to end the controversies which have prompted the studies.

Investigations are doomed to failure when it is assumed that the forces which actuate the meter represent only the true velocity. Under ideal conditions this may be very nearly true, but in turbulent waters the flow represents a combination of forces of which the velocity may be only a small part. Judging from the design of some well-known meters it must have been assumed that anything which may be rotated by the forces of flowing water may be rated and thus may become a current meter. If streams proceeded as parallel filaments, this assumption would be true, but such is not the case, and meter rotation is not a definite product to which correcting factors may be successfully applied. Meter rotation is the result of forces of irregular origin.

Other erroneous assumptions which have been made are that meter work can be properly done in both clear water and in water filled with floating débris, and that meters should be rated under field conditions similar to those in which they will be required to operate. This would be highly desirable, but it is impractical because of the ever-changing condition of both direction and velocity. No mechanical meter can produce accurate results unless the flow and operating conditions are identical with those under which it was rated. Under all other conditions the results are only approximate. The object of meter studies is, however, to produce an instrument that will approach accuracy as nearly as possible when operated under field conditions. This has proved to be a much more difficult task than was at first anticipated.

It is not possible to establish comparable ratings from meters of various types when simply held in streams of varying turbulence. The importance of maintaining a constant and definite relation between the position of the meter axis and the direction of flow does not seem to have been fully recognized in past investigations.

Theoretically, stream velocities can be measured as a function of the velocity force, but it is too much to assume that true stream velocities can be secured by mechanical means. In order to do so, the mechanical device must be capable of differentiating between true velocity forces and other influences. It is not likely that irregular stream conditions, in which the re-acting forces are caused by the influence of the meter itself, will result in

[12] Secy., Scientific Instrument Co., Berkeley, Calif.

consistent meter action. In turbulent or extremely irregular water, such as is found in the tail-races of power plants, it is too much to expect a meter to distinguish between true velocity forces and the many other disturbing and re-acting forces. Mechanical devices for stream-flow measurements have no place under these conditions, although many investigators apparently depend on records obtained under such conditions for stream flow data.

Any mechanical device or meter will act in accordance with the forces applied, and identical forces will give identical readings. It has been suggested that meters should be calibrated or rated under field conditions in order to have stream conditions the same as those in which the meter is to be used; but since the calibration of a meter involves the establishment of a true ratio between flow velocity and meter rotation, it presupposes definitely known velocities and a constant flow direction. In the field neither of these essentials is present and, therefore, meter ratings under these conditions are impossible. Current-meter rating consists of more than exposing a meter to stream flow or causing the meter to move through still water. The meter must be held in a stable, least flow-obstructing position during the rating process.

Some stations do not give identical ratings even for the same meter on repeated readings. This is due to limited cross-sections of the rating channel, instability of the meter support, and inaccurate measurement of both time and distance of travel.

The rating flume used by the authors was evidently not of standard dimensions. In order to effect an ideal flow the channel should be not less than 60 ft. long, with a boarded section the full width of the canal. When the flume is less than the full width of the canal, it should exceed 60 ft. in length, in order to overcome, completely, the entrance eddies. A cross-section of 3 by 4 ft. is insufficient even for meters of the small Price type where, under most favorable conditions, the flow-obstructing area is about 4½ in. horizontally and 2¼ in. vertically. With a limited cross-section of the rating flume such an obstruction creates changes from the normal flow condition which affects meter action beyond the allowable limit. Flow conditions become turbulent as the stream filaments come in contact with the meter (which is a flow obstruction) even though the natural flow before submergence of the meter may be ideal.

Turbulence as the result of the presence of the meter in the flow line is objectionable but unavoidable. It is particularly objectionable because its effect on meter rotation is difficult to determine. This factor is, however, subject to some control and, in fact, offers the greatest field for improvement in meters. Improvement may be accomplished by designing a meter rotor so that it engages automatically for its rotation the forward component of the approaching stream forces. An efficient meter must be sensitive; but sensitiveness may be of two kinds—minimum friction and responsiveness to changes in flow direction. In some vertical-axis meters the friction is almost negligible, and yet they are not affected by changes in direction of flow. Such meters appear more conservative when exposed to turbulent flows than actual conditions justify. Although the friction may be slightly greater in horizontal-axis

meters, they respond to changes in flow direction so readily as to appear erratic, thus making it impossible to obtain consistent meter indications when the flow is unfavorable to meter work. In neither case does the meter record true flow velocity. The means of testing these features of a meter as described in the paper are unique, but of little practical value. A meter should be as frictionless as possible in order to increase its sensitiveness. As a rule the sensitiveness of a meter is indicated by the lowest velocity at which it starts rotation. Such starting rotation, however (when the ratio between friction and flow velocity is very high), may be caused as much through turbulent forces as by true flow velocity, since these turbulent forces may be the result of the meter's presence in the stream.

The influence of friction in a meter is confined to low velocities and the low velocity curve for a highly sensitive meter is very short. Sensitiveness increases the range of velocities over which the meter is reliable.

Meters cannot be satisfactorily compared unless the tests are made under the most favorable conditions. Ratings made under these conditions bring out information on the efficiency and reliability of a meter. Meters exhibit their characteristics at their low velocity ratings. Accuracy is recognized by the regular distribution of rating points; efficiency, by the shortness of the low velocity curve; and sensitiveness, by the steepness of the slope of the rating curve.

With ideal flow and operating conditions, any meter will act reliably, but to select the proper meter for field conditions one should examine the rating curve carefully. A meter for general purposes, or one which will be required to operate under varying stream or channel conditions, should be of a design having the least flow obstuction; it should have a rotor that will engage the maximum of stream filaments consistent with its size; it should be immune from vertical forces so that it may be used in vertical integration; and, it should have some means of securing a stable position automatically.

Under favorable conditions the records from all meters will agree, but under unfavorable conditions they will differ. This disagreement, however, is no greater than that often obtained from repeated measurements by the same meter. The meter that produces the least interference to flow will produce the most nearly correct readings. To operate properly, it must be held rigidly in such a position in the stream, that it is least obstructing to flow, regardless of the velocity. The meter that presents the least resistance to the flow is most easily held in this position.

H. R. LEACH,[13] M. AM. SOC. C. E. (by letter).—This paper has re-opened the subject of the performance of current meters in turbulent water, a question that has never been satisfactorily settled. It has generally been recognized that, except under conditions closely approaching stream-line flow, current meters of all types may indicate velocities departing more or less from the true velocity of the current, and that as conditions depart further from stream-line motion and turbulence increases, the departures of the indicated from the true velocities become increasingly greater. During the thirty years pre-

[13] Prin. Asst. with Robert E. Horton, Voorheesville, N. Y.

ceding 1930 several investigators have made excellent observations to determine the magnitude of these departures, and although definite quantitative results have been obtained there has been little, if any, attempt to interpret them so that velocities observed under abnormal conditions could be modified to give more nearly correct results.

In performing these experiments the authors show their recognition of the futility of trying to dispose of a troublesome question by saying, as has been done by many writers on the subject, that current meters should not be used in turbulent water. This merely "sidesteps" a situation that frequently confronts the man engaged in stream measurement, who often has no choice but to use his meter in a turbulent stream or to give up the measurement altogether. Even an admittedly inaccurate measurement may be of value, particularly if some idea of the probable error can be obtained.

In attempting to solve this problem the authors first ran a series of experiments on meters in turbulent water, but found too many factors involved to permit a clear interpretation of the results. Therefore, "rather than leave the matter in this incomplete and unsatisfactory state, it appeared desirable to attempt to resolve the problem into simpler elements and to attack them separately." Accordingly, they performed two other series of experiments. They did not, however, follow up the results obtained in the later experiments and attempt to interpret the performance of the meters in turbulent water in the light of the results found in their subsequent work. This is the only criticism that the writer makes of an otherwise excellent account of well planned and carefully performed experiments. It is to be hoped that the discussions of this paper and the authors' closure will analyze these experiments and suggest some rational method whereby current-meter measurements, that must of necessity be made in turbulent water, can be corrected to give a fairly close value of the true discharge.

As far as the writer is aware, B. F. Groat, M. Am. Soc. C. E., is the only investigator who has suggested a definite method of correcting current-meter measurements made in turbulent water.[14] In connection with measurements of the discharge through turbines at Massena, N. Y., he used Price and Haskell meters and suggested that the true velocity be taken as that indicated by the Haskell meter plus one-seventh of the difference of the velocities indicated by the Price and the Haskell meters.

*Experiments on Current Meters by B. F. Groat.*—A few years after he had made this suggestion, Mr. Groat ran a series of tests in connection with a comparison of current-meter measurements with chemical gauging.[15] These covered a wide range of conditions. The writer has recomputed these experiments and the results are presented in this discussion to show to what extent they corroborate those of the authors.

The tests were made in the Naval Tank of the University of Michigan on a small Price meter, two low-pitch Haskell meters, and two Ott meters. The meters, with tails removed, were rigidly attached to arms on the rating car

[14] *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), p. 819.

[15] "Chemi-Hydrometry and Its Application to the Precise Testing of Hydro-Electric Generators," *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1231, Pt. V.

with their axes parallel to the axis of the tank and to the direction of motion of the car. The arms were arranged so that they could be oscillated in three directions, that is, vertically, horizontally at right angles to the axis of the tank, and longitudinally parallel to the axis of the tank. They were connected so that the same movement was imparted to each of the five meters. Their axes were always parallel to the direction of motion of the car except that in the longitudinal oscillations the arms gave the meters a slight rocking motion in a vertical plane. The manner in which the frame was oscillated was not stated. Mr. Groat plotted the observed revolutions per foot for different oscillations against the velocity of the car.

By first constructing a rating curve from the normal observations and then determining the indicated velocity for each observation, the writer obtained the difference between the indicated velocity and the forward velocity of the rating car. The rate of oscillation and the velocity of the car were added vectorially to obtain the absolute velocity of the water relative to the meter and the angle, $\alpha$, between the direction of the absolute velocity and the axis of the meter. This recomputation was made only for the observations on the Price and Haskell meters.

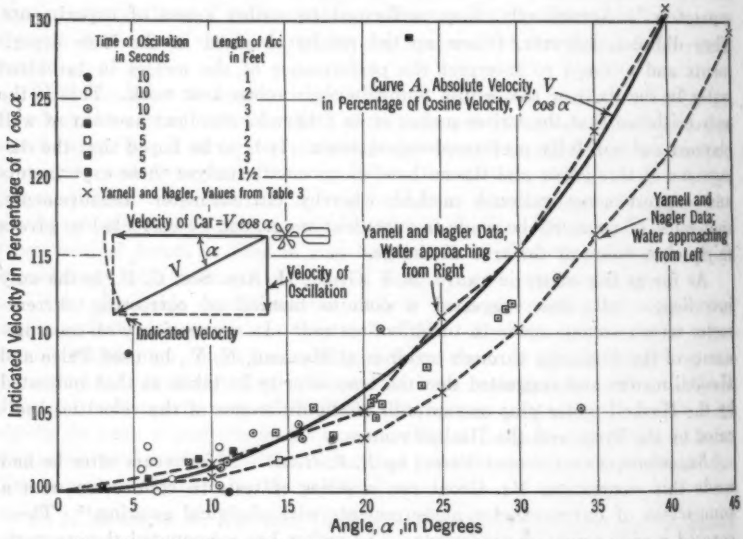

FIG. 23.—HORIZONTAL TRANSVERSE OSCILLATIONS ON SMALL PRICE METER.

*Small Price Meter: Horizontal Oscillations.*—The observations for horizontal transverse oscillations are plotted on Fig. 23. The indicated velocity in percentage of the cosine velocity is plotted against $\alpha$, the angle the tangent of which is the velocity of the horizontal oscillation, divided by the velocity of the car. The cosine velocity is the absolute velocity times cos $\alpha$, and is, of course, the velocity of the car. Curve $A$ is the absolute velocity of the water relative to the meter in percentage of the cosine velocity.

Were it not for the interference caused by the yoke supporting the bearings of the cups, the Price meter apparently would record the absolute velocity and, therefore, would over-register with respect to the cosine velocity. Up to angles of about 15° it does this. For angles greater than 15° the indicated velocity is a few per cent. less than the absolute velocity owing probably to the interference of the yoke.

The values presented by Mr. Groat are in good agreement with the average of the Yarnell and Nagler values for right- and left-hand inclinations. This would be expected from the fact that the oscillating movement would give the mean of the right-hand and left-hand effects. Although the Iowa experiments show that the ratio of indicated to cosine velocity depends to some extent on the velocity, this does not appear to have affected Mr. Groat's results appreciably.

*Small Price Meter: Vertical Oscillations.*—The observations for vertical oscillations are plotted on Fig. 24. Within the range, $\alpha = 0°$ to 25°, they

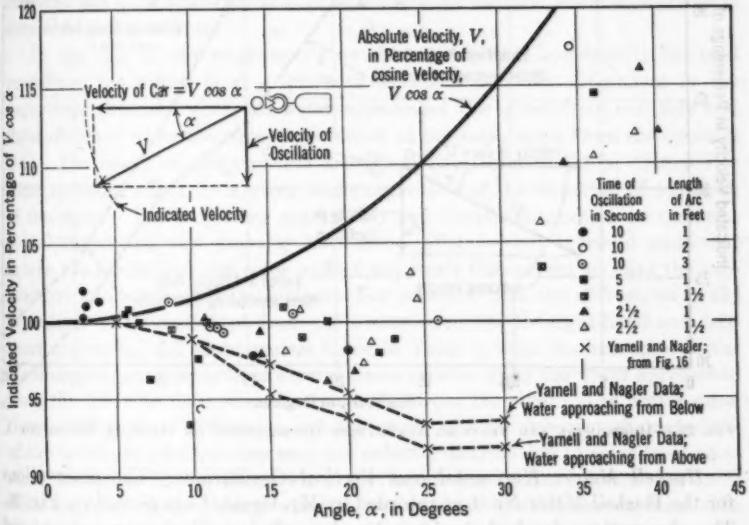

FIG. 24.—VERTICAL TRANSVERSE OSCILLATIONS ON SMALL PRICE METER.

show an indicated velocity slightly less than the cosine velocity. For angles greater than 25° the indicated velocities are greater than the cosine velocities. This does not agree with the results found by the authors because, in all cases up to the limit of their experiments, the indicated velocities were less than the cosine velocities. Experiments made by the U. S. Geological Survey in 1898,[16] on one of the earlier type Price meters, gave observed velocities in all cases greater than the cosine velocities. On the other hand, the results found by the authors fall between values observed by Brown and Forrest Nagler,[17] M. Am. Soc. C. E.

[16] Nineteenth Annual Rept., U. S. Geological Survey, Pt. IV, p. 30.
[17] "Stream Gaging," Liddell, First Edition, 1927, p. 144.

The difference may be due partly to the fact that in one case the meters were held at a constant angle of inclination against the current, while in the other they were oscillated, probably at a varying rate. It may be noted that the authors' results on the acoustic Price meter do not show as great departures from the cosine velocity as the electric Price and are in good agreement with Mr. Groat's observations up to an angle of about 20 degrees. Between angles of 20° and 30° the acoustic meter gave indicated velocities about 3% less than the cosine velocity.

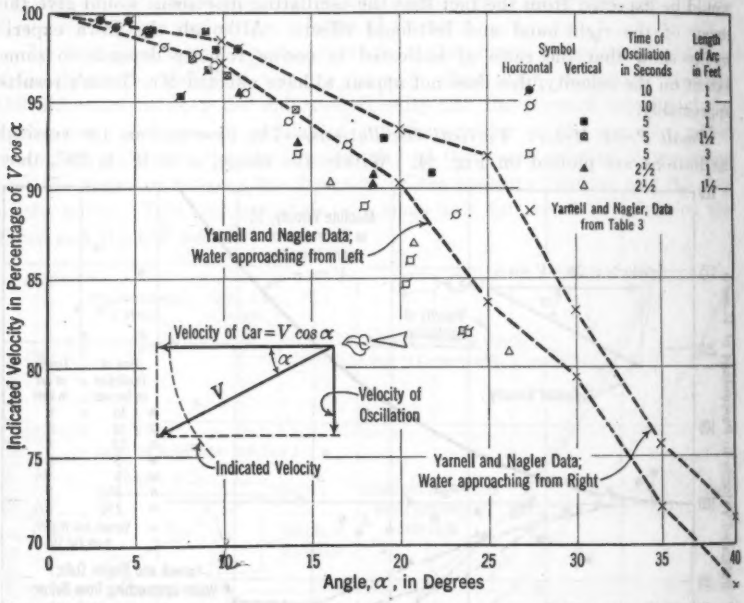

FIG. 25.—HORIZONTAL AND VERTICAL TRANSVERSE OSCILLATIONS ON HASKELL METER NO. 1.

*Haskell Meter: Horizontal and Vertical Oscillations.*—The observations for the Haskell Meter No. 1 as recorded by Mr. Groat,[18] are plotted on Fig. 25. The observations for both horizontal and vertical oscillations are given, and it can be seen that there is no marked difference between the two, although the latter may have slightly smaller departures. Mr. Groat's results agree well with the departures observed at Iowa for water approaching the meter horizontally from the left-hand side; but they are greater than the departures listed by the authors for water approaching from the right side.

*Longitudinal Oscillations: Pulsations.*—Mr. Groat's experiments on longitudinal oscillations indicate a slight under-registration, amounting to between 1% and 2%, for both the Price and Haskell meters when the oscillations were not at a high enough rate to give negative velocities relative to the meter. This may have resulted from the rocking motion of the frame which

[18] *Transactions*, Am. Soc. C. E., Vol. LXXX (1916), p. 1246.

produced a slight vertical component in the velocity of the water relative to the meter. When negative velocities were created, over-registration occurred, as was the case in the authors' experiments, and probably for the same reason, namely, as a result of contacts when the rotor was running backward.

*The Yarnell and Nagler Experiments on Inclined Meters.*—In general, Mr. Groat's observations agree fairly well with those obtained by Messrs. Yarnell and Nagler. The writer is inclined to believe that a part, at least, of the differences between the two, result from the fact that in the authors' experiments a steady flow impinged against a meter held at a constant angle, while in Mr. Groat's experiments the oscillations probably caused both a varying angle and varying velocity. For this reason the latter may be somewhat more representative of actual conditions in turbulent water. The departure resulting from a constant angle of impact is not the same as the average departure resulting from a varying angle having the average value of the constant angle. Furthermore, it is difficult to account for some of the results obtained by the authors.

In the case of the experiments on the meters with horizontally inclined propellers, the writer is at a loss to understand the wide differences in the departures obtained when the water approached the meter from one side and those obtained when the water approached at the same angle from the opposite side. The rotors of these meters are symmetrical and would be expected to show the same effect for a given angle regardless of the direction of approach of the water. The projecting contact box and electric connection on the horizontal supporting arm probably have some influence, but it would seem that it was too far behind the rotor and of too small dimensions to have the pronounced effect indicated in Table 3. For example, note the differences in the departures of the indicated from the cosine velocities for right-hand and left-hand approach. All screw meters listed in Table 3, with the exception of the Medium Ott, gave departures several times greater when the water approached from the left side than when it approached from the right. The writer questions whether these differences are the result of some inherent characteristic of the meters or whether they may not reflect a distribution of velocity or some other condition in the flume when the meter was inclined toward one side different from that existing when it was inclined toward the opposite side. If this was not the case then the screw meter loses an important advantage over the cup meter in that its departure is also dependent on the direction of approach of the water as well as the angle of approach.

*The Yarnell and Nagler Experiments on Meters in Turbulent Water.*—Taking into consideration that the authors' experiments show that the velocity registered by the meter depends on several factors—including (1) the angle of approach; (2) the direction of approach; (3) the velocity of the water itself; (4) the possibility of negative velocities; as well as (5) the type of meter—it is easy to understand the difficulty encountered in attempting to apply the results of the later experiments to the observations obtained in turbulent water in the first series. While the experiments on inclined meters are of considerable value, they are in effect stream-line ratings of the meter

at inclined angles, and do not strictly apply to turbulence consisting of variable velocities and angles of approach. To be of real value they must explain the performance of the meter in turbulent flow.

It is unfortunate that in the turbulence experiments the observations were not taken over a longer period so that the performance of each meter at a given point could be compared. In Experiments Nos. 8 and 9, in which "duplicate readings as shown in Table 1 were taken at each point in the cross-section in order to determine the possibility of error by taking observations for too short a time in turbulent water," it was found that "individual observations of velocity in this turbulent water, taken for the usual length of time, may vary as much as 10 to 20% * * *." Such errors, however, are largely compensating. In Experiments Nos. 8 and 8(*a*) (Table 1) the average difference between duplicate readings at each of the eight points, as well as the maximum difference at any one of the points, is given in Table 7.

TABLE 7.—COMPARISON OF VELOCITIES REGISTERED IN DUPLICATE EXPERIMENTS NOS. 8 AND 8(*a*). (TABLE 1.)

| Meter. | Maximum difference at single point, in feet per second. | Average difference for all eight points, in feet per second. |
|---|---|---|
| Electric Price | 0.28 | 0.03 |
| Acoustic Price | 0.31 | 0.05 |
| 4-blade Hoff | 0.46 | 0.03 |
| Small Ott | 0.22 | 0.12 |
| Large Ott | 0.31 | 0.02 |

The large maximum differences at single points show that the observations were too short to get the correct average value of the velocity indicated by any of the meters at any one point, and this renders impossible any comparison of the observations of the different meters at a given point. The small average differences, however, indicate the compensating nature of the errors resulting from too short an observation, and this makes the comparison of the average performance at the eight points more reliable.

Although the authors ran Series Nos. 2 and 3 for the purpose of obtaining data that would explain the performance of the meters in turbulent water, this cannot be done by the experiments thus far presented. Not only do the later experiments fail to account for the observations obtained in the turbulent flow experiments, but they indicate either that there is some hitherto unrecognized factor in turbulent flow, or that all the conditions existing in the flume when the flow was turbulent have not been clearly brought out in the paper.

Table 3 and Fig. 15, giving the results with inclined meters, indicate that, in all cases, the 4-blade Hoff meter should register a smaller velocity than the small Ott meter and that as the angle of inclination, $\alpha$, increases the difference in indicated velocities should increase. Although the magnitude of the departure depends on whether the water approaches the meter from the right or from the left, the direction of approach was presumably the same for both meters, and they should show the same relative departures. Moreover, the authors conclude that if, as was the case in Series No. 1, the electric con-

tacts are made at intervals of several revolutions, all meters will register the correct average of a variable velocity. When, however, the average of the duplicate readings of the small Ott and the 4-blade Hoff meters in Experiments Nos. 8 and 8(*a*) are compared, it is found that at four of the eight points the Hoff meter gave velocities from 4 to 17% greater than the small Ott meter. In Experiments Nos. 9 and 9(*a*) the Hoff meter indicated velocities from 12 to 42% greater than the small Ott. This is not explained by insufficient duration of observation or by anything shown by the oblique flow experiments.

The unusual condition of turbulence existing in the flume is shown by the fact that in three out of the eight experiments (two of the total of ten being duplicates) the screw meters registered from 25 to 50% greater velocity than the mean derived from the discharge over the standard weir. Considering that screw meters always under-register oblique velocities, it must be concluded that there was an area of zero or negative flow in the section and that the effective area of forward flowing water was materially less than the total cross-sectional area and therefore resulted in abnormally high velocities. While areas of stagnant or backward flowing water are sometimes encountered in stream-gauging work, particularly immediately behind obstructions, it is generally possible to recognize and to take this condition into account, and such highly abnormal conditions as were apparently created in the authors' flume would be almost unique in field work.

*Correction of Observations Made in Turbulent Water.*—The writer believes that notwithstanding the impracticability of attempting to obtain the proper correction to current-meter observation by evaluating each of the several factors influencing the registration of the meter, it is possible to carry out field measurements in such a manner as to reduce, if not entirely eliminate, the errors introduced by turbulent flow. There are several methods that should be given consideration by any one who must measure a stream that is more or less turbulent.

*Two Measuring Sections.*—If two measuring sections are close enough together so that there is no change in the quantity of water passing the sections and yet far enough apart so that the conditions at the sections are different, some indication is given of the amount of turbulence in the stream and also which of the two will give the best result. This is increasingly valuable if the shapes of the sections and the distribution of velocities are materially different. This, of course, does little more than show which of the two sections is the better measuring section. Where, however, measurements must ordinarily be made at an unfavorable section—for example, from a bridge supported by several piers—check measurements made from a boat or from a temporary cable a short distance up stream will give the correction to be applied to measurements made at the lower section.

*Elimination of Turbulence by Baffles.*—This is obviously the most satisfactory method of dealing with turbulence although it is necessarily confined to use in a stream of small dimensions. If, however, a number of measurements are to be made and accuracy is of more than usual importance, it may be the least expensive of the methods considered.

*Measurement of Turbulence.*—It seems to the writer that a rather simple device could be constructed that would give the horizontal and vertical

directions of the current at each point of observation. Knowing these directions, the correction to be applied to the registered velocity could be made by means of the departures shown on diagrams similar to those presented by the authors. The use of such an instrument would be confined to shallow channels or to streams having a low velocity.

*Inclination of Meters.*—In the case of rigidly suspended meters it would seem possible to arrange the suspension so that the instrument could be rotated in both horizontal and vertical planes through 15 or 20° from its normal position perpendicular to the section. In this way the direction giving the greatest velocity could be found by trial, and the velocity at the point of observation corrected accordingly. This method could not be used with a cup meter as moderate changes in its horizontal position would not change the velocity indicated. The disadvantage of this method, aside from the trouble of providing the special suspension, lies in the amount of time required at each point. Instead of a single observation of usual duration, four or five observations would be required and these should be for sufficient length of time to get the true average registration and eliminate the effect of differences resulting from pulsating flows.

*Use of Two Meters.*—If simultaneous measurements are made with two instruments, one of which is a cup meter and the other a screw meter, it may be assumed with considerable reliability that the true discharge lies between the flows indicated by the two meters. Unless the turbulence is caused almost entirely by vertical components of velocity, the cup meter will over-register. The screw meter will always under-register. It remains to determine at what point between the velocities indicated by the two meters the true velocity lies.

That this method merits more than passing attention is shown by the results it gives when applied to the highly abnormal turbulence existing in the authors' flume. Table 2 gives the departures of the velocities indicated by the different meters from the true mean velocity in the flume. Fig. 17 gives the relative registration of the meters when it is assumed that the current approaches the meter from all directions with equal frequency, and lacking any more specific data, it can be assumed that this was the condition in the flume. In general, the curves in this diagram indicate that:

(*a*) Under-registration of the 4-blade Hoff is four times as great as over-registration of Price meter.
(*b*) Under-registration of the medium Ott meter is twice as great as over-registration of Price meter.
(*c*) Under-registration of the small Ott meter is equal to over-registration of Price meter.

Therefore, in order to get a closer approximation to the true velocity than is given by any of the meters alone:

(1) Deduct one-fifth the difference between the Price and the 4-blade Hoff velocities from the Price velocity.
(2) Deduct one-third the difference between the Price and the medium Ott velocities from the Price velocity.
(3) Deduct one-half the difference between the Price and the small Ott velocities from the Price velocity.

The error in the computed velocities using this method is given in Table 8.

It is obvious that for even such highly abnormal turbulence as there was in the flume used for those experiments, and with nothing to indicate the predominating direction of approach, or the nature of the turbulence, this method gives much better results than were obtained by any single meter. Omitting Experiment No. 4, more than one-half the results with the two-meter method are in error by less than 2% and the greatest error is 6.2 per cent. With the single meters more than one-half the results are over 13% in error and the greatest error is 61.6 per cent. In all cases except one, the two-meter method gives a better result than any of the single meters.

TABLE 8.—Error in Velocity Computed from Velocities Registered by Two Meters.

| Experiment No. | Small Price and 4-Blade Hoff. | | | Small Price and Medium Ott. | | | Small Price and Small Ott. | | |

* Departure by Price meter, from authors' Table 2.
† Departure by screw meter, from authors' Table 2.
‡ Difference in departures.

In Experiment No. 4 the electric Price meter indicated a lower velocity than either the large or small Ott meters. It under-registered by 17.4%, while the acoustic Price over-registered by 18.5%; there is, therefore, some question concerning this run. Experiments No. 2, 5, 7, and 10 were omitted in the preceding comparison for the reason that in all but one the screw meters

indicated from 25 to 50% greater velocity than the true velocity, and in Experiment No. 7 three of the four screw meters over-registered. As has already been pointed out, this indicates a condition that is not entirely explained by the data presented.

*Cable Suspension.*—The preceding discussion relates to rigidly suspended meters whereas by far the greater number of current-meter measurements are made with cable suspension. Several of the methods described for handling measurements in turbulent water will apply equally well to cable suspension. It should be noted in the case of the two-meter method that the screw meter will not under-register as much with cable suspension as when rigidly suspended owing to the tendency of all meters, including the screw types, to point into the current and so register the absolute velocity.

In view of the results thus far presented the writer would suggest that further work be done to determine completely the effect of direction of approach on the registration of the nearly symmetrical screw meters, and that this be done in a channel of relatively large cross-section to eliminate, in so far as possible, the obstruction caused by the meter itself. It would also seem that turbulent conditions more nearly representative of those actually encountered in practice could be obtained in the 10-ft. hydraulic canal, and that some rational method of correction could be developed by comparing the performance of different meters at the same point with each other and with their registration with oblique flow.

In closing, the writer wishes to commend the work of the authors in their attempt to unravel an intricate problem. He well recognizes the impossibility of foreseeing before embarking on an experimental program, all the various phases that will develop during the course of the work. It is to be hoped that the authors will find the opportunity to carry out further investigation of this difficult question.

Dr.-Ing. Ludwig A. Ott,[19] (by letter).—The solution to numerous problems concerning discharge measurements is eagerly awaited by many engineers. This paper affords a welcome opportunity to discuss one of those problems, namely, the behavior of current meters with runners in turbulent currents.

During the sixteen years since 1914 the writer has repeatedly made practical experiments on this subject and has in general arrived at results similar to those described by the authors. The writer's experience has convinced him, however, that in studying current-meter behavior in oblique currents (always assuming the meter rigidly supported at the measuring section), it is inexpedient to distinguish between "screw wheels" and "cup wheels," the type of runner effecting a difference in grade only but not in principle. The essential feature is not the shape of the runner, but the position of its axis in relation to the plane of the measuring section.

With the shape of any runner fixed, the number of revolutions for a definite flow velocity represents a function of the angle formed by the direction of flow and the runner axis, and in principle all the directions situated on a conic surface around this axis are equivalent. Moreover, only in one position of the

[19] Math. Mech. Institut, Kempten, Bavaria, Germany.

axis, that is, perpendicular to the measuring section, is the number of revolutions a function of the angle between the direction of flow and the measuring section, as must be demanded of an instrument for determining the discharge.

Whether the runner is better provided with screw blades or cups is a question that cannot be answered offhand as long as behavior in the oblique current is the only consideration. Perhaps some other important factors must be considered, such as the disturbance of the flow, the sensitiveness of recording, the behavior near the surface or the bottom, etc. In either case, it is certain that a cup-wheel should be mounted in the same manner as a screw-wheel, with its axis of rotation vertical to the measuring section. Consequently, the plane of rotation should be parallel to the section.

In oblique currents, cup meters with their axes of rotation set parallel to the profile, show qualities similar to screw meters with their axes placed crosswise, provided the screw-wheel is of such a shape that it will revolve in this position. The writer has made a number of experiments with such runners. They were shaped like five-threaded twist drills and were 1 in. in diameter, $3\frac{1}{2}$ in. long, and had a pitch of 6 in. The generatrix of the helicoidal surface of one of the screws was a straight line, whereas those of the second and third were convex and concave curves, respectively. In the normal position, with the axis perpendicular to the measuring section, all three runners turned with equal numbers of revolutions like any other screw meter of suitable construction. When the axis was placed parallel to the profile the first runner remained at rest. The second and third turned forward and backward, respectively, with an increased speed (because the diameter was small compared with the pitch) analogous to that of right or left-turning cup meters.

To recapitulate: It is not the shape of the runner, but the position of its axis that is essential in researches on current-meter behavior in oblique currents.

In most of his researches the writer has placed the current meters at various angles in flowing water. Presumably Treviranus[20] was the first to adopt this method in his experiments. Experience has proved, however, that sufficiently accurate quantitative evidence is not obtained in all cases. There are errors to be anticipated in oblique currents, because in the equation of current meters:[21]

$$V = A + B\,N \qquad (1)$$

the coefficients, $A$ and $B$, do not, as a rule, change at the same rate for any given angular position of the axis.

Assume that a meter is rated by towing, keeping the axis parallel to the direction of the towing car. (See Fig. 26.) The result is expressed by Equation (1). Then the same meter is rated again with the axis at an angle, $\alpha$, with the direction of the car (see Fig. 27). The result is then expressed by:

$$V = a + b\,n \qquad (2)$$

[20] Treviranus, "Uber Verbesserungen in der Konstruktion und im Gebrauch des Woltman'schen Fluegels" ("On Improvements in the Construction and Application of the Woltman Current Meter"), *Allgemeine Bauzeitung*, Bd. 26, 1861, pp. 125–164.

[21] With regard to the theoretical derivation of this formula as a simplification of the general equation of the second order, see, Dr. L. A. Ott, "Theorie und Konstantenbestimmung des hydrometrischen Fluegels" ("Theory and Determining the Constants of Current Meters"), Berlin, 1925.

The component coinciding with the meter axis is thus shown to be,

$$v = V \cos \alpha \ldots\ldots\ldots\

If ratings have been carried out according to Fig. 27, or Equation (2), respectively, it is quite easy to determine the percentage of error which occurs in practice by applying Equation (5) instead of Equation (4). If $v$ denotes the velocity component computed from Equation (5) and $\Delta v$, the necessary correction, the result is expressed as follows:

$$\frac{\Delta v}{v} = \frac{b}{B}\cos\alpha - 1 - \frac{A}{v}\left(\frac{b}{B} - \frac{a}{A}\right)\cos\alpha \ldots\ldots\ldots\ldots (8)$$

As an instance the following equations may be quoted which are the results of very extensive researches executed in 1905 with the Ott Meter No. 385[22] (the units are in feet per second):

When $\alpha = 0°$,

$$V = A + B\,N = 0.064 + 1.660\,N \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

and, when $\alpha = 15°$,

$$V = a + bn = 0.034 + 1.746\,n \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Applying Equation (8) when using this meter in an oblique current of 15°, the percentage of correction for the flow component in the direction of the meter axis is,

$$100\,\frac{(\Delta v)}{v} = 1.5 - \frac{3.2}{v} \ldots\ldots\ldots\ldots\ldots\ldots (11)$$

As will be seen, the correction can be either positive or negative. It is +1%, 0%, and −1%, respectively, for the velocities, 6.4 ft. per sec., 2.1 ft. per sec., and 1.3 ft. per sec.

The writer has studied particularly the range from 0° to 20° at intervals of 2°, both to the right and to the left. These small intervals were deemed necessary, because otherwise irregularities in the run of the curve may easily be overlooked or assumed to be errors in measuring. Since experience has proved that in practice larger obliquities of current can nearly always be avoided, it appears to be sufficient to limit the range to 20° when determining the cosine qualities of a current meter.

The writer cannot fully agree with the statement in the "Introduction" of the paper restricting the use of current meters to measurements in natural streams and open artificial channels. In Europe, they are the most favored instruments for accurate discharge measurement in large pipe lines. In July, 1929, comparative discharge measurements by various methods (the Allen salt-velocity method, the Gibson method, with Pitot tubes and Ott current meters) were undertaken in one of the penstocks of the Walchenseewerk[23] under the impartial management of the Research Institute for Hydraulic and Hydro-Electric Structures in Munich. The measurements proper were carried out by experienced German and English crews. The results clearly showed the superiority of the current meter for this very kind of gauging, thus increasing every one's confidence in these instruments.

B. F. GROAT,[24] M. AM. SOC. C. E. (by letter).—In connection with this paper it will be of considerable interest and value to discuss a subject that bears directly upon the averaging of current-meter readings taken in a vertical velocity plane, or—what amounts to the same thing—to state those results, giving "rules" similar to those of Cotes, Newton, Simpson, and others, but especially formulated to supply averages in the form of the arithmetical mean. The observations and tables by Messrs. Yarnell and Nagler present opportunities for applying these suggestions.

All hydraulic engineers are familiar with the "two-tenths eight-tenths depth method" of averaging two readings to obtain the mean velocity in any vertical. This rule is based on the hypothesis that the actual vertical velocity curve approximates the arc of a parabola. The rule is exact for a parabola with its axis parallel to the current. It is also exact for a straight-line velocity gradient. It is known that, in particular cases, the actual velocity curve may depart widely from the arc of any parabola. However, if it is possible to state a rule, or rules, based on several point-velocity readings at various depths, such that the arithmetical mean represents the average for a curve of higher order than that of a parabola, the error of the mean can be reduced to an increasing extent as the number of such points is increased. In current-meter work, the appropriate arithmetical mean has the peculiar advantage that the extreme ordinates are not at the ends of the base line (water surface and bottom), as is the case with the usual rules of mensuration. The qualification, "appropriate", is made because there is an infinity of arrangements of ordinates of equal weight.

A general formula for mensuration was rigorously deduced by the writer in a paper, entitled "Mean Value of the Ordinate of the Locus of the Rational Integral Algebraic Function of Degree, $n$, Expressed as a Weighted Mean of $n + 1$ Ordinates, and the Resulting Rules of Quadrature", read before the American Mathematical Society, at Providence, R. I., on September 12, 1930.[24a] It furnishes not only the well-known formulas of mensuration (Newton's rule, Simpson's rule, etc.), as special cases, but also supplies, as other special cases, the rules conforming to the specification for current-meter readings (as previously stated) at various depths in the vertical-velocity plane.

These results may be stated briefly under eight headings, as follows:

(1) The "two-tenths eight-tenths depth method" is misnamed;
(2) Range of validity of mensuration rules;
(3) Weight ratios for "two-tenths eight-tenths depth method";
(4) Arithmetical mean of three ordinates;
(5) Arithmetical mean of four ordinates;
(6) Arithmetical mean of five ordinates;
(7) Arithmetical mean of six ordinates; and
(8) Arithmetical mean of ten ordinates.

*(1).—The "Two-Tenths, Eight-Tenths Depth Method."*—This method is misnamed. While the error caused by this inexactness may be moderate in some cases, yet such a name should be discarded because it is misleading.

[24] Cons. Engr., Brookline, Mass.

[24a] *The Am. Mathematical Monthly*, Vol. XXXVIII, No. 4, April, 1931, p. 212.

The correct relative depths (relative distances from the ends of the base line in mensuration) for the two velocity readings, when measured from either the water surface, or the bottom, are exactly, and, respectively, $\frac{1}{2} \mp \sqrt{\frac{1}{12}}$, or, approximately, in decimals, 0.211325 and 0.788675. It should be observed that this not only represents the true area of a parabola through the two points, but also the area bounded by a straight line passing through the two points, the base line, and end ordinates (water surface and bottom).

(2).—*Range of Validity of Mensuration Rules.*—The foregoing relation is a general truth in mensuration; if $n$ points lie on the locus of a rational, integral, algebraical equation of lower degree than $n-1$, then the true formula for $n$ points will not only be a true rule for the locus of a rational, integral, algebraical equation of the $n-1$th degree, but, also, for all loci of equations of lower degree than $n-1$. Therefore, the rule for a parabola works on a straight line; the rule for a cubic works on a parabola and on a straight line; the rule for a quartic works on a cubic, a quadratic, and a straight line, etc.

(3) *Weight Ratios for "Two-Tenths Eight-Tenths Depth Method."*—The rule for the so-called "two-tenths, eight-tenths depth method" results by making the weight of the middle (mid-depth) ordinate of the parabola equal to zero by properly locating the other two ordinates, so that Cotes' rule (the basis of Simpson's rule), 1:4:1, is replaced by 1:0:1, thus giving equal weights to two ordinates. It was shown in the paper before the American Mathematical Society that the ordinates may be located anywhere and their respective weights calculated; or *vice versa*, the weights may be chosen and the ordinate locations calculated. This method is applied to curves of higher order, thus obtaining further simple rules for averaging ordinates (point-velocity readings in a vertical velocity curve), some of which are indicated in Table 9.

Under Heading No. 7, in Columns (4) and (5), $c = z - z^2$. Thus, $r$ is a function of the coefficients of a cubic. The rules tabulated determine an average ordinate in terms of the arithmetical mean of $n$ properly located ordinates.

In Table 9 the column headings, $x$ ($x'$), $y$ ($y'$), and $z$ ($z'$), refer to the relative values of the abscissas corresponding to ordinates symmetrically located in pairs with respect to the center of the base line. Thus, $x + x' = 1$, etc. When there is an odd number of ordinates, $z$ and $z'$ (Column (4)) become identical as the relative abscissa of the mid-ordinate.

Abscissas are relative distances from either end of the given base line (surface, or bottom, for current-meter velocities). When a great number of averages, or resulting areas, are to be determined from drawings, or profiles, a diagram of radiating lines may be drawn on a separate piece of tracing cloth, so as to touch the ends of a base line within the limits of the tracing cloth and also to intersect the base line at intermediate points relatively distant from the ends by amounts proportional to the abscissas concomitant with the rule to be used. The diagram with its base parallel to the given base, and with its end lines touching the ends of the given base, will locate immediately all the intermediate points, along the given base line, at which ordinates are to be erected. The arithmetical mean of

these $n$ ordinates is the average value which, when multiplied by the length of the given base, gives the area enclosed by the profile, the base line, and two ordinates erected at the two ends of the given base on the drawing. The two end lines on the diagram may be used to locate convenient consecutive ends for a succession of bases into which a long line is to be divided.

TABLE 9.—SPECIAL QUADRATURE RULES FOR THE MEAN VALUE OF A FUNCTION, DERIVED FROM THE GENERAL RULE.

| Heading No. (1) | $x$ ($x'$). (2) | $y$ ($y'$). (3) | $z$ ($z'$). (4) | $r$. (5) | Ordinate spacing. (6) | Remarks. (7) |

| | 0.9162487 | 0.6872707 | ..... | 0.187270705 | ..... | $r_2$ in Column (5). |
| | (7) ARITHMETICAL MEAN OF SIX ORDINATES ($n = 6$) | | | | | |
| 7 | $\frac{1}{2} \mp 5r$ | $\frac{1}{2} \mp 3r$ | $\frac{1}{2} \mp r$ | $\sqrt{\frac{1}{4} - c}$ | $2r$ | ..... |
| | 0.07920706 | 0.2475242 | 0.4158414 | ..... | ..... | ..... |
| | 0.9207929 | 0.7524758 | 0.5841586 | 0.08415859 | ..... | ..... |

These consecutive bases need not necessarily be equal, but had better be chosen so as to secure greater accuracy, depending upon the nature of the profile to be examined. The end ordinates do not enter the arithmetical mean. If they did, the result would not be so accurate, since the relative weights of end ordinates, for symmetry about the center, are less than unity. The rules give the exact area under the curve of a rational, integral, algebraic curve of degree, $n - 1$ (that is, of a degree less by 1 than the concomitant number

of ordinates stated). If the ordinates are drawn to any curve of more or less smooth shape, the arithmetical mean of the ordinates is an approximation to the mean value of the ordinate of that curve, the degree of approximation increasing with the number of ordinates (and with the degree), as previously explained. The rule for $n$ ordinates not only gives the exact area for degree, $n-1$, but also for all lower degrees.

*Universal Applicability of the Rules.*—There can be no doubt that proper use of Rules (4) to (8), inclusive, will lead to greater accuracy in reducing field work, whether in water measurement or other classes of engineering. The accuracy of the formulas can be checked by applying them to curves for which the proper ordinates have been calculated. Use the radicals, $r$, because the symmetry causes them to disappear.

*Limitation on the Use of Weddle's Rule.*—When the base is divided into six equal parts by seven ordinates, one at each point of division, including the ends of the base, Weddle's rule states that the weights are, respectively, 1, 5, 1, 6, 1, 5, and 1, but it is not exact for seven ordinates to a curve of the sixth degree. The correct weights for this case are, respectively, 41, 216, 27, 272, 27, 216, and 41; the sum equals 840.

The arithmetical mean of ten ordinates representing generally the area under the locus of an equation of the ninth degree would furnish a most facile method for practical use, since it requires nothing more than addition and shift of a decimal point. The weights for ten ordinates which divide the base into nine equal parts are, beginning at either end, respectively, 2 857; 15 741; 1 080; 19 344; 5 778; 5 778; 19 344; 1 080; 15 741; and 2 857; total, 89 600.

*(8).—Arithmetical Mean of Ten Ordinates.*—Until the more exact rule for the arithmetical mean of ten ordinates is adduced, the arithmetical convenience of ten ordinates, together with an improvement in accuracy, can be had by using the rule for five ordinates on a base divided into two halves, just as one applies Simpson's (Cotes') rule to two, or more, sub-bases. The relative locations of the ordinates for this purpose are: 0.04187563; 0.15636465; 0.2500000; 0.34363535; 0.45812437; 0.54187563; 0.65636465; 0.75000000; 0.84363535; and 0.95812437. The arithmetical mean of ten ordinates thus located is the desired average to about seven places of figures; that is, accurate for two arcs of quintics which, together, pass through all ten points.

Tables 7 and 8 present the essence, and show the advantages, of the method of "aggregates" or the "statistical method".[25] In any good gauging section, the ratio of discharge to the aggregate revolutions per unit time (or aggregate velocities, if preferred) for readings taken at given points is a determinate function of the elevation of the water surface. When the discharge is constant, as in a mill-race, the function is constant. The usual statement that accuracy cannot be made less than 2% is too conservative. If one takes care to eliminate unknown influences as far as possible, including such conditions as rapidly fluctuating stages, and then determines proper constants by means of proper aggregates, the discharge can be gauged within a

[25] "Characteristics of Cup and Screw Current Meters; Performance of These Meters in Tail-Races and Large Mountain Streams; Statistical Synthesis of Discharge Curves," *Transactions*, Am. Soc. C. E., Vol. LXXVI (1913), pp. 819, 838.

fraction of 1 per cent. Most of the difficulties with current meters have arisen when trying to harmonize varying readings when the aggregate used was altogether too thin. Engineers must distinguish carefully between accidental errors and systematic, or constant errors.

Figs. 23, 24 and 25 show that there is some kind of relation between such widely separated conditions of rating as those at Iowa and in the rating tank of the University of Michigan. It does not seem that there should be any very close agreement between ratings in turbulent water and ratings in steadily flowing water, even if the average angle of approach and average direction should be the same in the two cases. This is best illustrated by the differences visible in Fig. 24. However, it is interesting to know that the relation is closer than might be suspected.

FORREST NAGLER,[26] M. AM. SOC. C. E. (by letter).—Exhaustive investigation on the effect of turbulence on current meters has long been lacking, and the paper under discussion fills a very definite gap in water-measurement practice. The work is exceptionally valuable, not only because of the methods used, but also because of the wide variety of current-meter forms tested. The meter performances investigated have to deal with solid angles, although they must be analyzed in horizontal and vertical planes for the purpose of showing their characteristics in diagrammatic form. It seems, however, that a polar diagram is slightly more appropriate than the rectangular diagram used by the authors for showing the detail meter characteristics.

Figs. 29 to 34 are submitted to show a line of investigation carried out by the writer, that parallels with surprising closeness a small portion of the work covered in the paper. Figs. 29 to 32, inclusive, show the detail work done on some of the meters available.

The initial experiments were made on a large sized Price meter in excellent condition. The curves in Fig. 29 show how it is affected by flows at angles with the horizontal. On account of the obvious inaccuracy of the meter in question, the work was not carried out farther than is indicated in the diagram. Later, in order to obtain an approximate comparison of the large Price meter with other meters, an arithmetical average was made between the vectors of Curve *D*, Fig. 29, and Curve *B*, Fig. 30, the latter being made on a small-sized, cup type of meter. The varying effect of different forms of frame will undoubtedly influence the form of Curve *B*, which is made in a horizontal direction, but for approximate purposes it was considered to be sufficiently accurate. The large Price meter was the least accurate of all those examined, and was particularly inaccurate if there was a preponderance of flow coming at an angle with the horizontal. It registered a velocity in excess of the desired resolved components under all conditions.

The small Price meter (Fig. 30) shows up unusually well up to angles of 25°, but it will be noted that this applies only for conditions of angular flow evenly distributed, horizontally and vertically. For such a condition this meter is probably very accurate, but it ceases to be so the moment there is a preponderance of angularity either in the horizontal or the vertical direction.

[26] With A. O. Smith Corporation, Milwaukee, Wis.

For example, if the preponderance is in a horizontal direction, the meter registers an excess velocity; and, if it is vertical, it registers less than the true amount up to about 40 degrees.

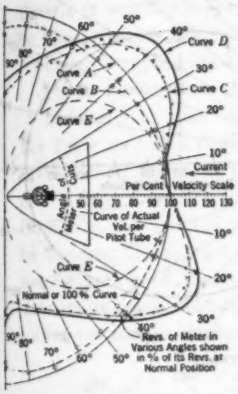

FIG. 29.—TESTS WITH A LARGE PRICE METER.

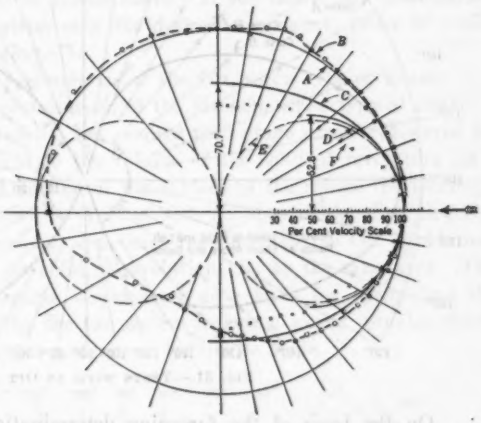

FIG. 30.—TESTS WITH A SMALL PRICE METER.

Examination of the results obtained with the screw type of meter shows that it is the ideal form for use in conditions of disturbed flow, because it makes the same effort to give resolved components regardless of the direction of the angularity. Of the two meters examined (see Figs. 31 and 32), the Ott meter is considerably the better. Incidentally, it may be mentioned that this applies not only to performance, but to the mechanical structure of meter bearings and housing. On the basis of the correction to be applied to Curve 4 in Figs. 33 and 34, making its semi-minor axis 35 instead of 32, it becomes evident that these two meters show results not differing widely, but in the same direction, from a true value.

The various meters were mounted on a vertical or horizontal axis on a frame installed in a 42-in. pipe in which water at a temperature of between 90 and 100° Fahr. flowed to a depth of about 14 in., at a velocity of approximately 4 ft. per sec. This velocity was very constant, the discharge being from several large condenser pumps. The pipe was of concrete, uniform in section, fairly smooth inside, and several hundred feet long, with constant slope. The flow was even and practically parallel by reason of the regular section, high velocity, and long smooth channel. Pitot tube readings were taken simultaneously with meter reading both at the zero position and at the angular positions so as to show whether the movement of the meter affected the flow. The tube was used for this purpose rather than to check the actual velocity reading of the meter, although this latter comparison is available.

In plotting results of the tests the curves could not be fixed with sufficient accuracy by inspection, so the method of least squares was adopted for determining the probable location and form of characteristic curve. This was used

for all meters, except the large Price, which was handled entirely by inspection and by an arithmetical average of the vectors of the two curves.

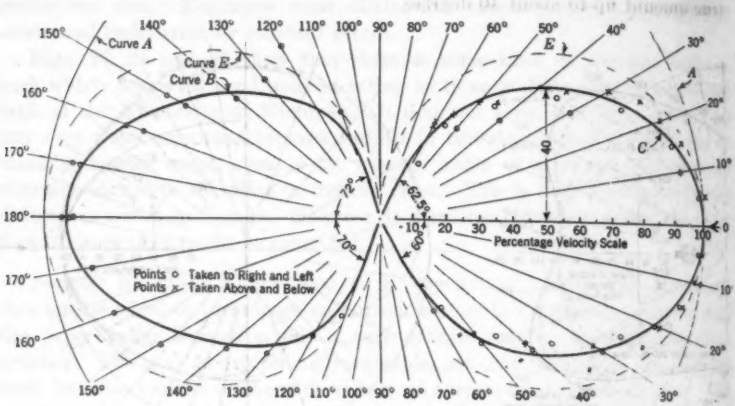

FIG. 31.—TESTS WITH AN OTT METER.

On the basis of the foregoing determination, the following semi-minor axes were determined:

| | |
|---|---|
| Small Price ..... | $B = 70.7$ |
| Ott ..... | $B = 40$ |
| Haskell ..... | $B = 32$ |

The determination for the small Price meter was also made on the basis of Curves $D$ and $2D$, shown in Figs. 30 and 33, in order to make possible a direct comparison of the probable characteristics of the three meters. The various ellipses determined on the foregoing basis are shown in Figs. 29 to 32, in which the circles, $A$ and $E$, are the two basic curves. To afford better comparison these various curves are replotted together in Fig. 33. Bringing together all curves in this form suggests a method of correcting differences between any two meters. In order to facilitate this comparison, the separate curves may be defined as follows:

Curve 1 represents the performance of a large Price meter rigidly supported and subjected to angular flow uniformly distributed. (If the preponderance is known or suspected to be in either the vertical or horizontal direction, reference, respectively, to Curve $D$ (Fig. 29), and Curve $E$ (Fig. 30), will indicate the direction and possible magnitude of error.)

Curve 5 represents a 100% curve, which would be expected from any good make of meter so supported as to be free to turn and measure the thread of the current, provided the support be such that the revolving element is given no sidewise motion.

Curve $2C$ represents the performance of the small Price meter rigidly supported and subjected to angular flow uniformly distributed. (The note given under Curve 1 applies here, referring to the horizontal and vertical curves ($B$ and $F$) of Fig. 30.)

Curve $2D$ represents a forced mathematical interpretation of the performance of a small Price meter made for the purpose of comparison only, and should not be used hereafter.

Curve 0 shows the ideal or cosine curve. If the meter had this characteristic it would always register only the desired component; hence it would be ideal (inertia effects neglected).

Curve 3 represents the performance of the Ott, screw type of meter.

Curve 4 represents the performance of the Haskell, screw type of meter.

Referring to Figs. 33 and 34, the average percentage excess registered by the Price meter is equivalent to the volume of the solid of revolution ($A$), divided by the area of that portion of the surface of the sphere the intercept of which is Curve 0, enclosed by a cone with an apex angle of 40 degrees. Similarly, the average percentage deficiency registered by the Ott is obtained by dividing the volume of the solid of revolution ($B$) by the same area. The determination of these averages would serve as a basis for reconciling the discrepant results obtained by the two meters in actual work. Similar determinations for the various other meters can readily be made.

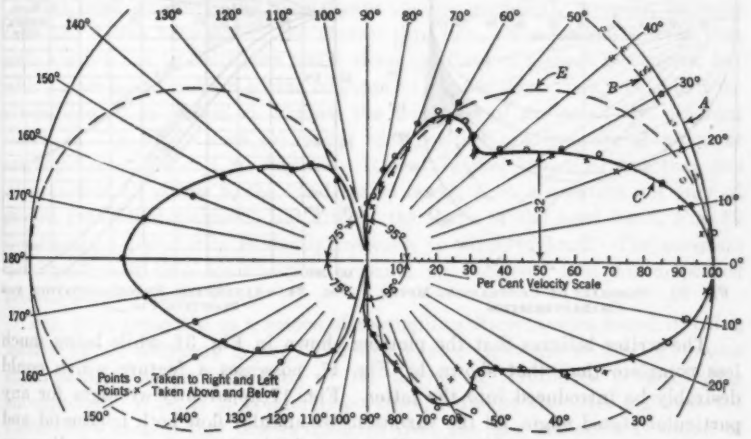

FIG. 32.—TESTS WITH A HASKELL METER.

In forming the computations, integration is difficult by reason of the complicated forms of some of the surfaces, but a simpler method is available. Fig. 34 is plotted directly from Fig. 33, the radii vectors of the various curves being plotted as percentages of the corresponding radii vectors of the zero circle for angles up to 45 degrees. These curves are plotted according to the small percentage scale at the left of Fig. 34. On this diagram the areas, $A$ and $B$, and, consequently, their respective volumes of revolution about the vertical axis, correspond to the similar areas and volumes for Fig. 33. Furthermore, the area of the surface described previously is now determined as the area of a circle of radius (20) in Fig. 34.

By inspection of Fig. 34 it is seen that the various curves are approximately parabolic in form, particularly near the origin. Therefore, the various volumes may be determined by multiplying the areas of the base of the solid of revolutions by one-half its height. Dividing this volume by the area of base, in turn, leaves a mean ordinate of one-half the height of the actual ordinate of the curve. This permits of a simple solution by dividing the vertical percentage scale by 2, resulting in the large percentage scale indicated at the left as plus and minus.

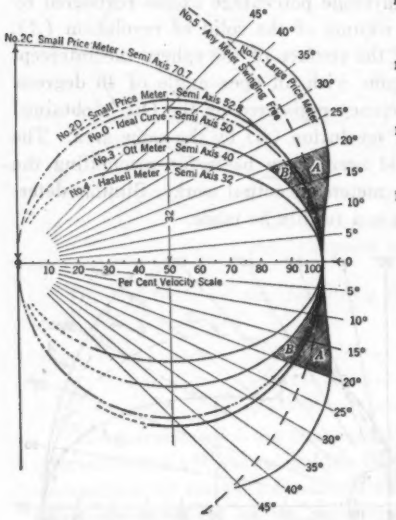

FIG. 33.—SUMMARY OF CONTRASTING METER CHARACTERISTICS.

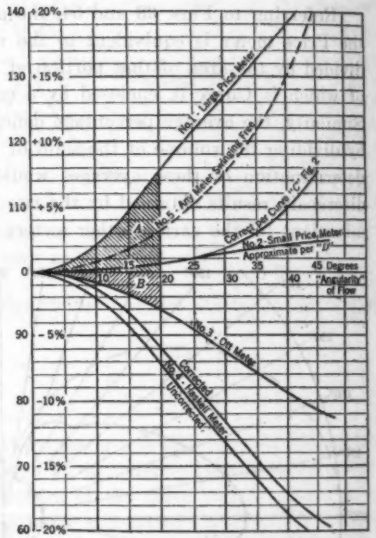

FIG. 34.—ALTERNATE RECOMMENDATION FOR PLOTTING FIG. 33.

The writer believes that the plotting shown in Fig. 34, while being much less complete than that shown by Fig. 17, possesses a feature which could desirably be introduced into the latter. Fig. 17 apparently averages for any particular stated angle, all the variations of angular flow both horizontal and vertical, but at that angle only. Fig. 34 is basically an integrated diagram and the plotted points of the curves at any angles (say, 20°) are not an average of angular effects at 20°; they are a summation or average of all the effects from zero to 20°, assuming that these effects exist a uniform length of time for all degrees up to that maximum. It is an attempt to define turbulence as being represented by constantly varying impact angles within and up to a certain maximum. This appeals to the writer as being a truer picture of turbulent flow and its angularity effect on a current-meter head.

The writer's work, done in 1913 and 1914, was premised on the assumption that all discrepancies in current-meter observations could be traced to disturbed conditions in the flow, and that all types of meters would register alike according to their still-water ratings if the flow were of stream-line charac-

teristics, straight, uniform, and parallel to the direction in which the meter is pointed. The extent to which the flow departs from this condition fixes the amount of divergence of any meter from true indication, and, of even greater importance, the extent of the disturbance fixes the relative discrepancy between the indications of any particular meters.

Analysis of the curves in Figs. 29 to 34 led quite positively to many of the conclusions arrived at in the paper under discussion. It led further to the conclusion that the only style of meter that may be used with absolute certainty, is a rigidly supported instrument with identical characteristics for horizontal, vertical, and all intermediate angularities of flow. This means that its axis of rotation must coincide with the direction in which it is pointed; in other words, it must be a screw type of current meter. The work led further to an attempt to build screw meters with modified helical surfaces generated by curved lines, rather than by straight-line elements, these curved lines being so disposed as to present the concave side of the helical surface to the normal direction of flow, so that any side angularities would amplify angular effects to counteract the evident under-registering indication of the existing types, and give more nearly the desired cosine function.

This work attained only a moderate success, sufficient, however, to indicate that it was basically in the correct direction. The writer believes that such a meter can be built very much along the lines of a small Ott meter, but with a more nearly correct cosine response to angular flow. It has been demonstrated that it is simple to increase the semi-axis of the small Ott diagram shown in Fig. 31, to such an extent that positive readings are obtained at angularities of 70 and 80 degrees. It was further demonstrated that the adherence of all points to the ideal cosine curve, *E*, is a question not only of curved generating elements, but also of the shape of the head itself, Fig. 32 illustrating a peculiarity evidently traceable to shape of head. The complete development of this combination presents an excellent field for improved present current-meter types.

Fig. 34 is presented as a means of reconciling discrepancies found in using meters of all different types. The discrepancy between meters of known characteristics is an indication of the degree of turbulence or angularity encountered. What is of greater importance, it might also offer a clue to the correct flow even if that flow is different from the flow indicated by either of the meters. In such application it is desirable to have the two meters under comparison, of diverse characteristics, so that correct flow will lie between them. This is merely because it takes quite a stretch of the imagination to use two such meters as the Ott and the Haskell (which, at an indicated angularity of 30 in Fig. 34, may under-register, respectively, 6% and 11½%), and increase the discharges of both of them by the amount in question merely because they happen to differ by about 5½ per cent. Such a procedure, however, is in line with a logical analysis of the data provided in the paper and in this discussion.

An investigation of completely shrouded meters would be very interesting. The shrouded Fteley meter analyzed[27] by Charles P. Rumpf, M. Am. Soc. C. E.,

[27] *Engineering News*, Vol. 71, No. 20, May 14, 1914, p. 1083.

shows an approach to the true cosine circle (Curve *A*), indicated by a semi-minor axis of about 45 units. Similar analysis of the large shrouded screw meter made by Gurley would be of interest.

To the writer the significant showing of the paper under discussion is in the extreme over-registering possible with both screw and cup type of meters under turbulent conditions. The under-registering of the Haskell type under good, but angular, flow conditions is the sole contrast, but it should be pointed out that under-registering resulting in a turbine efficiency exceeding 100% (as has actually happened) is instantly discarded; whereas, a result of 80% caused by over-registering carries no red warning flag labeled "impossible".

The authors are contributing a most excellent means of judging relative meter performance, to the end that wide inaccuracies in either direction may be prevented.

ROBERT E. HORTON,[28] M. AM. SOC. C. E. (by letter).—The paper under discussion presents the results of three different lines of investigation of the relation of the velocity registered by current meters of different types to the velocity of the stream. It suffers somewhat from seeming, if not actual, contradictions of statement and from lack of clarity. It is also difficult to check some of the figures and conclusions owing to absence of the original tabular data of the experiments.

To avoid uncertainty or confusion it has been found necessary at times in this discussion to set forth briefly what the writer understands to be the meaning of some of the statements and results presented by the authors.

Current meters for measuring the velocity of water are of two general types. In the cup type, illustrated by the Price meter, the axis of the rotor (as distinguished from the axis of the meter), is normal to the line of flow. Such meters are actuated by the excess of dynamic pressure on a flat surface over that on a curved or conical surface having an equal projected area. In the screw or helical type, the axis is parallel to the line of flow. Such a meter is actuated by impact of water on the inclined surfaces of the vanes.

Current meters serve, among many others, for three important uses:

1.—Determination of points on stage-discharge relation curves or rating curves for open-section stream-gauging stations. For this purpose cable suspensions are generally used.

2.—Measurement of flow in artificial channels, such as head-races and tail-races in power plant tests. Such channels often contain artificial turbulence, which is sometimes violent.

3.—Measurement of flow in channels, such as irrigation ditches, etc., commonly with smooth flow and slight turbulence. For these conditions rod mountings are frequently used. In the experiments described by the authors, rod mountings alone were utilized and, as was pointed out in the paper, the results and conclusions cannot with certainty be applied, unmodified, to meters used with cable suspension.

The most important use is in the measurement of natural streams. For this purpose the current-meter method is often the only one economically

[28] Cons. Hydr. Engr., Voorheesville, N. Y.

available. It permits the measurement of flow without loss of head and without disturbing natural conditions. Turbulence is nearly always present, particularly at higher stages. It seems worth while, therefore, to give some attention to the question of turbulence in natural streams.

*The Nature of Turbulence.*—In this discussion turbulence will be considered as consisting of eddies. For this purpose, an eddy may be defined broadly as a rotating mass of water regardless of the distribution of velocity within it, provided all the particles rotate around a common axis. A vortex is an eddy with a special velocity distribution such that for all radii, $R$, of rotating filaments the product, $Rc$, is constant, in which, $c$, denotes the tangential velocity of a filament at the radius, $R$. A vortex represents a stable system of motion in the sense that it can be destroyed only by friction. A part of the fluid may also rotate as a solid, that is, with uniform angular velocity at all radii. As the result of friction there may be a combination of a vortex and rotation *en masse* as, for example, a condition precisely intermediate. Table 10 indicates the characteristics of three types of rotating fluid masses.

TABLE 10.—CHARACTERISTICS OF ROTATING FLUID MASSES

| Type No. | Name | Relation of $c$ to $R$ | Relation of angular velocity, $\omega$, to $R$ | Relation of speed of rotation, $N$, to $R$ |
|---|---|---|---|---|
| 1 | Free vortex..... ..... | $c = \frac{\text{constant}}{R}$ | $\omega \propto \frac{1}{R^2}$ | $N = \frac{c}{2\pi R^2}$ |
| 2 | Rotation *en masse*..... | $c = 2\pi N R$ | $\omega = \text{constant}$ | $N = \text{constant}$ |
| 3 | Intermediate condition. | $c = \text{constant}$ | $\omega \propto \frac{1}{R}$ | $N \propto \frac{1}{R}$ |

The origin of eddies, particularly vortices in fluids, has been described by Dr. L. Prandtl, taking into account recent researches.[29] This need not be repeated further than to note that eddies originate where there is an obstruction to flow, such as a projection from the boundary of a natural channel, sufficient to produce a surface of discontinuity in the adjacent fluid. If there is a sufficiently marked difference in direction or magnitude of velocity on the two sides of this surface, an eddy is formed which grows in magnitude until it breaks away, carrying a mass of fluid with it. A new surface of discontinuity is then formed down stream from the projection and the operation is repeated.

The application of these results to the circulation of water in a natural stream will next be considered.

In a natural stream, eddies originate (except as hereafter noted) wholly around the margin of the cross-section and tend to travel normal to the boundary of the channel at the point of origin of the eddy, or at right angles

[29] "The Physics of Solids and Fluids—with Recent Developments," by P. P. Ewald, Th. Pöschl, and L. Prandtl, authorized translation by Dougall and Deans, pub. by Blackie & Sons, Ltd., Lond. and Glasgow, 1930.

to the line of flow. The normal component of eddy motion, is, however, combined with the velocity of the stream so that the resultant direction of motion is diagonally down stream and toward the center or surface of the stream. As the eddy travels, its energy is dissipated as heat. In a very wide channel, eddies thrown off horizontally at the sides may be dissipated before reaching the center of the channel. Eddies thrown off at the bottom, if weak, or if the channel is very deep, may not reach the surface. Strong eddies reaching the surface are spread out as visible "boils".

A vortex (like a smoke ring) carries with it part of the fluid out of which it is originally formed. Since eddies originate around the perimeter of the cross-section and hence in regions of low velocity and low unit volume energy, their propagation through the cross-section tends to equalize the velocity, as is in fact observed.[30] This theory of the circulation of water in rivers as influenced by turbulence has other important implications not relevant to the present discussion. One, however, may inquire: What becomes of the kinetic energy released by the equalization of velocities resulting from eddy cross-currents? On the other hand, the retardation of velocity due to viscous shear tends to equalize the velocities in a vortex and reduce that vortex to a simple case of rotation *en masse*, and any intermediate condition between that of a free vortex and that of simple rotation *en masse* may obviously occur. Changes taking place in eddy turbulence at different distances from the boundary where the eddies originate, have been studied experimentally.[31]

Mutual interference and coalescence of eddies do not greatly change the situation. They tend in many cases to accelerate the dissipation of energy and the disappearance of eddies. In other cases they accentuate the disturbance and may produce abrupt and violent changes or reversals of velocity such as are sometimes observed in current-meter work in violently turbulent water. Another interesting and important fact which, however, the writer has not seen described in engineering literature, is the "calving" of eddies of the vortex type. Energy changes due to external friction may cause the breaking up of an original vortex eddy formed at the boundary of the channel after it has risen part way or entirely to the surface. Under suitable conditions the original vortex eddy disappears, but it is succeeded by a series of small, active vortices, each containing a portion of the original vortex fluid. This phenomenon of "calving" of vortices may be successfully demonstrated by a simple experiment if carefully performed.[32] A minute drop of ink on the end of a toothpick is gently shaken into a glass of perfectly still water. A black vortex ring travels downward, expanding and presently breaking up into a group (usually five or six) of small, perfect vortex rings, radiating outward and downward. These, in turn, break up into other groups, the entire series resembling successive star clusters from a rocket. The breaking up of original eddies, therefore, is not followed necessarily by a heterogeneous or hit-and-miss

[30] "The Physics of Solids and Fluids—with Recent Developments," by P. P. Ewald, Th. Pöschl, and L. Prandtl, 1930, p. 281.

[32] "The Splash of a Drop," by A. M. Worthington, Smithsonian Inst., Annual Rept., 1894.

system of cross-currents, but, in part, by a new order of active eddies. The writer believes that a theory of the behavior of current meters in turbulent flow predicated on the composition of rotary and longitudinal motion (assuming the rotary motion to be of the character described), will provide a reasonably accurate "model".

*Effect of Artificial Turbulence.*—The first part of the paper gives the results of a series of experiments wherein artificial turbulence was induced in the experimental canal by horizontal and by vertical paddles (see Fig. 11). In these experiments the mean velocity in the canal was 2.0 ft. per sec. Different types of meters were used, and with each meter a velocity determination was made at each of the eight points in the cross-section as indicated on Fig. 10. Tests were made first with each meter, using horizontal paddles, and these were duplicated. Tests otherwise identical with the preceding were then made with vertical paddles, which were also duplicated. The resulting indicated velocities at the index points are shown in Table 1. The means of these velocities are given in Table 11.

TABLE 11.—MEANS OF VELOCITIES AT EIGHT POINTS OF MEASUREMENT IN FLUME WITH PADDLES

(Units are in feet per second)

| Meter (1) | Horizontal paddles (Test 8) (2) | Vertical paddles (Test 9) (3) |
|---|---|---|
| Small Price, electric | 2.18 | 2.12 |
| " " acoustic | 2.36 | 2.28 |
| Hoff | 1.74 | 1.90 |
| Small Ott | 1.76 | 1.95 |
| Medium Ott | 1.63 | 1.75 |
| Large Ott | 1.77 | 1.73 |
| Mean | 1.91 | 1.96 |

The figures in Columns (2) and (3), Table 11, for a given type of paddle, show the results obtained by taking one-half the sum of the means of the velocities measured at the eight index points in each of the two tests.

It was generally found that the agreement between mean velocities at a given index point in the two tests with a given meter and a given type of paddle was excellent. Therefore, only the average of the two tests is included in Table 11.

Comparing the velocities obtained, respectively, with horizontal and with vertical paddles, it will be seen that the differences are small but significant in the case of most of the meters, but that they greatly exceed the allowable limits for accurate measurement in some cases, particularly for the Hoff and small Ott meters. If the average of the six determinations of the mean velocity in the channel for the six different meters is taken, the result with horizontal paddles is 1.91 ft. per sec., while with vertical paddles it is 1.96 ft. per sec. In view of the close agreement of these figures and their small

departure from the true mean velocity of 2 ft. per sec., the writer believes that the differences in velocity shown by individual meters in this test with the two types of paddles are probably due mainly to fixed differences in distribution of velocity rather than to variations in the total amount or character of turbulence in the channel resulting from the types of paddles used.

There is evidence in Table 1 of a decidedly abnormal distribution of velocities in the channel. Furthermore, it appears probable that the turbulence produced by the paddles differed from that existing in a natural stream channel so materially as to make the applicability of these results in practice somewhat doubtful. This is unfortunate since these are the only experiments included in the paper in which turbulence occurs to any important extent in the water in which the meters were suspended.

Two conclusions, however, may be drawn from these experiments:

1.—In very turbulent water the small Price meter may over-register from 6 to 18%, while the Hoff and Ott meters may under-register by amounts varying with the type of meter from 2½ to 18 per cent. By methods somewhat similar to those used by the authors, Kirschmer and Esteren have confirmed[33] the over-registration of the Price meter and the under-registration of the Ott meter.

The Price meter over-registered more with horizontal than with vertical paddles, while the Hoff and Ott meters generally under-registered. This probably resulted from the difference of behavior of these meters in fixed cross-currents, as revealed by the third series of experiments.

2.—A second conclusion is that by the use of two or more meters so selected that over-registration of one kind is balanced by under-registration of the other kind, comparatively accurate results can be obtained with almost any degree of disturbance of the current by baffles or other obstructions. The use of two meters, one of which is known to over-register and the other to under-register, is a practice which has been followed by the writer and others in measurements of very turbulent flow in power plant tests and other similar situations. The authors' experiment so far as it goes, confirms the utility of this practice.

*Energy Consumed in Friction as a Measure of Turbulence.*—Correction factors to be applied to different types of current meters in use in turbulent water are greatly to be desired. In fact, the determination of such factors seems to be the proper primary object of experimental investigations such as those by the authors. It is to be regretted that they did not go much farther along this line. It might be inferred that since there is no quantitative method of measuring turbulence, such correction factors, even if available, would be of little practical utility. Although the point seems to have been overlooked heretofore, the writer believes that an index of the amount of turbulence in a stream can readily be obtained from the ordinary slope formula. Take, for example, the Manning formula,

$$v = \frac{1.486}{n} R^{\frac{2}{3}} \sqrt{s} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

[33] *Zeitschrift* des Vereines Deutscher Ingenieure, v. 74, pp. 1499–1504; also, *Engineering Abstracts*, Inst. C. E., Lond., No. 46, January, 1931, pp. 20–21.

in which, $v$ is the mean velocity of the stream, in feet per second; $n$ is Kutter's coefficient of roughness; $R$, the hydraulic radius; and $s$, the slope or fall, in feet per foot. By transposition this becomes,

$$s = \frac{v^2 n^2}{(1.486)^2 R^{\frac{4}{3}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

The slope, $s$, is the height through which each unit of volume or mass of the flowing water must fall per foot of linear travel in order to provide the energy necessary to overcome friction. If it is assumed that the energy consumed in overcoming friction represents turbulent or eddy energy which is converted into heat, then it is evident that Equation (13) is a direct measure of the rate at which eddy energy is being transformed. On the other hand, if the slope in the reach under consideration is uniform, then the rate at which energy is being dissipated or transformed into heat is necessarily identical with that at which eddy energy is being produced in the channel. In other words, it is a measure of the rate at which energy is being impounded, so to speak, in eddy formation around the channel perimeter.

Since the velocity under the conditions assumed is known, with a known rate of inflow, and the hydraulic radius is also known, it follows that a function—such as Equation (13)—which apparently is directly proportional to the amount of energy of turbulence in the stream, can always be derived for any cross-section if the coefficient of roughness, $n$, is known. This coefficient can easily be determined, of course, from slope measurements in connection with the known rate of discharge.

This method of procedure should show a definite relation between the function indicated by Equation (13) and the error of mean velocity determined by any given type of meter at a given velocity in the stream. It is possible that the character of turbulence may differ in two different streams even when the eddy energy per unit volume is the same. Whether the effect of the resultant turbulence on the operation of current meters would or would not be the same in the two cases is a question which cannot be answered definitely except as the result of experiments.

*Suggested Program of Experiments.*—The possibility of developing an index of turbulence, the value of which could readily be determined in connection with current-meter measurements and applied to their correction, deserves most careful consideration. Such a correction, if established on a sound basis, is as necessary and as well justified as, for example, the correction of astronomical observations for refraction. In spite of the extensive, although exceedingly unsatisfactory, literature regarding current-meter operation in turbulent water, the writer believes that much more could be accomplished along this line, by carrying out a campaign of experiments with the following technique and procedure.

With an experimental channel such as that used by the authors, for example, deliver an accurately known quantity of water into the channel in such a manner that it shall flow as smoothly and as nearly free from initial turbulence as possible. Next, induce artificial turbulence in the water by means of rotors similar, for example, to the propeller of an electric fan. These

rotors could easily be arranged on the bottom and sides of the channel at points up stream from the measuring section so as to produce cross-currents simulating those produced naturally by eddies thrown off from the channel perimeter in the manner already described.

The rotors should be propelled by electric motors or otherwise in such a manner that their speed can be controlled and determined so that the amount of energy put into the water in producing eddies or turbulence can be measured accurately. Measurements of the velocity would then be made at a sufficiently large number of index points in the cross-section to give an accurate determination of the apparent velocity with each type of meter, with different known velocities in the channel, and with different known amounts of energy being expended in producing turbulence.

If it develops that the departure of the measured mean velocity from the true mean velocity by any given type of meter bears a definite functional relation to the two controlled variables—the mean velocity, and the amount of energy expended in producing turbulence—a start will have been made toward a quantitative solution of the problem.

In that event it would seem worth while to conduct experiments under field conditions in natural river channels. In the case of the natural river channel the procedure would necessarily involve measuring the flow at a cross-section down stream, for example, from a dam or reservoir, where the quantity of inflow to the reach containing the measuring section could be accurately controlled and determined, and where the coefficient of roughness, $n$, for the adjacent reach of the river could also be determined.

Turbulence in air is measured quantitatively and its characteristics recorded graphically by means of a Dines pressure-tube anemometer. In experiments such as those suggested herein it would be a valuable adjunct to the results to have turbulence graphs taken by some type of Pitot-tube recorder. Possibly such an instrument might be attached directly to the current meter for experimental work. It is evident that either a means must be found for expressing turbulence quantitatively in terms of known variables and applying corrections to velocities measured by various types of current meters in turbulent water, or a considerable degree of uncertainty must be attached to measurements of stream velocity by current meters where the flow is markedly turbulent. The writer hopes that experiments along the lines indicated may be made forthwith.

*Varying Velocity Effect.*—The authors very properly subdivide the effect of turbulence on the operation of a current meter into two categories:

1.—The effect of varying velocities in the line of flow. This may briefly be called the "varying velocity effect". The expression, "line of flow", will here be used to indicate the direction of the current with no turbulence. It is also parallel with the direction of the axis of the meter as ordinarily used.

2.—The effect of currents approaching the meter at an angle to its axis, or at an angle to the normal line of flow, a condition which occurs in turbulent flow. This may be called broadly the "cross-current effect".

The second investigation by the authors consisted in determining the relation between the reading with the meter moved alternately backward and

forward in the channel, and the reading of the same instrument held stationary. In these experiments the meter was suspended at the center of the cross-section, and velocities of 1, 2, 3, and 5 ft. per sec. were created in the channel by the operation of the gates. No baffles were used.

Again, referring to Fig. 12, it appears that each meter was swung back and forth parallel with the line of flow, through a range of 2 ft., by a wheel and crank, using a connecting rod 2 ft. in length. The abscissas are in terms of the ratio of the velocity of the crank-pin of the rotating wheel to the stream velocity.

The maximum rate at which the meter travels in swinging back and forth was a little greater than, but may be assumed for purposes of discussion to have been practically indentical with, the velocity of the crank-pin. The velocity of the meter relative to the water varied approximately from $v - c$ to $v + c$ and *vice versa*, in which, $v$ is the stream velocity and $c$, the crank-pin velocity. The conditions, therefore, were closely similar to those which would exist in a stream containing eddies if the eddies passed the meter in succession in such a manner that the tangential component of the velocity of a filament of the eddy of a radius equal to the radius of the crank-pin was added to the stream velocity and if this was succeeded shortly by a second eddy, the opposite or retrograde-moving side of which passed through the center of the meter.

Following out the idea that the energy involved in turbulence is a controlling factor in the errors of registration of current meters in turbulent water, the following analysis has been made, assuming that the meter passes, successively, through the advancing and retrograding sides of eddies, $v$ being the stream velocity in the line of flow, and $c$, the maximum tangential eddy velocity encountered by the meter.

Let it be assumed that the conditions are such that the actual velocity encountered by the meter while passing through a reach of flowing water of length, $L$, increases uniformly from $v - c$ to $v + c$, the velocity at any moment being,

$$v' = (v - c) + \frac{2c}{L} l \qquad (14)$$

in which, $l$ is the distance the meter has traversed from the initial point. The kinetic energy per unit volume of water encountered by the meter at any point is,

$$E' = \frac{w\, v'^2}{2g} \qquad (15)$$

The mean kinetic energy per unit volume of water encountered in traversing the length, $L$, is,

$$E_{\text{ave.}} = \frac{w}{2gL} \int_{v-c}^{v+c} v'^2 \, dl \qquad (16)$$

but $dl = \frac{L}{2c} dv'$. Substituting and integrating, Equation (16) becomes:

$$E_{\text{ave.}} = \frac{w}{4gc} \times \frac{v'^3}{3} = \frac{w}{2g} \times \frac{1}{6c} [(v + c)^3 - (v - c)^3] \qquad (17)$$

Expanding and simplifying,

$$E_{\text{ave.}} = \frac{w}{2g}\left[v^2 + \frac{c^2}{3}\right] \quad \ldots\ldots(18)$$

Let $c = k\,v$; then,

$$E_{\text{ave.}} = \frac{w}{2g}\left(v^2 + \frac{k^2\,v^2}{3}\right) = \frac{w}{2g}\left(1 + \frac{k^2}{3}\right)v^2 \quad \ldots\ldots(19)$$

The average kinetic energy per unit volume at the constant velocity, $v$, is,

$$E_v = \frac{w\,v^2}{2g} \quad \ldots\ldots(20)$$

If, therefore, the velocity varies between the limits described in the distance, $L$, the meter will encounter excess kinetic energy in each cubic foot of water over that encountered with uniform velocity amounting to,

$$E_{\text{ave.}} - E_v = \frac{k^2}{3} \times \frac{w\,v^2}{2g} \quad \ldots\ldots(21)$$

It appears, therefore, that with a velocity varying uniformly there is available an amount of kinetic energy to re-act on the meter greater than with equal mean but uniform velocity. The effect of the varying velocity, therefore, should be proportional to $\frac{k^2}{3}$, and should be equal to $\frac{k^2}{3}$ times a factor, $f$, which may or may not be a simple proportionality factor. Fig. 12 shows the percentage of over-registration for two types of small Price meter with varying velocities and a mean velocity of 2.0 ft. per sec. In the experiments the velocity did not vary uniformly from $v - c$ to $v + c$. This point will be considered later.

In Table 12, Column (1) shows the value of the crank-pin velocity ratio, $\frac{c}{v}$; Column (2), the kinetic energy excess over that for a uniform velocity, or the value of $\frac{k^2}{3}$, expressed as a percentage. Column (3) shows, for the small Price meter, the percentage excess of meter reading over that for uniform velocity; Column (4) shows the computed excess, using a value of the factor, $f = 0.60$; and Columns (5) and (6) give similar data for the U. S. Geological Survey improved Price meter. Observed excess meter readings in Columns (3) and (5) are taken directly from Fig. 12. The values of $f$ are derived by taking the average ratio of these quantities to the energy excess given in Column (2).

Fig. 35 offers a comparison with Fig. 12 for the two small Price meters with symbols showing the computed over-registration of these meters as given in Table 12 for various values of $c$. The agreement of the computed with the observed values is practically perfect and is certainly within the limits of errors of observation except for the smaller values of $k$, for which, apparently, the friction or inertia of the meter rotor has a stabilizing effect and reduces the over-registration. Fig. 12 shows that, for the Mensing-Ott and the three-blade meters, the medium Ott meter, and the Hoff four-blade meter, the value of $f$ is zero. For the small Ott and the Hoff three-blade meters, the value of $f$ is about 0.033.

TABLE 12.—RELATION OF OBSERVED OVER-REGISTRATION OF PRICE METER IN A CURRENT OF VARYING VELOCITY, TO OVER-REGISTRATION COMPUTED FROM ENERGY EXCESS

| $k = \frac{c}{v}$ | Energy excess ratio, $\frac{E_{ave.} - E_v}{E_v} \times 100$ | Excess Meter Reading, Percentages | | | |
|---|---|---|---|---|---|
| | | Small Price | | U. S. Geological Survey Improved Price | |
| | | Observed | Computed, $f = 0.60$ | Observed | Computed, $f = 0.54$ |
| (1) | (2) | (3) | (4) | (5) | (6) |
| 0.5 | 8.3 | 1.5 | 4.8 | 1.0 | 4.0 |
| 1.0 | 33.3 | 16.0 | 20.0 | 14.0 | 18.0 |
| 1.5 | 75.0 | 45.0 | 45.0 | 42.0 | 40.5 |
| 2.0 | 133.0 | 80.0 | 80.0 | 76.0 | 72.0 |
| 2.5 | 208.3 | 125.0 | 125.0 | 116.0 | 112.0 |
| 3.0 | 300.0 | 175.0 | 180.0 | 160.0 | 162.0 |

An interesting fact brought out by the preceding analysis is that the over-registration of a cup meter in varying velocity can be determined analytically and expressed rationally in terms of the excess kinetic energy of varying flow.

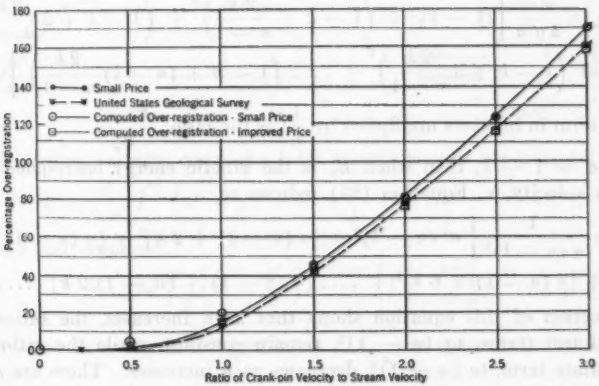

FIG. 35.—RELATION OF OBSERVED ERROR OF PRICE METERS IN VARYING FLOW TO ERROR COMPUTED FROM EXCESS KINETIC ENERGY.

The data indicate that $f$ is a constant for a given meter and also that it is an important characteristic of the type of meter. It is apparent that the value of this constant can readily be determined for a given type of meter by the use of apparatus similar to that described by the authors. Some such standard apparatus should be developed and determinations of the factor, $f$, should be made in conjunction with the rating of meters which are to be used in turbulent water.

The authors' experiments were confined to a single current velocity, $v = 2$ ft. per sec., with various crank-pin velocities. It now appears that the

results are applicable to any current velocity, providing the correction factor used is that applying to the proper value of $k = \frac{c}{v}$. In other words, the correction for over-registration of a Price meter, due to varying velocity, is the same for $v = 3$ and $c = 1.5$ as for $v = 2.0$ and $c = 1.0$, since $\frac{c}{v} = 0.50$ in both cases. Experimental verification of this point, however, is desirable. The preceding analysis is based on uniform velocity variation from $v - c$ to $v + c$.

Referring to Fig. 36, $a\,b$ is the velocity curve for uniformly varying velocity. It is evident that the velocity curve may follow an infinity of paths—one of which is shown by $m\,n$, Fig. 36—in changing from $v - c$ to $v + c$, for each of which the mean velocity will be $v$, the minimum, $v - c$, and the maximum, $v + c$.

If the velocity increases from $v - c$ to $v + c$ by $n$ equal steps,

$$E_{\text{ave.}} = \frac{w}{2\,g\,n}\left[(v-c)^2 + \left(v - c + \frac{2\,c}{n-1}\right)^2 + \left(v - c + 2\,\frac{2\,c}{n-1}\right)^2 + \left(v - c + 3\,\frac{2\,c}{n-1}\right)^2 + \ldots\ldots \left(v - c + (n-1)\,\frac{2\,c}{n-1}\right)^2\right] \ldots\ldots (22)$$

or, since $c = k\,v$,

$$E_{\text{ave.}} = \frac{w\,v^2}{2\,g\,n}\left[(1-k)^2 + \left(1 - k + \frac{2\,k}{n-1}\right)^2 + \left(1 - k + 2\,\frac{2\,k}{n-1}\right)^2 + \left(1 - k + 3\,\frac{2\,k}{n-1}\right)^2 + \ldots\ldots \left(1 - k + (n-1)\,\frac{2\,k}{n-1}\right)^2\right] \ldots\ldots (23)$$

The term in brackets multiplied by $\frac{1}{n}$, is the ratio, $\frac{E_{\text{ave.}}}{E_v}$.

Let $a = 1 - k$, then when $E_v$ is the kinetic energy corresponding to a uniform velocity, $v$, Equation (23) reduces to,

$$\frac{E_{\text{ave.}}}{E_v} = \frac{1}{n\,(n-1)^2}\Big\{a^2\,(n-1)^2 + [a\,(n-1) + 2\,k]^2 + [a\,(n-1) + 4\,k]^2 + [a\,(n-1) + 6\,k]^2 + \ldots\ldots [a\,(n-1) + (n-1)\,2\,k]^2 \ldots\ldots (24)$$

Inspection of this equation shows that as $n$ increases, the ratios of the first and last terms, to $(n-1)^2$, remain constant, while the ratio of any intermediate term, to $(n-1)^2$, decreases as $n$ increases. There are $n$ terms. Consequently, as $n$ approaches infinity the average value of the terms will decrease. The minimum value will be that corresponding to a uniform change of velocity, or the ratio of the excess kinetic energy to that for a constant velocity will approach asymptotically the value of this ratio for a uniformly changing velocity. The same result can be readily obtained in a particular case by numerical examples, using varying values of the number of steps, $n$, by which the velocity changes from $v - c$ to $v + c$. The general result may be stated in terms of the following theorem:

> In a mass of water having a mean velocity, $v$, and in which the velocities of different filaments vary between the values $v - c$ and $v + c$, the kinetic energy per unit volume is a minimum when the velocity changes uniformly from $v - c$ to $v + c$.

If the change of velocity is not uniform, the excess kinetic energy will be $> \frac{1}{3} \times \frac{c^2}{v^2} \times \frac{w\, v^2}{2\, g}$, and the over-registration of the meter will be greater than that for the same $v$ and $c$ with a uniform velocity gradient. In the authors' experiments the velocity variation followed approximately the law,

$$v' = v - c \cos \frac{l}{L} \pi \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (25)$$

Hence, the excess energy was greater than $\frac{1}{3} \times \frac{c^2}{v^2} \times \frac{w\, v^2}{2\, g}$.

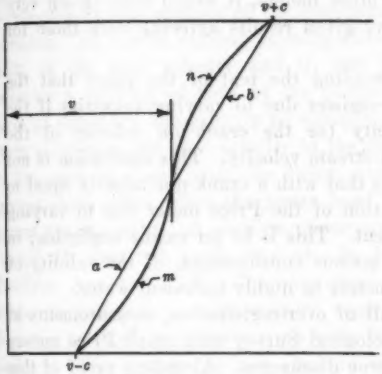

FIG. 36

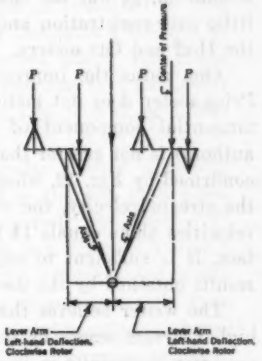

FIG. 37

For the cosine velocity curve the total kinetic energy per unit volume is,

$$E = \frac{w}{2\, g} \int_0^L \left( v^2 - 2\, c\, v \cos \pi \frac{l}{L} + c^2 \cos^2 \pi \frac{l}{L} \right) d\, l \ldots\ldots (26)$$

Integrating and reducing,

$$E_{\text{ave.}} = \frac{w}{2\, g} \left[ v^2 + \frac{c^2}{2} \right] = \frac{w}{2\, g} \left[ 1 + \frac{k^2}{2} \right] v^2 \ldots\ldots\ldots\ldots (27)$$

The excess kinetic energy in this case is $\frac{k^2}{2} \times \frac{w\, v^2}{2\, g}$, as compared with the value, $\frac{k^2}{3} \times \frac{w\, v^2}{2\, g}$, in case of uniform velocity variation.

Where the experiments are made with an apparatus that gives a cosine velocity variation as in the authors' experiments, the factor, $f$, should be computed on that basis. The values of $f$ for two Price meters on the two different bases are as follows:

| | Uniform change | Cosine law |
|---|---|---|
| Small Price | 0.60 | 0.40 |
| U. S. Geological Survey Improved Price | 0.54 | 0.36 |

It is perhaps immaterial what law of velocity change is used, provided a fixed standard is adopted for experimental purposes. Uniform change of velocity has

a quality of simplicity and definiteness and gives the minimum excess energy per unit volume.

Referring to Fig. 12, the measurements taken by the Haskell meters are not comparable with those taken with the other meters for which results are shown on this diagram. The reader needs to be cautioned not to fall into the error of assuming that the Haskell meter, if used in the same manner as the other meters, would over-register—as the diagram indicates—to substantially the same extent as the Price meter. The contrary is the fact as shown at the end of the section entitled "Effect of Fluctuations in Speed of Flowing Water". Had the Haskell meter been operated to register every fifth or tenth revolution, as was the case with the other meters, it would have shown very little over-registration and would have given results agreeing with those for the Hoff and Ott meters.

One gains the impression from reading the text of the paper that the Price meter does not materially over-register due to varying velocities if the tangential component of eddy velocity (or the crank-pin velocity of the authors) is not greater than the mean stream velocity. This conclusion is not confirmed by Fig. 12, where it appears that with a crank-pin velocity equal to the stream velocity, the over-registration of the Price meter due to varying velocities alone equals 14 to 16 per cent. This is by no means negligible; in fact, it is sufficient to require most serious consideration of the validity of results obtained by the use of Price meters in highly turbulent water.

The writer believes that as a result of over-registration, measurements at higher stream stages by the U. S. Geological Survey with small Price meters are often materially in excess of the true discharges. Abundant proof of this can be adduced, but need not be presented here. To some extent this effect of over-registration is partly offset by the fact that most of the stream measurements at higher stages are made when the river stage is falling or after the crest of a flood has passed; the slope and, consequently, the velocity of the stream are, therefore, somewhat less than the normal slope and velocity for the same stream stage.

In view of the preceding, the writer cannot agree with the authors' conclusions that the meters tested will not be influenced by varying velocity of flow if up-stream currents are not encountered. Certainly, an error of 14 to 16%, as shown on Fig. 12 for the Price meter, with no up-stream velocity, does not confirm this conclusion.

*Current-Angle Effect.*—Meters of the cup type measure the effect of the current in the direction of its actual flow, whether or not they are held parallel to the line of flow. When operating in a cross-current such a meter with its axis parallel to the line of flow will measure approximately the actual velocity of the cross-current. If it measures correctly the velocity of the cross-current in the direction in which that current is flowing, then the error of the measurement (as distinguished from the error of the meter), will be the difference between the measured velocity and the product of the measured velocity by the cosine of the angle of the cross-current to the line of flow.

If, under these conditions, the meter does not correctly measure the actual velocity of the cross-current in its direction of flow, then the inherent error of

the meter will be the difference between the actual velocity of the cross-current and the indicated velocity. If, as in the third series of experiments, the angle of the cross-current is known, its cosine value can be determined and the inherent error of the instrument can be found, as was done by the authors by comparing the velocity indicated by the meter with the true cosine value of the cross-current velocity. Meters of the cup type fail to some extent, and meters of the screw type to a greater extent, to measure the true velocity of the cross-current.

In practice, both varying velocity and cross-current effects are nearly always present together and the percentage error of the measured velocity is reflected by the product of the two percentage ratios of indicated to true velocities. If, due to varying velocity alone, the meter indicates a velocity of 115% of the true velocity and if, due to cross-current effect, the meter indicates a velocity of 95% of the cosine velocity, then for this particular angle of deflection the velocity as actually measured is $1.15 \times 0.95$, or 1.0925 times as great as the true velocity in the line of flow.

The authors found that the Price meter in particular showed a greater current-angle effect when the meter head was turned to the left than when turned to the right. A similar phenomenon was observed[34] by Charles P. Rumpf, M. Am. Soc. C. E., and also by E. H. Brown and Forrest Nagler,[35] Members, Am. Soc. C. E. These observations apparently establish the reality of the phenomenon. In the writer's experience, Price meters generally have clockwise rotation, but they are made for both clockwise and counter-clockwise rotation. The authors do not state in which direction the rotor revolved. Neither do they state the point at which, or the manner in which, the angle of deflection was measured. Presumably, it was measured by setting the meter at a certain angle before immersion.

Two possible causes of asymmetrical current-angle effects with Price meters are: (1) Deflection of the meter to a different angle than the measured angle, due to differential torsion of the suspension rod; and (2) a similar effect due to unbalanced dynamic pressure on the revolving rotor, something like that resulting from twirling a baseball in throwing a curve.

The first effect might result from the excess pressure on the cups over that on the cones or backs of the cups, as shown on Fig. 37, with the result that the lever arm of the torque on the suspension rod is greater when the meter is deflected in one direction than when deflected in the opposite direction, depending on whether the rotor has clockwise or counter-clockwise rotation. From the viewpoint of a scale model, the speed of a meter rotor and the velocity of a current in a fluid of the density of water, may be of the same order as the speed of rotation and velocity of a baseball in air.

Assuming that the meter is sufficiently rigid against torsion, the combined effect of these causes, if any, on the meter rotor, could readily be determined by experiments with a clockwise rotor with equal right and left-hand deflections of the meter, followed by identical experiments with a counter-clockwise rotor.

[34] *Engineering News*, Vol. 17, 1914, pp. 1083–1084.
[35] *Proceedings*, Eng. Soc. of Western Pennsylvania, Vol. 30, 1914–15.

In this connection, it seems worth while to suggest that something might be added to the knowledge gained through experiments, such as those of the authors, on current-meter operation by studying the form and behavior of the water filaments passing the meter rotor.

This result could easily be accomplished with slight depths of submergence by suspending crystals of some soluble coloring matter, such as potassium permanganate, at intervals across the stream just up stream from the meter. This would provide colored streaks in the fluid acting on the meter without in any way interfering with the meter operation.

RICHARD VAN VLIET,[36] JUN. AM. SOC. C. E. (by letter).—During the thirty years, 1900 to 1930, numerous experiments have been performed by various parties in an endeavor to ascertain the errors resulting from the use of a current meter when subjected to various conditions of flow. A review of the results obtained indicates that the several parties practically agree on the errors caused by a meter when subjected to the various manipulated flows. The results obtained by experiments, such as those performed by Messrs. Yarnell and Nagler, are not very helpful to one who desires to correct actual field measurements made in perturbed waters.

A study of the results of these several experiments leads one to believe that measurements of perturbed water, made by a current meter, are subject to considerable error. The writer believes that the error in measurement due to turbulent water has caused more consternation among the members of the Engineering Profession than is warranted. The best proof of this is the result obtained where simultaneous readings measured by a current meter are compared with those measured by a carefully calibrated weir, or sluice, or by volumetric means, etc. Volumetric measurements are extremely valuable and are far more applicable for correcting actual stream measurements of perturbed waters than experiments performed in laboratories with manipulated flows.

In contrast to the voluminous data obtained as the result of laboratory experiments with manipulated flows, there is a dearth of information available as to the relation that exists between discharges measured in the field by current meters and those measured by carefully calibrated weirs, sluices, etc. Probably the best series of experiments representing the comparison between the discharge measured by a current meter and that obtained from calibrated sluices, were those performed at the Assuan Dam on the Nile by Sir Murdoch MacDonald and H. E. Hurst.[37] The sluices at the Assuan Dam had previously been calibrated carefully by volumetric means so that the discharge through them could be computed with negligible error.

Forty experiments were performed, using either a small or a "medium" sized Price meter. On inquiry, the type of instrument referred to as the "medium" sized meter was found to be that corresponding to the commonly known large sized Price meter with a 6-in. bucket wheel. Of these forty experiments, twenty-five were made with the small Price meter. Numerous

[36] Asst. Engr., with Robert E. Horton, Cons. Hydr. Engr., Voorheesville, N. Y.

[37] "Measurement of the Discharge of the Nile Through the Sluices of Assuan Dam," *Minutes of Proceedings*, Inst. C. E., Vol. CCXII, 1920–21, Pt. II, pp. 228–301.

velocity determinations were made for each vertical. As the sluices were carefully calibrated, a comparison between the discharges measured by the current meters and those given by the sluices will be a fairly good indication of the error encountered in measuring a stream by a Price meter. Table 13 is a summary of the results obtained by the small Price meter.

TABLE 13.—COMPARISON OF DISCHARGES AS MEASURED BY CURRENT METER AND BY SLUICE

| Limit of discharge, in cubic meters per second | Number of tests | Average percentage of error* |
|---|---|---|
| Less than 700 | 2 | + 0.4 |
| 700 to 800 | 8 | + 3.5 |
| 800 to 1 000 | 4 | + 0.5 |
| 1 000 to 1 200 | 5 | − 0.1 |
| 1 200 to 1 438 | 6 | + 1.7 |
| Total | 25 | ..... |

* Minus, when meter discharge is greater than sluice discharge.

The maximum under-registration for any individual test was 7.0%, with a discharge of 703 cu. m. per sec., whereas the maximum over-registration was 5.6%, with a discharge of 1 174 cu. m. per sec. The measurements made by current meter were performed in the natural stream channel in the vicinity immediately below the dam.

As in all work of this type some results are obtained, which deviate far from the average. It is only by performing a sufficient number of such experiments that an estimate of the average error can be reached. The question of correcting current-meter measurements of turbulent water does not permit the use of results obtained by small-scale models or manipulated canal currents. Data of the type similar to those obtained in connection with the experiments at the Assuan Dam are meager, and the writer feels that it is only by similar experiments that the mooted question of correcting current-meter measurements can be settled.

It is unfortunate that the authors have included only papers of investigations conducted in America in their bibliography (see Appendix). A paper by Mr. M. A. Hogan gives the results of numerous experiments performed in Great Britain.[38] In general, the various results agree with those obtained by Messrs. Yarnell and Nagler. The general conclusions reached as a result of Mr. Hogan's studies and experiments were, as follows:

1.—The error in registration was dependent on the position of the meter with reference to the sides of the channel.

2.—The error in registration caused by the obliquity was greater in a small channel than in a large channel.

3.—The results showed a smaller error in registration for a shielded meter, such as the Stoppani, than for an Ott or an Amsler meter.

4.—Where considerable turbulence exists, a meter of the Price type will give results in excess of the true value. On the other hand, a meter of the screw type will give results which are deficient as compared with the true value.

[38] "River Gauging," by M. A. Hogan, Dept. of Scientific and Industrial Research, Lond., H. M. Stationery Office, 1925.

The experiments relating to oblique flows were performed on Amsler, Ott, and Stoppani meters only, because the writer thought that the experiments performed by Brown and Nagler[39] on the Price meter were sufficient to establish the peculiarities relating to this type and did not warrant any duplication.

DAVID L. YARNELL AND FLOYD A. NAGLER, MEMBERS, AM. SOC. C. E. (by letter).—The many valuable suggestions for additional experimental work on current meters presented in the discussions reveal the unsettled status of the current meter, in the minds of many engineers, for water measurement under certain conditions. Although unable to proceed with this additional experimentation at this time, it is hoped that the work may be undertaken and reported upon in the near future. The specific suggestions which seem to warrant further investigation are:

(*a*) Comparative tests of flow measurements by the various meters with cable suspension in turbulent water.
(*b*) Further investigation of the cause for the difference in registration of the various meters in oblique flow approaching the meter from the right or left.
(*c*) Experiments on propeller shapes to develop a meter with the true cosine characteristic of rotation through a wide angle.
(*d*) Experiments with meters to determine the correction for turbulence along the line suggested by Mr. Leach.
(*e*) Experiments on meter registration with varying turbulence, following the suggestion of Mr. Horton concerning the rotating paddle; and,
(*f*) Comparative tests of the behavior of various meters near the water surface and sides and bottom of the channel.

It is with gratification that the writers have noted the comparisons by Messrs. Leach and Forrest Nagler, showing that their data checked exceptionally well with the results of similar tests performed by other experimenters.

The conditions of turbulence produced by means of paddles in the initial series of tests were probably more excessive than would ever be encountered in practice, as was surmised by Messrs. Nettleton, Leach, and Horton. Extreme conditions of turbulence were produced for the very purpose of exaggerating the discrepancies in registration of the various meters. It is a fact that the meters encountered sharp changes in speed and direction of flow. Eight points of measurement in a section under such violent disturbance were scarcely sufficient to establish a valid comparison between the average velocity recorded by the meters in comparison with the weir. However, in spite of this fact, it may be observed that with only one exception the meters listed in Table 2 arranged themselves in the same general order of accuracy in over-registration or under-registration as that indicated by the curves in Fig. 17, when the integration of the average deviation is computed in the manner suggested by Mr. Forrest Nagler.

In connection with these same tests, the impression that reliable rating curves were not available should be corrected. Recent curves were at hand

[39] *Proceedings*, Eng. Soc. of Western Pennsylvania, Vol. 30, 1914–15, pp. 280–323.

for every meter tested, and values from these curves were used in the compilation of Table 2, which, therefore, should be quite accurate. The unusual turbulence is responsible for the variations in the listed values in Tables 1 and 2, since the ordinary period of observation (40 to 90 sec.) was insufficient to secure a true integration of the flow at each point (as suggested by Mr. Bennett and mentioned by the writers under "Constancy of Experimental Conditions"). Furthermore, the various meters had rotating elements of different diameters, and, in turbulent water, the large propeller might be actuated by a water filament of large diameter which had an average speed entirely different from the velocity of the smaller filament that strikes the meter with the small propeller, although the center of both propellers may have been at exactly the same point in the stream.

In performing their elementary experiments on meters with rod suspension, the writers purposely eliminated the possible variations that might have resulted when the meter was allowed the freedom of cable suspension. The performance of a meter with cable suspension would vary somewhat with different tail-pieces, and varying lengths of cable. With cable suspension, it is believed that the various meters would arrange themselves in practically the same order with regard to over- or under-registration, and as concluded by Mr. Leach:

"The screw meter will not under-register as much with cable suspension as when rigidly suspended, owing to the tendency of all meters, including the screw types, to point into the current and so register the absolute velocity."

Some experimenters have found that the Price meter rotates only slightly slower with cable suspension than when rigidly held on a rod; hence, experiments with cable suspension would probably favor the screw meter more than the writers' experiments with rigid rod suspension have indicated.

Mr. Horton suggests some causes for the difference in registration of the Price meter when the current strikes at equal angles from the right or left, mentioning the fact that the experiments of C. P. Rumpf, M. Am. Soc. C. E., and of Mr. Forrest Nagler, as well as those of the writers, establish the reliability of these phenomena. The curves for the Pegram screw type of meter described by Major Somervell also showed this same characteristic, which was likewise observed by the writers on other meters with propellers of the screw type. The phenomenon seems to result from some unsymmetrical interference of the current leaving the rotating propeller with the frame of the meter. For some meters the magnitude of the deviation was different at different velocities. Local disturbance, as suggested by Mr. Leach, may possibly have been responsible for some of the deviation, although tests performed with current flowing in the main canal (which was 10 ft. wide) also showed similar differences between the registration of currents from the right and left direction. However, many tests in which screw meters have been towed in still water, have shown no great deviation.

TABLE 14.—PHYSICAL CHARACTERISTICS OF CURRENT METERS USED IN TESTS

| Name of meter | Meter number | Fig. | Type of Propeller | | | Number of revolutions per contact | Linear* distance for one revolution of propeller, in feet | Outside diameter of propeller, in inches | Distance, center of support to center of wheel, in inches | Direction of rotation of wheel‡ |

‡ Looking downward or down stream at meter

In response to requests for additional information with regard to the meters used by the writers, Table 14 is presented giving physical characteristics of the various meters.

Numerous tests in which measurements by current meters have been checked by flow determinations by other methods, have been made during the ten years, 1920 to 1930, in the hydraulic canal at the Laboratory of the State University of Iowa. When the conditions have been favorable and care has been taken to traverse the measuring section adequately, the measurement of flow with current meters has always proved exceedingly reliable. In connection with experiments on the flow through box culverts in 1922 to 1924, one hundred and ten discharge measurements were made by Mr. Yarnell of flows between 5 and 165 cu. ft. per sec., by means of a Pitot tube, the small Ott current meter, and a sharp-crested rectangular weir.

More than one-half the comparisons showed less than 2% variation between the measurements by the weir and those by the current meter, and most of the measurements that showed a greater departure were performed under conditions not entirely ideal for the best current-meter measurement. However, in presenting the paper, the writers decided that it was advisable to compare the various meters purely on the basis of their registration of current velocity, rather than to compare the measured quantities of flow. In the latter case the location and number of metering points, the method of computing the mean velocity, and the measurement and method of computation of area of cross-section, often introduce other possible errors of no small magnitude.

The writers were greatly interested in Mr. Groat's discussion of rules for obtaining the average velocity in a vertical plane from velocity readings at definite points. The analysis and results are similar to those suggested by Patnutij Tchebycheff. The work of Tchebycheff was brought to the writers' attention in 1925 by A. Streiff, M. Am. Soc. C. E., in an unpublished paper entitled "The Use of Tchebycheff's Formula in Current Meter Measurements." The formula has been derived by the Naval Architect, J. H. DeHeer.[40] A comparison of the ordinates derived by Mr. Groat (see Table 9) with those obtained by Tchebycheff is given in Table 15. The results for two, three, and five ordinates are identical. The writers have tested the Tchebycheff rule on a number of mathematical curves and generally have found sufficiently close agreement to the true average for accurate practical work.

To average the measurements made by two different types of meters (the Ott and the Price, for example) appears now (1931) to be the "only rational method" of obtaining a reliable measurement of the discharge of turbulent water. This suggestion made by Mr. Leach follows the proposal[41] made by Mr. Groat, and has been specified in the A. S. M. E. Power Test Code, for measuring water by current meters in the testing of hydro-electric plants. The curves presented by the writers are useful in the determination of the comparative over- or under-registration of the meters being used. In extremely turbulent water, the use of a single meter does not appear feasible until some method is devised for determining an index of the relative degree of turbulence.

# WATERWAY TRANSPORTATION FROM THE VIEWPOINT OF OPERATION

By T. Q. Ashburn,[2] Maj. Gen., U. S. A.

## Synopsis

This paper gives a discussion and comparison of private, contract, and common carriage, as well as common carriage under joint rail and water rates, on three types of inland waterways: Lake type (Great Lakes and connecting channels), per ton-mile cost, 0.64 mill; lock-canal type, closed by ice part of year (New York Barge Canal), per ton-mile cost, 3 mills; and river type, adequate channel open the year round (Mississippi River, St. Louis, Mo., and South), per ton-mile cost, 1.07 mills.

The expense and difficulty incident to the development of, and also the benefits to the general public from, these types of water carriers increase in the order in which they are mentioned.

The development of private and contract carriage on the waterways creates monopolies which destroy healthy competition. To prevent this, common carriage should be developed, and the benefits of this type should be extended to communities off the waterways through the establishment of joint routes and rates in which both water and land carriers participate.

The Inland Waterways Corporation is an agency set up by Congress to develop joint land and water common carriage. Analysis of the Barge Line dollar shows a deficit of 3 mills in 1927 and a net income of nearly 6 cents in the succeeding year. The Corporation has demonstrated that it can operate on freight rates which give a substantial saving under all rail rates and, at the same time, by fair divisions of the revenue afford each participating carrier a living, thus proving that the Nation's policy to render its streams navigable in order to reduce transportation costs is not a mistake.

From Noah's time to this—a lapse of thousands of years—every man who throws himself whole-heartedly into the struggle for inland and coastwise waterways transportation meets the same objections and criticisms that old Noah met; but they have continued determinedly, and time and experience are dumfounding their critics, even as Noah did when his ark, with its precious burden of freight, rose upon the crest of the waters and saved the faithful few of those days, who believed in water transportation.

## Expansion of Civilization and Transportation

The expansion of civilization is coincident with the expansion of transportation. Wherever civilization may have first appeared, it spread solely through

[2] Chairman and Executive, Inland Waterways Corporation, Washington, D. C.

contact with the outside world; and only as fast as such contact could be made. First, such contact was made by means of the legs of the human being; then through the animals he trained to support him; then through the slow-running vehicle, developing into the railroad trains, the automobiles, and the airplanes of to-day. The log that drifted down stream, the sluggish flat-bottom raft propelled by poles, developed into the ocean racers and the marvelous towboats of to-day.

In its ultimate analysis, all communication between individuals, between communities, between States and nations, is some form of transportation. Speech is the transportation of sound through the air; the telephone, the telegraph, the wireless, the heliograph, all depend upon the transportation of sound or signals; and as civilization expanded, its onward course was marked and limited by the development of transportation.

With the growth of civilization began the growth of trade and commerce. As these took the form of water carriage and venturesome voyages, the necessity for agreements between neighboring sea cities became apparent—harbors and lighthouses had to be constructed for the safety of trade, and thus began that slow growth of mutual agreement or mutual accommodation, which is the basis of whatever international law exists.

### Necessity Develops Transportation

Transportation brings from one end of the world to the other the products of Nature and of Man, and as the necessity of these products grows, be they raw or manufactured, so must transportation facilities advance.

Civilization brings in its train the demand for necessities, comforts, and luxuries, in the order named. Nature has ordained that the raw material needed in the manufacture and production of necessities, comforts, and luxuries should grow in widely separated portions of the globe. Certain kinds of grain, rice, and sugar cane, grow only in certain localities; various kinds of ores are produced at one place and turned into steel and iron at another place. The silks of China and Japan are as actual necessities to American women as are the farming implements of America, the products of great steel industries, the locomotives, in fact, all American exports, to South America, Europe, Asia, Africa, and Australia.

The laws of economical production demand that great manufacturing centers shall be located where cheap raw material can be obtained, and where the cost of distribution of the manufactured article is cheapest, provided there is no great difference in labor costs. A combination of these two elements, where the raw material is an import, naturally suggests a seaport. If the distribution can also be made from that seaport, so much the better. The sea is a universal highway—the cheapest means of transportation known. The reason for this is self-evident.

Consequently, every inland city, located upon a navigable waterway, dreams of the time when it shall be an inland seaport. If navigable highways are developed as they should be, it will only be a matter of a few years until such cities as the "Twin Cities" of St. Paul and Minneapolis, Minn., Cincinnati, Ohio, Pittsburgh, Pa., St. Louis and Kansas City, Mo., Omaha, Nebr., Mont-

gomery, Ala., Albany, N. Y., Cairo, Ill., Memphis, Tenn., Birmingham, Ala., Vicksburg, Miss., and many others will be actually, if not geographically, seaports. In a somewhat limited sense the Great Lakes cities are already seaports.

## Three Distinct Problems

The navigable inland waterways of the United States, from an operating standpoint, naturally fall into three distinct classes, the Great Lakes, improved rivers, and canals. An examination of the required investment in floating equipment, physical conditions of operating channel, terminals, and overhead, necessary for successful operation upon these various water highways, is profitable regardless of the cost of creating these channels.

Since no charges are made for the utilization of any of these waterway avenues, the practical operator is not concerned with their cost of construction, nor is he inclined to view with alarm any enormous expenditures made, so long as they have been made, and so long as all the avenues are open to him without cost.

He accepts the situation as it is, and leaves to economists, statisticians, and college professors the academic question of whether Congress was right or wrong in spending money for such purposes. He says, in effect,

"The Government may have been right or wrong in spending money to create these channels, but so long as the money has been spent, it has been spent, and academic discussion does not concern me; what does concern me is whether I can profitably operate upon the channels which have been created by the Government by the expenditure of such funds."

## Physical Conditions

The amount of money to be expended for the creation of a successful single unit for operation depends largely on physical conditions of operations. The Great Lakes are open for navigation approximately eight months of every year. The New York Barge Canal rarely has more than seven full months of navigation, but for comparative purposes it will be credited with eight. The Upper Mississippi, extending from the "Twin Cities" to St. Louis; the Missouri, from Kansas City to St. Louis; and the Chicago-Illinois River route are ice-bound approximately 3½ months per year. On the other hand, the Lower Mississippi is open the year round for navigation, as is the Warrior River. Ice obstructions on the Ohio are negligible during the entire year.

It is evident, therefore, that successful operation upon the Great Lakes, the New York Barge Canal, the Upper Mississippi, the Illinois-Chicago River route, and the Missouri, requires the accumulation of enough profits in eight months to make a reasonable return upon the investment for a whole year, or that some other use of the equipment must be found during the closed season.

The closing of the Port of St. Louis has no appreciable effect on the revenues of the Federal Barge Line, as joint rates remain effective from St. Louis *via* Cairo (the northern port when St. Louis is closed); and the shipper is not even cognizant that the river may be ice-bound from St. Louis to Cairo.

### Limits of Discussion

In discussing the Great Lakes it is necessary to consider the canals and rivers connecting them as an integral part of one system. These rivers and canals being necessary for inter-lake communications, and connecting a series of navigable lakes extending approximately 1 000 miles east and west, can not be considered therefore in the same category as the New York Barge Canal, which, in turn, is different from the Dismal Swamp Canal.

Exception might be taken to thus including the Welland Canal in treating connecting lake canals as integral parts of the Great Lakes System, because it is Canadian owned; but that does not affect operating conditions, except for tolls, and the United States could easily connect Lakes Erie and Ontario as cheaply as Canada did. Without entering into any argument relative to the merits of the all-American route *via* the New York Barge Canal to the sea *versus* the Canadian route, it is feasible to discuss actual existing physical conditions, and demonstrate therefrom how utterly different are the various costs of lake, river, and canal transportation.

In discussing canals, the New York Barge Canal will be taken as typical, because it is the longest and best equipped canal in the United States, and of the greatest potential National importance. The operating costs there will be higher, of course, than on a canal free from locks.

Discussion of rivers will be confined to the Lower Mississippi, which is open for twelve months each year, and is, so far as operations are concerned, the most available in the United States.

One point needs emphasis—this discussion being solely to determine comparative costs deals only with the best existent type of channel in each case. Further, it is assumed that certain conditions, which do not now exist, will eventually exist, in order to arrive at what will be the eventual cost per ton-mile when the situation is practically perfected.

### Type of Equipment Discussed

The many lake lines have various equipment, depending upon the service in which they are engaged. At least one line has self-propelled barges capable of navigating both the Great Lakes and the New York Barge Canal. Generally speaking, self-propelled barges for bulk cargoes on rivers and canals are uneconomical units. The New York Barge Canal and the Mississippi-Warrior Service also have different types of equipment, hence, to obtain comparative costs, an operating season for the most practicable single unit for each of these transportation lanes, will be studied. Such a comparison will assume the most favorable conditions possible for the three separate water avenues.

On the Great Lakes, take a 16 000-ton steamer having an average speed of 10 miles per hour, plying between Cleveland, Ohio, and Duluth, Minn., and capable of carrying coal from Cleveland to Duluth and iron ore in the reverse direction. Its cost would be approximately $1 500 000. Return on this cost at 6% plus 3% depreciation will be $135 000 per annum; this is the amount that must be earned in 8 months to yield a reasonable return.

On the New York Barge Canal, assume a unit consisting of a self-propelled barge, capable of carrying 300 tons of cargo, and pushing seven barges of

500 tons capacity each at an average of 5 miles per hour. This rate is used because a greater speed causes a very expensive wave wash, entering into cost of canal maintenance. Such a unit as used by the most efficient organization now operating on the canal, could be built for about $400 000. Return and depreciation, as before, would here equal $36 000 per annum to be earned in 8 months to offer a reasonable return.

On the Lower Mississippi, assume a towboat and 8 barges capable of carrying 16 000 tons down stream, costing $650 000. The average speeds will be down stream 6 miles per hour and up stream 3 miles. The return of $58 500 per annum (9%) may require 12 months and still offer reasonable earnings.

Types of equipment actually used on the Mississippi River are shown in Figs. 1 and 2, including the method of towboat and barges taken as a basis for comparison.

### Effect of Seasonal and Channel Differences

A lake steamer can carry the same tonnage in either direction, at about the same speed, without difficulty. The Barge Canal unit can never carry up stream the same tonnage as down stream, because there is always some current in the Mohawk, and sometimes it appreciably affects the carrying capacity. Normally, it should carry three-quarters as much.

The Lower Mississippi always has some current. A towboat which will successfully push 16 000 tons down stream at a certain speed can rarely make the same speed up stream with only one-half that total. Even then the cost of fuel up stream for the half cargo is approximately double that for the maximum, down stream.

Neither the Great Lakes System nor the Barge Canal will be subject to low water, but, at times, the canal will have to contend with very high water and strong current, while the Mississippi will be subject to such changes of high and low water that the carrying capacity of the fleet will be a variable. All these factors, it will be observed, will have an appreciable effect on the carrying cost per ton-mile of each unit.

The direct route varies in each instance. From Cleveland to Duluth by lake, it is 810 miles; from Buffalo to Troy, N. Y. by canal, it is 341 miles and has 36 locks; from St. Louis to New Orleans by river it is 1 154 miles.

In order to strike a fair comparison the further assumption is made that the lake, canal, and river cargoes are delivered to the various units at one port of call. By thus reducing these operations to the simplest possible terms a definite cost basis results, which is fair to all concerned; but even with this condition, due to the necessity of shifting barges for loading and unloading, the lake ship will save at least a day loading and a day delivering the same cargo.

### Comparative Round Trip Costs

It will be instructive to follow the lake steamer. Exclusive of interest and depreciation, it costs about $325 per day to operate. Allow it 2 days at Cleveland for loading, 2 days at Duluth to unload, 2 to reload, and 7 days en route, or 13 days for the round trip. That would permit 19 round trips during the season of 8 months.

The actual running expenses for this would be $245 \times \$325 = \$79\,625$. With the necessary interest and depreciation, this would give a total of $214 625

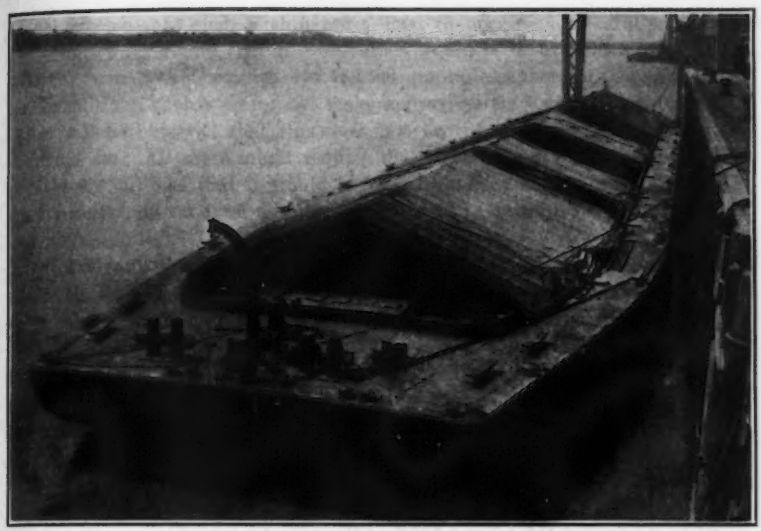

FIG. 1.—STEEL BARGE WITH 70 000 BUSHELS OF GRAIN, INLAND WATERWAYS CORPORATION.

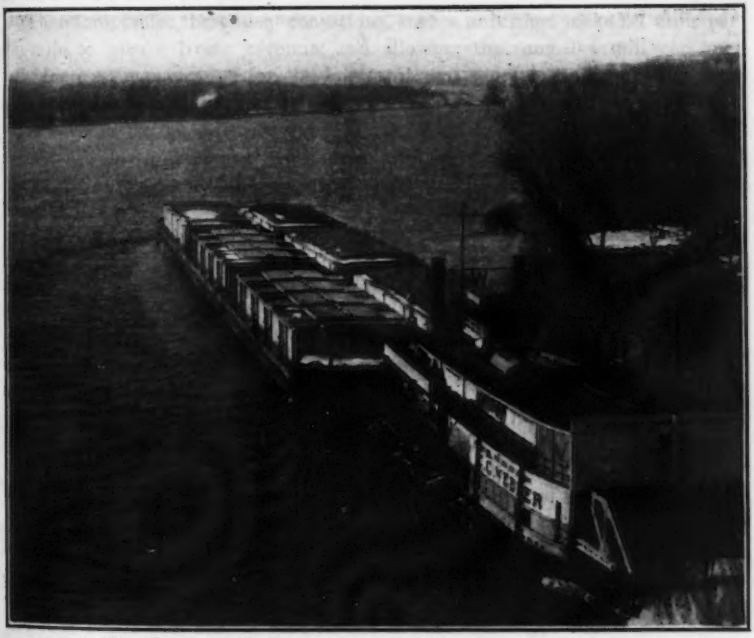

FIG. 2.—STERN-WHEEL STEAMER AND TOW, MISSISSIPPI RIVER.

annual income that such a ship must earn to operate successfully. Since 16 000 tons for a round trip of 1 620 miles would be 25 920 000 ton-miles, 19 trips per year would require 492 480 000 ton-miles; therefore, under these ideal conditions, such a ship must make approximately 0.44 mill per ton-mile, but it will be observed that this does not provide for overhead, insurance, accidents, etc. All these might require the addition of 0.4 mill per ton-mile, possibly 0.2 mill; so that it would be practicable for such a unit to operate quite successfully on 0.84 mill per ton-mile and, theoretically, even at 0.64 mill per ton-mile.

Similarly, on the New York Barge Canal, a unit would need 3 to 4 days at Buffalo to load, 6 to 7 days to unload and load at New York, 4 to 5 days down stream, and 5 to 6 days up stream, or an average round trip of 20 days. Lockage difficulties and delays account for these variables, allowing a total of 12 round trips per unit per season. Operating expenses of such a fleet aggregate roundly $192 per day. The actual expenses for this time would be $(245 \times \$192) + \$36\,000 = \$83\,040$, which is the actual return necessary to operate successfully.

Assume the load to be the same each way, although that up stream will normally average only three-quarters of that down stream, and the speed up stream will vary. The total traffic will be 3 800 tons $\times$ 341 miles $\times$ 2 $\times$ 12 = 31 099 200 ton-miles per year.

Therefore, under these ideal conditions, such a unit must make 2.7 mills per ton-mile to earn a living revenue, and allowing the same 0.4 mill per ton-mile for contingencies, as for the lake unit, the canal unit can operate successfully on 3.1 mills per ton-mile. Actually, its contingent expenses ought to be covered by 0.3 mill per ton-mile, so, theoretically, it ought to operate successfully for 3 mills per ton-mile.

On the Lower Mississippi, with the same time allowance as for the lake unit, namely, 6 days for loading, unloading, and reloading, with a round trip, St. Louis to New Orleans, of 2 308 miles, and with an average speed of 4 miles per hour, the actual running time would be 24 days. This would give 30 days per trip and 12 trips per annum. It must be assumed under general conditions, that the maximum down-stream tonnage will be 16 000, while the up-stream maximum will be 8 000, giving an average of 12 000 tons. River conditions, however, as shown by Government records, would reduce the yearly average to 6 000 tons per trip. Both high and low water appreciably affect the tonnage and speed.

The actual expenses of this operating fleet would be $430 per day, and the total for the year would be $\$430 \times 365 = \$156\,950$. To this must be added the carrying cost of $58 500 per annum, making a total of $215 450 necessary to yield a reasonable return. Then, 6 000 tons $\times$ 1 154 miles $\times$ 2 trips each way $\times$ 12 round trips = 166 176 000 ton-miles; and $\$215\,450 \div 166\,176\,000 =$ 1.3 mills per ton-mile. Add to this the same 0.4 mill per ton-mile to cover expenses not otherwise provided for (this is the actual cost on the Mississippi), and it is found that such a unit on the Lower Mississippi could operate successfully for 1.7 mills per ton-mile. At its maximum carrying capacity this

0.4 mill per ton-mile could easily be reduced to 0.2 mill, and successful operation be carried on at 1.5 mills per ton-mile. The direct operating cost would also be reduced.

Summing up, a theoretically successful operation by lake could be carried on with an operating income of 0.64 mill per ton-mile; on the Lower Mississippi, with one of 1.7 mills per ton-mile; and on the New York Barge Canal, with one of 3 mills per ton-mile.

While the difference in cost under these assumed ideal conditions on the Great Lakes and the Lower Mississippi is 1.06 mills per ton-mile, yet when this is applied to the 166 176 000 ton-miles on the Lower Mississippi, it adds a total of $176 146.56 per annum to the gross income necessary to operate at a fair profit.

Such an itemized estimate of the theoretical incomes necessary to operate successfully upon the three types of lake, canal, and river channels under ideal conditions, is necessary because in most public discussions ardent waterway advocates point to lake costs as the ultimate cost by river, and the opponents of waterways point to the Erie Canal as the great failure whereby river transportation should be judged. As has been shown, neither of these is a correct assumption; nor is it correct to group the three together as a whole. So much for the ideal situation. The next question concerns the actual conditions under which rivers and canals may be utilized.

### Private, Contract, and Common Carriers

Lakes, canals, and navigable rivers can be utilized by private, contract, or common carriers. The cost of operation of these three carriers, and their value to the public, increase in the order named.

The utilization of navigable streams by private and contract carriers alone does not justify the expenditures of the money of all the people for their creation. Indeed, if such utilization were the sole purpose of public construction, a large part of the people would be unjustly taxed for the benefit of a few who would reap the advantages.

Any thinking man must realize that the utilization of streams by private and contract carriers alone may lead to serious consequences, so that to extend fully the benefits to all the people who have been taxed to create them, to offset the serious menace to National prosperity that such utilization alone may lead, these private and contract carriers must be supplemented by powerful and efficient common carriers. This is not to be assumed as decrying the fullest possible utilization of streams by private and common carriers; rather it will be pointed out how the menace of such utilization can be absolutely neutralized by powerful and efficient common carriers, and how such joint utilization will result in the greatest good for the greatest number.

The private carrier requires the least organization and operates purely by water. It can balance its freight savings against the cost of operation and if the freight savings are the larger of the two, it can be said to be a successful carrier.

The contract carrier may operate purely by water or by water and rail. It has comparatively small overhead. As a water operator, pure and simple, it

has no offset against its cost of operation, because the freight saving does not accrue to it, and it has to have a gross income larger than its gross expenses to operate at all. If it has any relations with railroads, they are limited and simple, and it avoids the tremendous overhead of the common carrier.

If the common carrier is a carrier by water only, it still has expenses which a private or contract carrier does not have, because it needs organizations at each port touched by it. The private or contract carrier may only have one port of origin and one of destination.

If the common carrier by water fulfills its highest function of serving all the people, it must have a large overhead, and this overhead is fixed by its activities, not by the size of its fleet. In other words, the overhead of such a common carrier is scarcely any greater if the fleet be doubled.

## Value of Three Types

One of the dangers of the utilization of navigable streams and canals only by private carriers which are big corporations, is that the construction of the fleets necessary to carry the tremendous bulk essential to economical operation involves such a large original investment of capital as few corporations can afford. Hence, those fortunate enough to be able to create and operate their own fleets, can transport their products cheaper than their competitors and undersell them, thus destroying healthy competition.

A contract carrier may be of great advantage, or a positive detriment, to a large portion of the country. To illustrate, if coal operators in Southern Illinois owned their own facilities for transporting coal cheaply to Minnesota, and did so, and sold it cheaper, every consumer of heat, gas, light, and other power served by the "Twin Cities" would be benefited. If such coal operators, in addition, contracted to carry back ore from the Mesabe Ranges in Minnesota, their cost of transporting their own coal would be cheapened, the user of ore for manufacturing purposes would be benefited, and if the manufactured article bore a proportionate decrease in price to the decreased transportation costs, vastly more people would be benefited.

On the other hand, suppose a contract exists between certain grain dealers in, say, Kansas City, Mo., and Omaha, Nebr., a railroad connecting with St. Louis, which owns its own elevator, and a contract river carrier. If this railroad guarantees to maintain its elevator full enough of these particular operators' grain to keep the water carrier busy, and if the water carrier transports only for these particular operators, the combination can practically set the purchase price of grain in Kansas City and Omaha. Not only can it cripple all other grain operators who have to depend upon all-rail rates, but it can compel the farmer who sells to their competitor to accept a lower price for his grain, because he has to deduct from his purchase price the higher cost of transportation. However, if there exists in competition with such private and contract carriers, a great common carrier, offering to all the people the same facilities that the others offer to a few, and at the same price, there is no chance of the private and contract carriers creating a monopoly that will throttle competition.

Broadly speaking, the conditions precedent to the success of a great common carrier are not necessarily present for the success of a private or contract carrier. At the same time, to extend the benefits of cheaper water

transportation on inland rivers and canals to all requires the utilization of great common carriers. To create these conditions precedent to success it has been found necessary to have a governmentally owned corporation, functioning as a private corporation, but backed by the great powers of the Government itself. Railroad opposition had been successful in practically annihilating common carriers on navigable streams and lakes.

A private carrier requires:

(*a*) A suitable navigable river.
(*b*) Suitable boats.
(*c*) Terminal facilities, which may be very simple, suitable for handling only one commodity.
(*d*) A small operating force.

A contract carrier requires, in addition:

(*a*) Terminal facilities, which are more complicated than those necessary for handling one commodity only.
(*b*) An operating force probably one-half greater than a private carrier.

A common carrier, to be of nation-wide benefit, must have in addition to the requirements of both the private and contract carrier:

(*a*) Balanced freight.
(*b*) Terminal facilities, dependent upon conditions in each locality both ashore and afloat; and more of them.
(*c*) Interchange with other carriers.
(*d*) Equitable division of revenue accruing from joint rail-water haul.
(*e*) A very large operating, traffic, and auditing overhead.

What follows refers to a great common carrier of nation-wide benefit, and not to a common carrier by water alone. These latter are highly desirable, but of no great National benefit.

A great common carrier must be organized along the lines of good railroad practice, must have as keen a traffic and operating manager, and other officials, as any railroad organization, and must be as closely co-ordinated through an executive as are the various divisions of a railroad. In order to be successful, it must also have much and costly equipment and powerful financial backing.

A demonstration by the present fully empowered governmental body (Inland Waterways Corporation) has been considered as necessary by Congress until such time as conditions precedent to success are established and private capital is willing to invest in an operation no longer hazardous. From this standpoint the experience of the Corporation with its Barge Line is instructive.

### Inland Waterways Corporation Operations

Freight transported by common carriers is carried under what are known as class and commodity rates. These class rates vary considerably, for example, the first, second, third, fourth, and fifth class rates *via* the Barge Line from Minneapolis to East St. Louis, Ill., are, in cents per hundred pounds, 77, 63½, 51, 36½, and 26; whereas the similar rate on export grain from St. Louis to New Orleans is only 11½ cents.

Relative to the actual operations of the Inland Waterways Corporation, Table 1 provides a basis upon which calculations regarding the economics of water transportation may be made. Its practical value is enormous, and

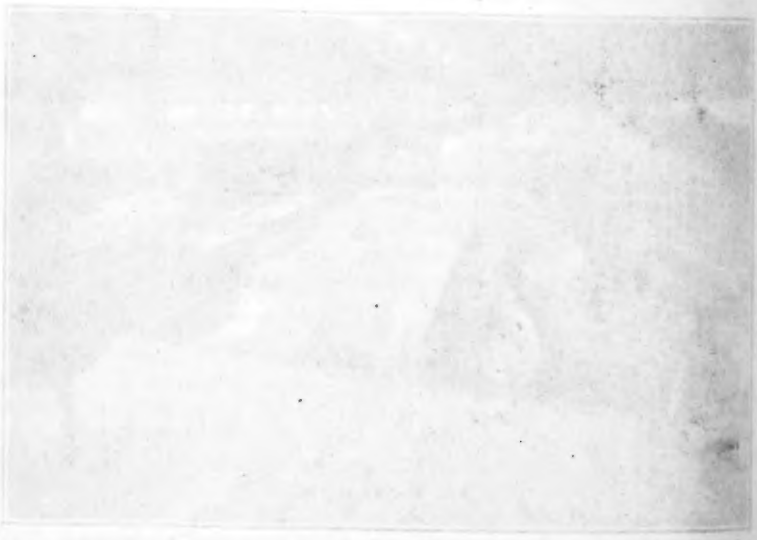

FIG. 3.—SELF-PROPELLED BARGE, MUNICIPAL WHARF, ST. LOUIS, MO., SHOWING METHOD OF LOADING AND STOWING FREIGHT.

FIG. 4.—INTERIOR OF BIENVILLE STREET WHARF, NEW ORLEANS, LA., SHOWING CLASSIFICATION OF FREIGHT.

furnishes a mark "to shoot at" in getting a reasonable ratio between costs of operation and accruing revenue.

As will be observed the maintenance and operation of terminals comprise 39.3% of the total costs of operation. That is because the terminal facilities, generally speaking, are owned by the cities in which they are located, and the Barge Line not only operates and maintains them, but pays 15 cents (in one case, 20 cents) for every ton of freight handled over them. The erection of these terminals by the various cities was essential to promote that co-operation between them and the Barge Line so necessary to build up a profitable freight-carrying business. Of course, the city is stimulated and encouraged to utilize the terminals as much as possible to get a greater revenue, and this 15 cents per ton is supposed to be sufficient to take care of the interest on the bonds, pay taxes, and amortize the investment. For example, in 1928, the City of Memphis received an approximate total of $50 000 for the use of its terminal, and the Barge Line kept it in repair. As traffic increases, this annual payment increases. This is the answer to the public statement so frequently made that the tax-payer is being mulcted by the Barge Line to pay for terminals. The amount of local freight that passes over these terminals is small compared to the interchange freight, and while the city is being reimbursed for its original expenditures, it has been helping those in the hinterland to save money on freight bills, and thus increase their purchasing power, which purchasing power is directly reflected in the city's prosperity.

TABLE 1.—THE BARGE LINE DOLLAR AS INCOME AND DISBURSEMENT.
(Calculated on the total revenues and total expenses of the Operating Divisions of the Inland Waterways Corporation.)

| | 1927. | 1928. |
|---|---|---|
| Where the Dollar Came From: | | |
| Total revenues | $0.997 | $1.00 |
| Operating deficit covered by Corporation | 0.003 | ..... |
| Total | $1.00 | $1.00 |
| Where the Dollar Went: | | |
| Maintenance and operation, Line vessels | $0.439 | $0.403 |
| Maintenance and operation, terminals | 0.407 | 0.393 |
| Traffic expenses | 0.045 | 0.041 |
| General expenses | 0.045 | 0.049* |
| Loss and damage | 0.032 | 0.029 |
| Maintenance and operation, railroad | 0.021 | 0.021 |
| Charter expenses | 0.011 | 0.005 |
| Net income | ..... | 0.059 |
| Total | $1.00 | $1.00 |

* The increase in general expenses of 1928 over 1927 of 4 mills in the dollar was due to: (a) Higher cost of insurance due to tonnage increase and greater protection; (b) salaries and expenses of upper river officials; and (c) increased office rent and expenses at New Orleans.

Originally, no attempt at standardization of the type of terminals was made, nor could it be made. There were no standard barges, and no data available as to the expense of operating, so that in the existing system may

be found the direct-lift, escalator type, and the inclined railroad with floating terminal. In the operation of terminals there is thus an essential difference between rail and water transportation. Figs. 3 and 4 show the appearance and the operation of two of the terminals in use on the Mississippi River.

Interior water transportation has inherent advantages and equally inherent disadvantages when it comes to the question of reflecting savings to those not fortunately located on navigable streams. The physical nature of waterways limits the ports at which tows may touch or cargo be received, but rail or motor transportation has no such limitation. There thus results in Barge Line operations a costly transfer from car or truck to barge, or *vice versa*; and sometimes a second costly transfer, where the freight originates on a rail line, is transferred to barge, and again to rail as, for example, on a shipment from Chicago to Houston, Tex. Here, the freight moves by rail to St. Louis, is transferred to barge, and re-transferred from barge to car at Baton Rouge, La. These costs of transfer must be absorbed in rail-water-rail transportation; and still the resultant cost of the movement must be less than the all-rail movement. Otherwise, there is no virtue in such a form of transportation.

A shipper by rail can put his freight in a car at Chicago, and it will move through to destination without change of container, so that by a joint rail-water-rail route two transfers are introduced which are unnecessary in all-rail movements, but which cannot be obviated in joint movements. When the point of origin and the destination are river ports, and the same barge can carry its cargo from point of origin to point of destination then, and then only, can water transportation offer a comparable service to an all-rail service.

If it be necessary, as it now is, to transfer cargo moving between upper and lower river points, there is introduced a burdensome cost. Good business practice demands that this should be eliminated, but it could not be done as long as one fleet was designed to operate on a 4-ft. channel and the other on a 9-ft. channel.

It is to be noted that the costs of these transfers must be absorbed in the joint rail-water-rail rates, lower than all-rail rates, or the public will receive no advantage from such joint rates.

## A Successful Policy

The whole National policy of rendering streams navigable, upon which so much money has been spent and will be spent, was based on the hope that by their utilization cheaper transportation would result. The Inland Waterways Corporation, a Congressional agent, was organized for the purpose of demonstrating that this policy is not a colossal failure.

It safely may be said that the demonstration has convinced the people of the United States that the policy of Congress, far from being a great mistake, has been the result of far-sighted vision; and the people themselves have demanded further and further expansion of the operations of this Corporation. They have seen its practical effects—cheaper transportation for all through co-ordination of rail, water, and motor transportation, with an accruing revenue to the joint carriers which, when fairly divided, will afford each participating carrier a reasonable living revenue.

# RAILWAYS VERSUS WATERWAYS: AN ECONOMIC COMPARISON

By L. D. Cornish,[3] M. Am. Soc. C. E.

## Synopsis

The purpose in preparing this paper has been to assemble authoritative facts relative to past rail and waterway traffic in a form convenient for study and analysis so that conclusions or opinions relative to the economics of present and future railway and inland waterway transportation could be subjected to the acid test of a fair comparison with past records of freight transportation upon the railroads and waterways of the United States.

The essential railway statistics from 1890 to 1924, inclusive, were assembled in graphic form in 1926, and on the theory that the past trend is the most probable indication of the trend in the near future, the demands of transportation and railway requirements to meet them are forecasted to the year 1950. It is shown that the railways during the 25-year period must expend approximately $11 000 000 000 for freight capital cost of additional transportation facilities.

The cost of completing the Mississippi Valley Inland Waterways System and providing thereon floating equipment and terminals for 60 000 000 000 ton-miles of traffic is developed from known costs and shown to be $600 000 000. It is shown that equivalent railway facilities will cost more than three times as much.

The past growth of waterway transportation is developed and forecast to 1950, and it is shown that the completion and utilization of the Mississippi Valley System by that time will be of economic benefit to the amount of more than $90 000 000 per annum.

Forecasts and future requirements are based on statistics to 1925, but the graphs and tables are brought as nearly up to date as published data would permit and serve as a check and confirmation of the original predictions.

## Introduction

The history of mankind shows conclusively that the predominating influence in the rise and fall of nations and cities has been the relative cost of transportation. The life of nations has been, and still continues to be, a life of warfare—if not the warfare of bloody battlefields, it is the bloodless warfare of trade and commerce, which begets real conflict.

[3] Chf. Engr., Div. of Waterways, State of Illinois, Chicago, Ill.

Bacon said: "There be three things which make a nation great and prosperous: A fertile soil, busy workshops, and easy conveyance for men and commodities from one place to another." The easy conveyance of commodities in these and future days means cheap transportation facilities. In the United States the ease of transportation is now measured by freight rates in mills per ton-mile.

In 1924 the railroads of the United States transported 392 000 000 000 ton-miles of freight at an average rate of 11.32 mills per ton-mile. In the same year the report of the St. Marys Falls Canal shows lake shipments of 72 000 000 000 ton-miles at 1.2 mills per ton-mile. In six years, 1923 to 1928, the Government Barge Line on the Mississippi River between New Orleans, La., and St. Louis, Mo., transported more than 6 000 000 000 ton-miles of freight for an average revenue of 3.90 mills per ton-mile. This economy of water transportation is impressive. Coupled with the appeal of the agricultural and manufacturing interests of the Middle West for lower freight rates to seaboard ports, it suggests the economic necessity of completing the improvement of the Mississippi River and its main tributaries for navigation purposes as soon as possible and of developing thereon a water-borne commerce at lower freight rates. Then, the products of the fertile soil of this region may compete in the markets of the world on a more profitable basis with similar products from Canada, the Argentine, and Russia. Then, the workshops of the region may again become busy manufacturing goods for the Pacific Coast and the Orient. Thus, they may regain customers lost to them for years past on account of the advantage of the low freight rates by water *via* the Panama Canal possessed by their Atlantic Coast competitors.

## Modern Waterway History

The Mississippi River, with its tributaries, comprises a natural waterway system more than 15 000 miles in length. About 5 000 miles, when the authorized improvements are completed, will constitute the trunk lines, reaching from Pittsburgh, Pa., to Kansas City, Mo., and from New Orleans to Chicago, Ill., and St. Paul, Minn. The area reached by these trunk waterways alone is so vast in extent, so rich in its products of agriculture, mining, and manufacturing, that the controversy over the relative economy of transportation by railroads *versus* inland waterways must inevitably be settled by actual operation with modern equipment upon modern waterways.

The movement for the development of the inland waterways of the United States appears to have run in cycles of about 20 years' duration, which have culminated in legislative authorization for the construction of one or more important waterways. During these cycles the persistent efforts of waterway advocates to educate the public and to secure legislative authorization for their projects have been as persistently opposed by interests which fear the competition of waterway transportation, or by persons who cannot, or will not, visualize the transportation needs of coming generations.

The waterway controversy which culminated about 1904 resulted in the construction of the New York Barge Canal and the Panama Canal. A barge, instead of a ship, canal across the State of New York was an economic mistake

for which the selfish or misguided interests of the Cities of New York and Buffalo are solely responsible. At the time, waterway advocates and engineers were nearly unanimous in recommending a ship canal. This mistake has since been acknowledged by the effort of the State to have the Federal Government reconstruct part of the Barge Canal into a ship canal, instead of participating in the proposed St. Lawrence River improvement.

The Panama Canal has proved to be the wonderful military and commercial success which was anticipated by its advocates. Together, the high rail rates and the economic advantage which the Panama Canal gives to the Atlantic and Pacific Coasts are responsible for the unanimity of opinion of agricultural and manufacturing interests in the Middle West in favor of promptly completing the improvements of the Mississippi River and its tributaries for navigation purposes and of connecting them with the Great Lakes at Chicago. The cost of construction and maintenance and also the operating efficiency of the Lakes to the Gulf Waterway are dependent on a diversion of water from Lake Michigan at Chicago through the completed Chicago Sanitary Canal, thence through the Illinois Waterway, the Lower Illinois River, and the Mississippi River.

## Opposition to Waterways

A subtle, persistent, and effective opposition to the Illinois Waterway has existed for forty years among the interests naturally opposed to waterways in general and to this waterway in particular. The diversion question is limited to this particular part of the inland waterway system of the Mississippi Valley and may be dismissed as having only a minor influence on the relative economic importance of railroads and inland waterways in solving the future transportation problem of the United States.

The opposition to the development of waterways for transportation purposes is in the main from two classes, namely, railroad officials, or interests, and professional economists. The arguments of the railroad class are naturally biased by its concern as to the possible effect water transportation might have on its income and net earnings. Both classes are deeply perturbed at what they call the economically unsound and commercially unfair policy of developing waterways at public expense, and usually point out some particular waterway as a horrible example because of its small tonnage as compared with the large annual expenditures charged against it.

Conclusions relative to waterways in general are worthless if based entirely upon the results obtained from a study of isolated examples. Opponents of the improvement of waterways seldom, if ever, give any consideration to the total future transportation needs in such a rapidly growing country; nor will they admit the economic necessity of any section of the country being given lower freight rates than other sections in order to have a fair chance in competition for a profitable existence.

## The Transportation Problem

Railroads are and probably always will be the principal National agencies of transportation, but the rapidly increasing demand for transportation coupled

with the periods of rail-traffic congestion and demoralization during past years, gives rise to several questions relative to the expected status of the National transportation problem twenty years hence, or, say, by 1950.

The principal questions are as follows:

(*a*) What will be the probable transportation demand upon the railroads of the United States in 1950?

(*b*) What will be the cost of additional railroad trackage and equipment required to supply the probable increase in transportation demand?

(*c*) How much of the transportation demand can be supplied by inland waterways now authorized, but uncompleted?

(*d*) What will be the probable cost of providing inland waterway transportation facilities, terminals, and operating equipment?

(*e*) What will be the relative benefit to the public for freight shipments by rail or inland waterways?

## Demand and Cost of Increased Traffic

*Railroad Traffic Data.*—The questions as to the growth of transportation and its cost depend upon such a complexity of circumstances and conditions so difficult to forecast that the best solution lies in assuming that the trend of transportation progress in the United States during the past forty years will continue for the next twenty years.

TABLE 2.—United States Railroad Data Projected to 1950.

| Curves. | Item. | Probable amount by 1950. | Reference, Interstate Commerce Commission reports. |
|---|---|---|---|
| *A* | United States population, in millions | 150 | |
| *B* | Traffic, all roads, in billions of ton-miles | 870 | 1924, p. XCV |
| *C* | Freight density, in millions of ton-miles per track-mile | 1.6 | 1924, p. XXXIX |
| *D* | Track length, total, in thousands of miles | 555 | 1924, p. XCII |
| *E* | Length, main track, in thousands of miles | 355 | " |
| *F* | Length, yards and sidings, in thousands of miles | 200 | " |
| *Ff* | Length, yards and sidings, in percentage of total | 36 | |
| *G* | Average capacity, freight cars, in tons | 53 | 1924, p. XCII |
| *H* | Average load, freight cars, in tons | 23 | 1924, p. XCVI |
| *I* | Travel of freight cars per annum, in thousand of miles | 12.2 | 1924 pp. XCVI, XCII |
| *J* | Work of freight cars per annum, in thousands of ton-miles | 281 | |
| *K* | Total number of cars, in millions | 3.1 | 1924, p. XCII |
| *L* | Aggregate car capacity, in millions of tons | 164 | |
| *M* | Average locomotive tractive capacity, in tons | 31 | 1924, p. XCII |
| *N* | Total tractive capacity, in millions of tons | 2.4 | 1924, p. XCII |
| *P* | Number of locomotives, in thousands | 78 | |
| *S* | Total capital cost, in billions of dollars | 33.7 | 1924, p. XCIII |

The Annual Reports of the Interstate Commerce Commission on the "Statistics of Railways in the United States" contain tabulated transportation statistics for all railroads and for each Class I railroad. In order to simplify the visualization of certain statistics the data have been plotted as shown in Figs. 5 to 8. In each case the solid lines show the data as given in the reports, and the broken-line continuations indicate the writer's opinion as to the probable future trend to 1950. The various graphs are lettered for convenience and the results indicating the expectancy in the several items by 1950 are given in Table 2, together with reference to the source of information.

In Curve *B* (Fig. 5) the prolongation of the mean curve answers Question (*a*) by indicating 870 000 000 000 ton-miles as the expected traffic by 1950. This is more than double the traffic of 1925, and it will undoubtedly require huge expenditures of capital to provide additional tracks, yards, and equipment. Curve *C* (Fig. 5) shows the density of traffic and indicates the average efficiency of the railroads with respect to their freight movement. A scrutiny of the records for individual roads develops an amazing variation in this measure of railroad performance and shows that an average of more than 1 000 000 ton-miles per track-mile is due to the coal-carrying roads of the Eastern and Southern Districts.

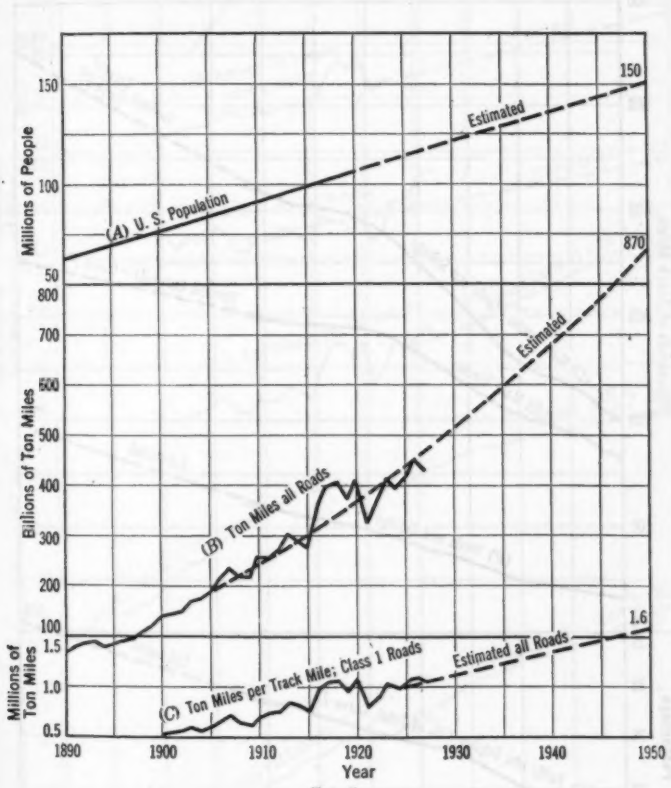

FIG. 5

*Track Requirements.*—Curves *D* and *E* (Fig. 6) were not directly extended because of the change of trend in recent years. New trackage requires heavy expenditures of new capital. During and immediately following the World War new capital was almost unobtainable, and the railroads were forced to provide for the unprecedented traffic demand by improving their operating

efficiency. This resulted in a cessation of main-line track construction and disrupted the trend of Curves *D* and *E*. However, the construction of new track for yards and sidings had to be continued, as shown by Curve *F* (Fig. 6), and this provides a method for forecasting main-track requirements and for projecting Curves *D* and *E*.

Curve *F* shows a remarkably uniform trend of yard and siding construction which apparently is not much affected by periods of business depression or difficult financing. Therefore, this curve may be prolonged to 1950 (Fig. 6) with reasonable accuracy.

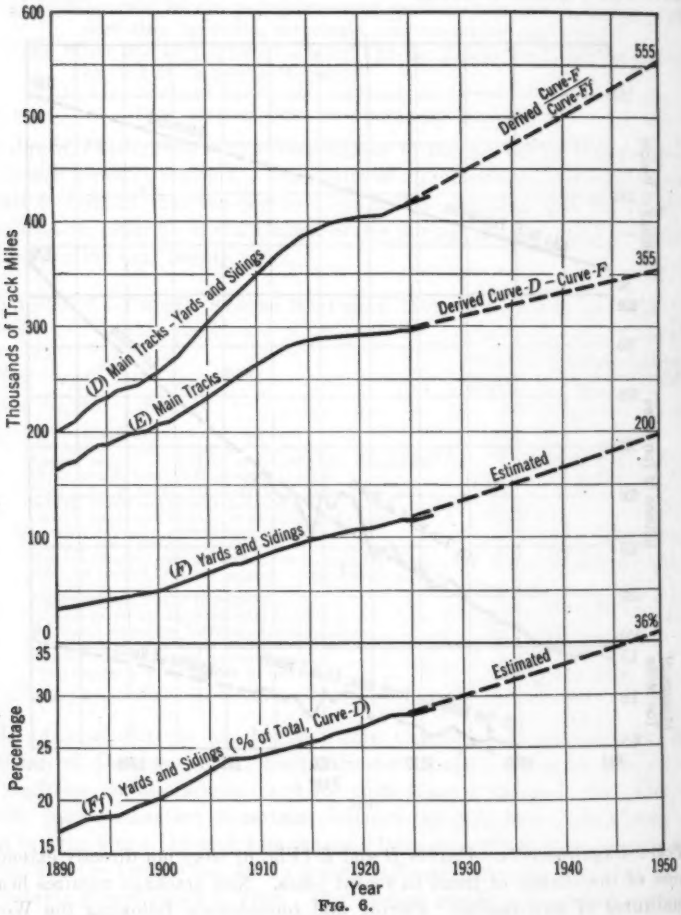

FIG. 6.

Curve *Ff* (Fig. 6), prepared to show what percentage of all tracks is in yards and sidings, also shows a steady increase. Prolonging its definite trend

FIG. 7.

indicates that by 1950 about 36% of all tracks will be in yards and sidings. Since both curves, *F* and *Ff*, seem reasonable and consistent as projected to 1950, their relation to one another should hold true. This will give the projection of Curve *D* to about 555 000 miles by 1950. The main-line trackage needed then becomes the difference between Curves *D* and *F*, as shown by Curve *E*. These diagrams indicate that, between 1925 and 1950, about 60 000 miles of additional main tracks and 80 000 miles of additional yard and siding tracks will be needed in order to provide adequately for the expected increase in freight movement (Curve *B* (Fig. 5)).

*Operating Equipment.*—Freight cars and their operation statistics are shown by Curves *G* to *L*, inclusive (Fig. 7). Curve *H* was obtained by dividing the ton-miles (Curve *B* (Fig. 5)), by the sum of the loaded and empty car-miles.[4] By excluding the known abnormal loadings of the post-war period, 1917 to 1920, a very definite trend is shown which can be prolonged to 1950.

The data for car-miles per annum (Curve *I* (Fig. 7)) are obtained by dividing the sum of the loaded and empty car-miles[4] by the total number of cars.[5] By plotting 5-year averages (Fig. 7), the general trend is shown. The extension of Curve *K* (Fig. 7) from 1930 to 1950 is derived by dividing the ton-miles (Curve *B* (Fig. 5)) by the ton-miles per car (Curve *J* (Fig. 7)).

The location for Curve *L*, the aggregate car capacity, including its extension, is also derived, being the product of the number of cars (Curve *K*) times the average capacity (Curve *G*). It is seen that between 1924 and 1950 about 57 000 000 tons of additional car capacity will be needed. The cost of 50-ton freight cars averages about $2 000 each, or $40 per ton of capacity. Therefore, capital expenditures of about $2 300 000 000 by 1950 are indicated for additional freight cars alone.

Similarly, for total locomotive tractive capacity (Curve *N* (Fig. 8)) an additional 1 014 000 tons is indicated between 1924 and 1950. Locomotives of 60 000-lb. tractive power cost from $75 000 to $80 000 each, or about $2 500 per ton of tractive power. Therefore, additional locomotives to 1950 will cost about $2 500 000 000 for combined freight and passenger service.

The small increase in the number of locomotives (Curve *P* (Fig. 8)) is due to the large increase in tractive capacity. The average mileage per year per locomotive (Curve *R* (Fig. 8)) is shown merely to point out the pronounced policy of the railroads to increase locomotive power and train loads and decrease the travel of locomotives. This undoubtedly decreased the operating personnel and probably is partly due to the effect of the full-crew laws on operating expenses.

A careful study of Interstate Commerce Commission reports shows that passenger car-miles are about 13% of the total passenger and freight car-miles; that passenger revenue is 19.7% of combined passenger and freight revenue; and that passenger car-miles per locomotive-mile are about 14% of total car-miles per locomotive-mile. This is assumed as justification for

estimating that about 85% of the additional track and locomotive requirements indicated by Figs. 5 to 8, or, say, 50 000 miles of main track, 70 000 miles of yard and siding track, and 862 000 tons of locomotive tractive power, are chargeable to freight traffic.

*Capital Cost of Additional Railroad Requirements.*—The Interstate Commerce Commission reports contain no data to justify an estimate of the cost of new buildings, repair, and equipment, for the increased freight movements. Hence, the estimate for this cost is a guess.

As to the average cost per mile of track construction for the United States in recent years, information is not available in published Government reports. An appeal to the Interstate Commerce Commission for such information elicited the reply that while the data were in the records submitted by the railroads, no one at the time was in a position to tabulate them. A search through the statistical numbers of *Railroad Age* disclosed reports of 43 items by 27 railroads which summarize as follows:

| | |
|---|---|
| Main-line track ..... | 612 miles at $76 000 per mile |
| Yard tracks ..... | 177 miles at $77 000 per mile |

On the basis of these data, the writer has assumed for the purposes of this paper $60 000 and $40 000, respectively, as the cost of construction for additional main-line and yard and siding tracks.

Question (*b*) may now be answered by stating that the probable cost of additional railroad trackage, equipment, etc., between 1925 and 1950 for freight traffic alone will be about as follows:

| | | | | |
|---|---|---|---|---|
| Main tracks ..... | 50 000 miles | @ | $60 000.. | $3 000 000 000 |
| Yard and siding track..... | 70 000 miles | @ | 40 000.. | 2 800 000 000 |
| Freight car capacity .....57 | 000 000 tons | @ | 40.. | 2 280 000 000 |
| Locomotive tractive power... | 862 000 tons | @ | 2 500.. | 2 155 000 000 |
| Buildings, miscellaneous equipment, etc..... | | | | 765 000 000 |
| Total..... | | | | $11 000 000 000 |

In Curve *S* (Fig. 8) is shown the total investment in roads and equipment, and it is extended from 1925 to 1950 by the addition of the $11 000 000 000 estimated. A large amount of new capital investment also will be required to provide for the future growth of passenger traffic, but this subject is not under discussion.

It may be noted that in 1922 to 1927, inclusive, the railroads spent $3 873 000 000, or at the rate of $645 000 000 per year. The foregoing estimate of $11 000 000 000 for freight requirements during the 25-year period is at the rate of $440 000 000 per year, and is thought to be conservative in view of the relative needs of freight and passenger traffic.

For convenience these capital costs will be reduced to a cost per ton-mile of annual freight traffic. This will simplify a comparison with inland waterway transportation costs, which will be discussed later. Curve *C* (Fig. 5) indicates a density of traffic of 1 600 000 ton-miles by 1950. Hence, the additional 120 000 miles of freight trackage will take care of 192 000 000 000 ton-

miles of annual traffic. At a cost of $5 800 000 000, this trackage will average 3.02 cents per ton-mile of freight capacity.

The 57 000 000 tons of additional car capacity (Curve *L* (Fig. 7)) are 35% of the total for 1950 and, therefore, the hauling capacity is 35% of 870 000 000 000, or 305 000 000 000 ton-miles. The cost of this additional car capacity was shown to be $2 280 000 000, which is at the rate of 7.5 mills per ton-mile of annual freight-carrying capacity. The 862 000 tons of additional tractive power are 36% of the total for 1950 and, therefore, the annual hauling capacity is 313 000 000 000 ton-miles, and the additional locomotive cost is 6.9 mills per annual ton-mile capacity. The cost of buildings, etc., distributed over 313 000 000 000 ton-miles amounts to about 2.5 mills per ton-mile of annual traffic.

The sum of these unit costs amounts to 4.7 cents per ton-mile of annual freight capacity. This amount is presented as the probable unit cost of providing additional railroad facilities adequately to handle the increase in freight ton-mileage, which may be expected by 1950.

### Transportation Possibilities of Mississippi Valley Waterway System

The completion of the projects now (1929) authorized by Congress and by the State of Illinois will provide trunk waterways extending east and west between Pittsburgh and Kansas City; and between New Orleans in the south and St. Paul, Minneapolis, and Chicago in the north. The transportation capacity of these waterways depends principally upon the reliable width and depth of the channel and on the size of the locks. The minimum width of these channels will be 200 ft. The locks on the Ohio River and Illinois Waterway are identical in usable horizontal dimensions, 600 ft. long by 110 ft. wide, and the minimum navigable depth will be 9 ft. The locks on the Upper Mississippi River vary in size and this has been given proper consideration in preparing the statistics of this waterway presented in Table 3.

The estimated capacity by 1950 is materially less than that claimed by the exponents of each waterway and is listed to give a general idea of the transportation possibilities of this waterway system. The total of 60 000 000 000 ton-miles may not be unreasonable in view of the probable growth of transportation in the territory served, provided proper water freight rates should be established. However, such a huge figure should not be considered without, at least, some investigation of the potential tonnage in the area served by these waterways.

According to statistics of the Interstate Commerce Commission report for 1924 the total ton-miles for 30 railroads serving the Mississippi Valley were more than 162 000 000 000. Several of the roads served other territories. After making allowances for these conditions, it was found that about 100 000 000 000 ton-miles might be assumed as within the Mississippi Valley, which comprises 65% of the area of the United States.

Based on the prospective increase indicated by Curve *B* (Fig. 5), an additional 120 000 000 000 ton-miles will materialize by 1950. It does not appear unreasonable to assume that the waterway system could take care of one-third this increase, or 40 000 000 000 ton-miles, equivalent to a water-haul of about 60 000 000 000 ton-miles. This is in view of the fact that the annual traffic

of the Federal Barge Line alone on the Mississippi River now (1929) exceeds 1 000 000 000 ton-miles and the uncompleted (1929) Ohio River System produces in excess of 2 000 000 000 ton-miles.

| Mississippi River | Cairo, Ill., to New Orleans, La. | 970 | 9 | 150 000 000 | 100 | 26 |
| Total | | 3 460 | | | 210 | 60 |

Assuming 60 000 000 000 ton-miles per annum as the probable traffic demand available for this waterway system by 1950 raises the question as to whether the past growth of water transportation has been such as to indicate a future growth to a total of 60 000 000 000 ton-miles by 1950. The usual reply of waterway advocates to such a question is "provide a dependable completely improved waterway between important terminals and the operating equipment, terminal facilities, and tonnage will be developed." Such a statement is merely a prophecy and without supporting evidence is unconvincing. The writer believes that such a prophecy with regard to the Mississippi River System will eventually come true and that there now exists sufficient evidence in support of such a claim.

The past growth of waterway traffic for the entire Mississippi System cannot be shown, as so much of the system is incomplete and has no traffic. However, the tonnage statistics of all important waterways of the United States are available in public documents, giving the data shown in Table 4. The capacity of the Monongahela River is about 25 000 000 tons, hence, no further material increase may be expected until additional locks are provided.

The other waterways in Table 4 show an annual traffic increase of from three to five times the rate of increase shown by railroads. Such increases are remarkable; if they are maintained, the capacities of all these waterways would be reached in less than fifteen years.

The average annual rate of increase in tonnage for these waterways is 14.4 per cent. This rate, if maintained for a period of twenty-five years, would result in a tonnage and probably ton-mileage thirty-six times as great

as in 1925. To those who would dispute the assertion that an annual increase of 15% in the next twenty-five years is not only possible but probable, it is pointed out that not one of the rivers in the Mississippi Valley is completely improved for navigation except the Monongahela River and the Mississippi River below Cairo, and even the latter is subject to interruption of traffic for months at a time due to insufficient depth and width of its dredged channels.

TABLE 4.—Traffic on Certain Important United States Waterways.

| Waterway. | Tonnage, 1919. | Tonnage, 1925. | Annual increase, percentage (100 $R$).* |
|---|---|---|---|
| Ohio River | 5 000 000 | 15 737 015 | 21.1 |
| Monongahela River | 17 137 501 | 23 716 121 | 5.6 |
| Allegheny River | 2 058 069 | 4 744 843 | 15.0 |
| Mississippi River Division: | | | |
| Federal Barge Line | 109 218 | 910 755 | 42.0 |
| Tennessee River | 600 107 | 1 940 972 | 21.6 |
| Erie Division, New York Barge Canal | 673 000 | 1 945 466 | 19.4 |
| Panama Canal | 6 981 996 | 23 958 826 | 22.8 |
| Total | 32 559 891 | 72 953 998 | 14.4 |

* $R = \sqrt[n]{\frac{T}{t}} - 1$, in which, $R$ equals annual rate of increase, $n$, number of years in period; $t$, tonnage for 1919; and $T$, tonnage for 1925. The percentage equals 100 $R$.

Until these rivers are completely improved, transportation upon them must be considered as in its infancy and, hence, subject to a rate of increase somewhat comparable to that of the early days of the Sault Ste. Marie ("Soo") Locks and the St. Marys Falls Canal in Michigan. As shown by Government reports, the freight passing through the "Soo" Locks in 1856 was 33 817 tons and, in 1880, it was 1 321 906 tons. This 25-year period shows 15.7% annual increase. In 1905, the tonnage was 44 270 680, equivalent to an annual increase of 15.1 per cent.

The "Soo" Locks are the bottleneck of the greatest inland waterway system of the world. They are frequently cited as an example so favored by Nature that no other waterway could be comparable with them as to tonnage possibilities. Yet neither for the first fifty years of their history, nor for any 6-year period subsequent to 1890, was the annual rate of tonnage increase as great as the rate for the waterways listed in Table 4, the Allegheny and Monongahela Rivers excepted. This certainly indicates that, since 1919, transportation interests, exclusive of governmental, have been utilizing the principal unconnected and incomplete waterways of the Mississippi River System as fully as could be expected. Hence, the claim of opponents to waterway development that the public would not use them is without justification.

Those who so severely attack the policy of improving American waterways as uneconomical dwell at great length on the small volume of tonnage on certain of the waterways listed in Table 4. Such individuals lose sight of or ignore the power of compound interest.

For many years the New York Barge Canal has been a conspicuous and favorite object of attack, yet the main division of this canal, inadequate in

size for modern transportation methods, shows an annual tonnage increase of 19.4 per cent. The Erie Division of the New York Barge Canal was designed for a maximum of 20 000 000 tons. The tonnage in 1925 was more than 1 900 000; hence, if the tonnage continues to increase for 25 years at one-half the past rate of increase, or, say, 10%, the capacity of the canal will be reached by 1950.

The waterways of Table 4 show an average rate of increase in tonnage of 14.4 per cent. If the Monongahela River is excluded, the rate is 21.4 per cent. On Fig. 9 are shown graphically these annual tonnages. From 1925 the curves are extended to indicate prospective tonnage based on an annual increase of 10 per cent.

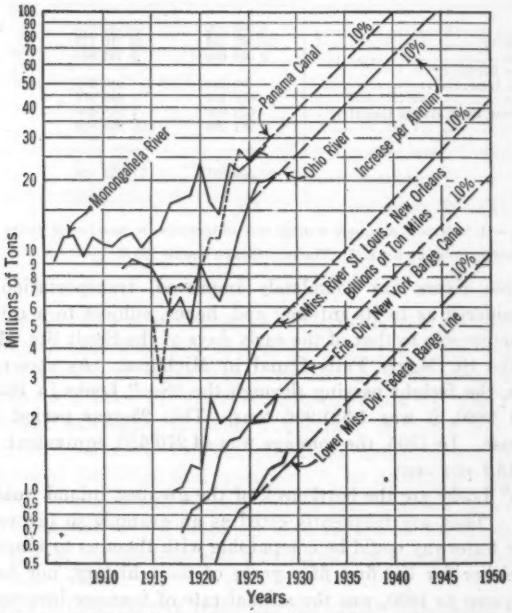

FIG. 9.—TONNAGE STATISTICS FOR UNITED STATES WATERWAYS.

There is also shown on Fig. 9 a record of the ton-miles of total traffic on the Mississippi River between St. Louis and New Orleans. The tonnage between the principal terminals—St. Louis, Cairo, Memphis, and New Orleans—is published each year in the "Commercial Statistics," volume of the reports of the Chief of Engineers. The 1924 report also gave the average haul in detail, from which the ton-mileage for 1923 was computed and it is, therefore, correctly shown. For other years the tonnage was combined with the average haul of 1923 to obtain the ton-miles as plotted. The error is probably small and on the conservative side as it is known that the increase in tonnage is largely on longer haul freight. Fig. 9 shows an annual increase of 18% between 1917 and 1926 and 28% for the years 1924 to 1926. If this

particular curve is continued at a 10% rate, it reaches a probable ton-mileage of 44 000 000 000 by 1950.

It would seem that the requirements of conservatism would be sufficiently satisfied if 10% be taken as the annual rate on which to base the future growth of transportation on the Mississippi River System. This rate will produce an eleven-fold increase in 25 years.

Government reports show that in 1925 the Ohio River System, exclusive of the Monongahela, carried more than 1 000 000 000 ton-miles. At 10% annual increase this would amount to 11 000 000 000 ton-miles for 1950.

Thus, the Mississippi below St. Louis and the Ohio below Pittsburgh should supply 55 000 000 000 ton-miles in 1950. It is reasonable to expect that new traffic on the Upper Mississippi and the Missouri augmented by that resulting from opening the Illinois Waterway about 1931, will produce enough traffic to increase the total well in excess of the 60 000 000 000 ton-miles by 1950 estimated in Table 3. On the basis of the foregoing discussion, the writer answers Question (*c*) by stating that the progress in waterway transportation from 1919 to 1925 justifies the assertion that by 1950 the inland waterways of the Mississippi and its tributaries can supply an equivalent amount, or 40 000 000 000 ton-miles of the expected railroad transportation demand of the Mississippi Valley.

## Cost of Waterway Transportation Facilities

The costs of providing trackage and operating equipment for railroad transportation were based entirely upon the records of the Interstate Commerce Commission to eliminate as far as possible personal opinions. The following derivation of waterway costs, whenever possible, will also be based on Government data.

The best data on inland waterway costs are the annual reports of the Federal-operated Inland Coastwise Waterways Service which, in 1924, became the Inland Waterways Corporation. This Corporation and its predecessor have operated barge lines on the Warrior and Mississippi Rivers since 1919. The Warrior Division is still in the experimental stage and its operations are unprofitable.

The Mississippi Division hereinafter referred to as the Barge Line has shown steady and persistent progress whenever a proper navigable channel was available. The great variety of general freight carried by the Barge Line and its field of operations in the heart of the Mississippi Valley make it an ideal example for comparing inland waterways and railroads.

The Barge Line in 1925 transported 910 000 tons an average distance of 960 miles, or a total of 875 000 000 ton-miles. In 1925 its total investment in real property and equiment was $8 079 833. 43, or at the rate of 9.24 mills per ton-mile of actual traffic.

This value is not a fair one for two reasons: First, the Barge Line uses municipally owned terminals, the cost of which should be considered; and, second, the line did not operate at its normal capacity because the channel was shallow and narrow for several months.

From data furnished by the Inland Waterways Corporation, Table 5 was prepared.

The writer finds that the 9 towboats are equivalent to 7½ standard towboats, each of which normally tows a cargo of 10 000 tons. These towboats at 20 000 miles per year, and normal cargo, could give 1 500 000 000 ton-miles of service. Actually three of these towboats averaged in excess of 20 000 miles for twelve consecutive months and the entire towboat fleet averaged 19 400 miles for a fiscal year.[6] The towboat capacity in Table 5 was found to be 91% of what the capacity would be if assumed on the basis of actual performance by several towboats for continuous periods in excess of a calendar month, including all delays and lay-overs at port; also the estimate of barge capacity of 1 314 000 000 ton-miles was 69% of the capacity assumed on the basis of actual performance for a calendar month.

TABLE 5.—INLAND WATERWAYS CORPORATION, MISSISSIPPI DIVISION.

| Item. | Practical capacity, in ton-miles per annum. | Replacement cost. | Cost per ton-mile, in mills. |
|---|---|---|---|
| U. S. terminals, harbor vessels, etc., municipal terminals used | 2 000 000 000 | $3 490 000<br>$2 510 000 | 3.00 |
| Nine towboats | 1 500 000 000 | 2 810 000 | 1.87 |
| Fifty-one barges | 1 314 000 000 | 3 933 400 | 3.00 |
| Three self-propelled barges | 142 500 000 | 840 000 | 5.90 |

The Barge Line terminals and equipment are not balanced as to capacity. A balanced system may be as shown in Table 6.

This indicates 8 mills per ton-mile of capacity as the unit cost of providing terminals and operating equipment for a barge system for long hauls and a diversified class of freight, the lowest class being grain.

The unit cost of terminals would be higher for shorter haul business of the same class. However, it may be noted that the barge equipment of the Mississippi Division is of the covered compartment type, costing about $45 per ton of cargo capacity; whereas open barges as used on the rivers for coal, ore, lumber, sand, and gravel, cost less than $25 per ton of cargo capacity.

TABLE 6.

| Item. | Normal capacity, in ton-miles. | Unit cost, in mills. | Total cost. |
|---|---|---|---|
| Terminals and harbor equipment | 1 000 000 000 | 3.00 | $3 000 000 |
| Towboats | 900 000 000 | 1.9 | 1 710 000 |
| Barges | 900 000 000 | 3.0 | 2 700 000 |
| Self propelled barges | 100 000 000 | 5.9 | 590 000 |
| Total for System | 1 000 000 000 | 8.0 | ..... |
| Total cost | ..... | .... | $8 000 000 |

To the unit cost of 8 mills for terminals and operating equipment must be added the unit cost for completion of the Mississippi River System as

[6] Annual Rept., Inland Waterways Corporation, 1923, p. 52.

authorized by Congress and the State of Illinois. The U. S. Engineer Department estimates that $125 000 000 will complete all authorized projects in the Mississippi River System. To this should be added $20 000 000 authorized by the State of Illinois to connect the Chicago Sanitary Canal with the Government-operated Illinois River at Utica, Ill., and $5 000 000 or less to provide a 9-ft. open channel in the Illinois River from Utica to Grafton and in the Mississippi from Grafton to Cairo. The total cost for the completion of this Waterway System may be placed at $150 000 000, which for the 60 000 000 000 ton-miles of expected annual traffic previously estimated would amount to 2½ mills per ton-mile.

Thus, on the basis of the foregoing estimates, the cost of completing approved waterways and providing barge transportation facilities on the main arteries of the Mississippi Valley Waterway System and the Lakes-to-the Gulf Waterway (Question (*d*)) is found to be about 1 cent per ton-mile of annual traffic estimated for 1950.

## Costs of Freight Transportation

The railroads being common carriers, the cost to the public of freight transportation by rail is established by published freight rates, as approved by the Interstate Commerce Commission. A different condition exists relative to waterways, due to the fact that the right of way or river channels are public waters which may be freely used by any or all, subject only to navigation regulations established by law. This condition, therefore, permits of three classes of carriers on waterways, namely, common, private, and contract carriers.

Common carriers, such as the Inland Waterways Corporation, have regular routes and schedules; they accept whatever business is offered by the public. Private carriers, on the other hand, are owned and operated solely for the benefit of their owners in transporting their own products. Among existing private carriers may be mentioned several coal companies on the Upper Ohio and Monongahela Rivers, the West Kentucky Coal Company operating on the Tennessee, Ohio, and Mississippi Rivers, the Carnegie and the Jones and Laughlin Steel Companies, and the Standard Oil Company, on the Lower Mississippi River and New York Barge Canals. Contract carriers, many of which have been operating for years on inland rivers, function similarly to the tramp freighters on the oceans.

The water common carrier, to be successful, must have joint rail-and-water rate agreements with the railroads. Hence, these rates are subject to the approval of the Interstate Commerce Commission. The Barge Line is the only water common carrier of consequence in the Mississippi Valley. Its rates, as authorized by the Commission, are made by deducting from the all-rail rate from point of consignment to point of delivery 20% of the all-rail rate from the Barge Lines' port of shipment to port of discharge. For example, at present, a Chicago company desiring to ship agricultural implements to New Orleans can utilize water shipments only between St. Louis and New Orleans, and its saving would be 20% of the $13.00 (St. Louis-New

Orleans rate), or $2.60 per ton. The all-rail Chicago-New Orleans rate is $14.60 per ton; hence, the joint rail-water rate is $14.60 less $2.60, or $12.00 per ton.

In 1926, the Mississippi Division of the Barge Line handled 1 044 649 tons of freight on which the direct freight-bill saving to the shipper averaged $1.75 per ton, or a total saving of $1 828 135. All water carriers are free to set their purely all-water port-to-port rates without reference to the Commission. Hence, it may be expected that all-water rates will be governed by the necessities of competition.

The Barge Line has no competition at present and its "water rates, like all other transportation charges, are in the original instance made to secure as high revenue as the traffic will stand and develop." The high revenue, however, as charged by the Barge Line is 80% of the corresponding all-rail rate and the general shipping public saves the 20 per cent.

The future development of privately owned and operated water carriers must depend upon the profit to be gained in this line of business. The average profit or loss per ton of freight handled by the common carrier is the margin between the average operating cost and revenue. The annual reports of the Inland Waterways Corporation show in great detail the operating costs of the Barge Line, some of which are summarized in Table 7. Maintenance and depreciation is more than 10% of the property investment, which on December 31, 1927 amounted to $10 993 361.23. Neither taxes nor interest are paid as this is a Government-owned corporation.

TABLE 7.—Mississippi River Division Operating Cost and Revenue per Ton.

| Year. | 1923. | 1924. | 1925. | 1926. | 1927. | 1928. | Average. |
|---|---|---|---|---|---|---|---|
| Terminals: | | | | | | | |
| Operation | $1.52 | $1.36 | $1.41 | $1.56 | $1.42 | $1.27 | $1.42 |
| Maintenance and depreciation | 0.21 | 0.14 | 0.18 | 0.21 | 0.21 | 0.17 | 0.19 |
| Vessels: | | | | | | | |
| Operation | 1.11 | 0.96 | 1.01 | 1.02 | 1.05 | 0.84 | 1.00 |
| Maintenance and depreciation | 0.63 | 0.80 | 0.64 | 0.58 | 0.77 | 0.60 | 0.67 |
| Damages | 0.08 | 0.14 | 0.07 | 0.09 | 0.14 | 0.12 | 0.11 |
| Traffic, general, and miscellaneous | 0.35 | 0.40 | 0.29 | 0.36 | 0.42 | 0.37 | 0.36 |
| Total cost | $3.90 | $3.80 | $3.60 | $3.82 | $4.01 | $3.37 | $3.75 |
| Revenue | 3.40 | 3.64 | 3.91 | 4.32 | 4.22 | 3.86 | 3.90 |
| Profit | −0.50 | −0.24 | 0.31 | 0.50 | 0.21 | 0.49 | ..... |

As shown by Table 7 the Barge Line has established a cost of operating towboats, barges, and terminals, which information is vitally necessary for prospective future operators of private lines. The average length of haul of the Mississippi Division is slightly less than 1 000 miles. Therefore, Table 7 gives very closely the cost per ton-mile of haul by reading mills instead of dollars for the costs as given.

The minimum, yet very profitable, rate charged by the Barge Line is 2 mills per ton-mile on export grain. The cost of loading and unloading is borne by the consignor. The rate on bauxite ore is about 2½ mills per ton-mile, which includes loading costs only.

In making comparisons between railroads and waterways, the difference in distance *via* rail or water should be considered. For the Mississippi Valley System as a whole 1 mile of rail haul is equivalent to about 1½ miles of water haul. In Table 8 are given typical rail and river distances, together with corresponding rates.

TABLE 8.

| New Orleans, La., to: | Distance, in Miles. | | Cost per Ton. | |
|---|---|---|---|---|
| | Rail. | River. | Rail, fifth-class. | All-river. |
| Cairo, Ill. | 554 | 969 | $15.00 | $3.90 |
| St. Louis, Mo. | 716 | 1 167 | 17.20 | 4.24 |
| Chicago, Ill. | 921 | 1 519 | 19.40 | 4.84 |
| St. Paul, Minn. | 1 330 | 1 850 | 24.20 | 5.40 |
| Cincinnati, Ohio | 836 | 1 468 | 18.80 | 4.75 |
| Pittsburgh, Pa. | 1 147 | 1 937 | 22.10 | 5.55 |

The all-river costs are estimated from the six years, 1923 to 1928, assumed as average revenue per ton between New Orleans and Cairo plus 1.7 mills per ton-mile of additional river distance to cover added cost of vessel operation. About 70% of the total river traffic consisted of grain, sugar, and bauxite ore, hence the river rates offer no basis of comparison with fifth-class rail rates, except to indicate how profitable fifth-class freight would be to water carriers.

It is quite evident that a privately owned line with fixed charges of taxes and interest could not survive as a common carrier under the operating costs and revenues allowed this Federal Barge Line. However, there are two items which give promise of substantial reduction, namely, wharf labor, now costing more than 90 cents, and fuel, 60 cents, per ton of freight handled. The type of equipment is steadily being improved and the effect of this on operating costs is marked. For instance, the cost of operating the Barge Line's tunnel-propeller towboats for 10 months in 1925 was 1.29 mills per ton-mile, whereas that for two stern-wheel towboats was 2.56 mills.

While the profitable operation of common carriers by private capital is yet to be demonstrated, the same is not the case with respect to private or contract carriers. The private carrier usually will be a quantity producer, also, occasionally, a distributor of a more or less specialized product. The investment and operating cost of terminals and floating plant for quantity products will always be materially less than for the common carrier, which at all times must be prepared to handle a great variety of items of commerce in relatively small quantities. If such were not the case, many large corporations would have utilized the Federal Barge Line on the Mississippi River instead of developing their own private lines. Smaller corporations with occasional barge-load shipments will be a prolific source of business for the contract carrier.

At the present stage of the renaissance of inland waterway transportation too little consideration is apt to be given to the contract carrier. A towboat provides a very attractive and comfortable home for an entire family as well as a means of livelihood. There are many such on the rivers to-day, and their number will increase rapidly as commerce develops. In fact, their existence in numbers might prove very embarrassing to the common carriers on account of competitive rate-cutting on port-to-port business.

### Economic Advantage of Inland Waterway Transportation

The minimum direct benefit of waterway transportation to the shipping public has been fixed by the Interstate Commerce Commission for the Barge Line at 20% of the rail rate from port-to-port of the water haul. It is fair to assume that this will hold for the entire Mississippi Valley System.

The average rail rate of the United States is about 11 mills per ton-mile; hence, the minimum freight-rate saving will be 2.2 mills per ton-mile of rail-haul, or about 1.5 mills per ton-mile of water-haul. On the basis of 60 000 000 000 ton-miles of water-borne traffic by 1950, the total freight rate saving would amount to about $90 000 000 per annum.

Another very substantial economic advantage of waterway transportation is the saving in interest on the difference in capital cost of rail or water-transportation facilities now under discussion. The additional capital requirements for railroad construction as developed in this paper are premised upon an improvement in the efficiency of railroads amounting to about 50% between 1925 and 1950. Then there would be no doubt but that the railroads would earn 5½% in excess of the stipulated fair rate of return, and hence this rate of interest on capital cost may be assumed.

As previously developed 60 000 000 000 ton-miles of waterway transportation facilities at 1 cent per ton-mile of capacity, would cost $600 000 000, whereas the equivalent railroad capacity of 40 000 000 000 ton-miles at 4.7 cents per ton-mile, would cost $1 880 000 000. The difference in favor of waterways is $1 280 000 000 and the interest charge saving at 5½% amounts to $73 600 000 per annum.

It may be argued that this interest on saved capital cost may not be set up to the advantage of waterways as an economic saving, on the ground that it is immaterial to the investing public whether the capital is invested in railroads or elsewhere. This may be true so far as the owners of capital are concerned, but it is not true with regard to industry. The interest on capital invested in an industry, where the product can be furnished at the same or less cost by other methods without using the additional capital, is wasted so far as that industry or the users of its product are concerned.

Capital saved from investment in an industry where it is not needed remains available for investment where it is needed, or as part of a capital surplus tending to reduce the interest rates which are a tax on industry and on the economic welfare of the Nation.

Therefore, the writer presents as his answer to Question (*e*) that the minimum economic advantage of inland waterway transportation on the Mississippi Valley System by 1950 will be an annual freight-charge saving of

$90 000 000 plus an interest-charge saving of about $73 600 000, or a total annual saving of about $160 000 000 based on a waterway freight movement of 60 000 000 000 ton-miles per annum.

## Conclusions

The writer's conclusions, as developed in this paper, are as follows:

(*a*-1).—The annual freight transportation demand of the United States by 1950 will be 870 000 000 000 ton-miles, or 470 000 000 000 in excess of 1925.

(*a*-2).—Railroad renewals and increased operating efficiency may provide for an increase of 240 000 000 000 ton-miles.

(*a*-3).—Additional transportation facilities must be provided for about 230 000 000 ton-miles.

(*b*).—Additional railroad facilities for 230 000 000 ton-miles will cost about $11 000 000 000, or 4.7 cents per ton-mile of practical ton-mile capacity.

(*c*-1).—Additional freight demand of the Mississippi Valley by 1950 will be 120 000 000 000 ton-miles, 60 000 000 000 of which will require additional transportation facilities.

(*c*-2).—The Mississippi Valley Inland Waterway System, when completed, will provide an improved right of way sufficient to accommodate more than 200 000 000 000 ton-miles of freight traffic, if it were available.

(*c*-3).—The growth of waterway traffic on the Mississippi System between 1919 and 1928 has been equivalent to more than 15% annual increase. If this is continued at 10% annual increase with new completed waterways added, it will produce 60 000 000 000 ton-miles per annum by 1950, or the equivalent of 40 000 000 000 ton-miles of railroad traffic.

(*d*).—The cost of completing present approved project waterways and providing transportation facilities thereon at 1 cent per ton-mile of traffic expectancy will be about $600 000 000 for 60 000 000 000 ton-miles capacity of floating plant and necessary terminals.

(*e*).—The economic advantage of completing and utilizing the Mississippi Valley Inland Waterway System by 1950 will amount to a minimum of $160 000 000 per annum.

# RELATION BETWEEN RAIL AND WATERWAY TRANSPORTATION

By E. A. Hadley,[7] M. Am. Soc. C. E.

Synopsis

The proposition to improve and maintain inland waterways at Government expense, particularly on the larger rivers, leads to the consideration of the economic aspects of such an undertaking which may result in a reduction of earnings to other transportation agencies through Government subsidized competition.

The writer endeavors to set forth the situation in such manner as to point out the inequalities which he believes would result from expenditure of the vast amounts of Government funds which would be required to provide and maintain adequate navigation channels on the principal American rivers to be used in competition with the railroads.

The paper traces the development of transportation in the United States and sets forth the present relation of the railroads to the Government through its regulation of rates and profits from operations.

The result of Government operation of barge lines in the Mississippi-Warrior Service is commented upon and comparison is made of the cost of construction of railroads in place of the proposed improvement of the St. Lawrence Waterway.

The paper closes with an appeal for consideration of the economic phases of expenditure of Government funds to foster private enterprise when such funds are secured largely from taxation of the whole people.

Although this subject is sufficiently broad to include transportation on the Great Lakes as well as coastwise traffic where interchange is had with the railroads, the treatment will be confined largely to the relation between the railroads and the inland waterways, as represented by the larger rivers.

## Early Development

In the beginning of the Nation's history waterways were the natural highways. With the invention of the steam engine and its application to boats, their use for transportation purposes became almost universal. The Civil War broke in twain these lines of communication between the North and South and that infant industry, the railroads, ever pushing westward, attracted and took the business, offering facilities cheaper, more convenient, and more expeditious than the rivers.

[7] Chf. Engr., Mo. Pac. R. R., St. Louis, Mo.

It was transportation, particularly rail transportation, that speeded up agricultural development. Water transportation, in the early days, made collection and distribution possible, but the great West would have remained unsettled had not steam been found applicable to the purpose of transportation.

In the "good old days" of steamboat transportation the farmer's wheat came from such fields of the Northwestern States as were adjacent to the water routes and was handled down the river by steamer to the great markets of the time—St. Louis, Mo., and New Orleans, La. Examination shows that the rates were much in excess of any current charges.

To permit shipment by boat the farmer was obliged to pack his grain in 2-bushel sacks costing approximately 20 cents each or, say, 10 cents per bushel. Grain is now hauled in bulk by the railroads from the "Twin Cities" to Chicago, Ill. (425 miles) for 8.1 cents per bushel, or less than the cost for sacking alone prior to the Civil War.

To meet the railroad competition it was necessary for the steamboats to adopt more efficient methods and to provide better facilities. Special grain barges came into existence and did away with the necessity of sacking the grain. For many years following the "period of reconstruction" there was probably the best co-ordination of rail and water transportation that the United States has ever experienced.

The necessity for transfer between barges and railroad cars involved expense as well as extensive elevator facilities at both the north and south ends of water routes. As the sources of grain extended back into the interior and the haul by rail increased into the Northern elevators, it was found more expedient and economical to carry the grain the entire distance by rail to the exclusion of the steamboats and barges.

### Status of American Railroads

The United States, with less than 8% of the world's area and less than 6% of the world's population, has more than 85% of the world's railroad mileage. It is generally conceded that American railroads give the best service at the lowest cost; that no other transportation medium can handle the enormous crops or the immense amount of raw materials, as their lines reach to all producing centers and into all markets of the country, both great and small.

The rivers do not produce any new traffic. What they do haul is taken away from the railroads, which, as a whole, are now equipped to handle a greater amount than that represented by their present traffic plus that handled by the barge lines. It is questionable whether inland water transportation on the rivers can be revived and improved to such an extent as to enable it to compete successfully with the railroads of to-day, which are increasing in efficiency from year to year and rendering it correspondingly more difficult for other methods to compete with them.

### Limitation of Rates and Profits

The statement often made, that the development of the inland waterways and their operation will lower freight rates, is contrary to the facts. River rates are now placed at a percentage of the railroad rates. Therefore, no

incentive exists for the railroads to lower their rates, as the river rates would then be correspondingly lowered and the same percentage of differential would continue to exist.

The Transportation Act of 1920 provides that the railroads shall be permitted to earn a reasonable percentage on the value of their property devoted to transportation purposes. Obviously, any other agency tending to take revenue away from the railroads, whether operated by private capital or subsidized by the Government itself, is not working toward a lowering of rates but, on the contrary, will have a tendency to increase the rates in order to provide gross earnings necessary for the fair return contemplated under the law.

The Government restricts the profits of the railways as it does not those of any other large industry. It subsidizes competition with them as it does not with any other industry, by spending billions of dollars in improving highways and waterways upon which other carriers operate without paying adequately or submitting to such regulation of their service and rates as do the railroads.

## Competition with Subsidized Waterways

The territory known as the Mississippi Basin is the chief wealth-producing section of the United States. This area contains 54% of the nation's population and 66% of its rural population. It covers 64% of the total area and produces 70% of the total agricultural products, 52% of the total manufactured products and 68% of the total exportable products. It is in this territory that the Government is carrying forward its "experiment", under the direction of the Inland Waterways Corporation, to demonstrate the supposed economies of a water-transportation system by improvement of the navigable rivers and operation of barge lines thereon.

It is the privilege of the American people to undertake the development of any transportation agency they desire. On the other hand it is contrary to American principles to expend the money of all the people for the development of an enterprise which, due to its location, can be helpful to but a small percentage of the people and even then only by doing great injury to another branch of the same industry upon which all the people must depend.

If river transportation can be produced at a substantially lower cost to the public than railroad transportation, the public would be justified in encouraging such development and using such a method of transportation in place of railroads. As the railroads cannot be discarded they must be supported. Any arrangement entered into by the Government whereby the public pays more for transportation and the individual shipper less is not economically sound.

## Real Cost of Transportation

It has been stated that:[8]

"Our Great Lakes carry more freight and at a cheaper rate per ton-mile than any other inland waterway system of the world. The annual savings

[8] In an address by the late Edgar Jadwin, Major-General (*Retired*), U. S. Army, M. Am. Soc. C. E., before a joint meeting of the Society of Terminal Engineers and the New York Post of the Society of American Military Engineers.

in transportation costs on the lakes are also greater than the entire cost of all improvements that have been made."

Nothing approaching this situation, however, can be said of river transportation as now sponsored by the Federal Government.

In considering the real cost of any form of transportation it is necessary to take into consideration all factors entering into that service, not only those which are positive in character but also those which may be negative, this latter being best exemplified by the item of taxation. The railroads of the United States pay in yearly taxes almost $400 000 000; the Government-operated barge lines pay nothing. The railroads furnish and maintain at their own cost their right of way, roadway structures, and signal systems. All these items are furnished to the barge lines by other departments of the Government without charge.

If all the costs incurred by the Government through its various departments to maintain navigation on rivers were assembled and charged against the cost of operation of the barge lines, the cost per ton of freight transported would be so enormous that its realization would doubtless discourage further development along these lines. Looking at the matter any way, if the railroads were relieved of taxes and the cost of maintenance of roadway and if their terminals were provided at the expense of the large cities, as is now done for the barge line service, doubtless their rates could be reduced far below those now charged by the barge lines.

The rates now assessed for water transportation are certainly not all that is paid through some source for the service which is rendered. The railroads not only lose the traffic handled by the river, but see a part of their annual tax payments go toward paying the cost of supporting their Government-operated competitor.

The real question at issue regarding the proposed further development of inland waterways is whether or not the cost of transportation to the public as a whole will be decreased or whether only individual shippers would benefit by this service, the deficits through operation and the cost of the improvement work to be paid from taxes or buried in the records of other departments of the Government. If the benefit is to accrue to individual shippers only, then it is unfair to the remainder of the people.

### Results from Government Barge Line

Since 1920 the Mississippi-Warrior Barge Line, owned and operated by the Government, has carried about 7 775 000 tons of freight at an average annual loss of approximately $440 000, based on its own system of bookkeeping, covering transportation expenses only. The public deserves to have the accounts stated in such manner that it may find out whether the Barge Line shippers are paying the full cost of transporting their shipments or whether they are being subsidized, and to what extent, by the Federal Government at the expense of the people as a whole.

At the time the Inland Waterways Corporation was established the people were told that the sole purpose was to demonstrate that river transportation

was a sound investment for private capital. Until this enterprise can be made to show a profit, taking into account capital investment, taxes, and maintenance, and all other items of expense now subsidized by the Government, there can be no hope of interesting private capital in its operation. Another fact to be noted, especially in connection with the present proposals to extend barge service into the Upper Mississippi and its tributaries, is that these waterways are open for navigation only seven or eight months of the year.

Direct expenditures on these natural waterways, including tributaries, have already exceeded $600 000 000. It cannot be considered sound public policy to reduce railroad earnings, impair railroad credit, and render railroad service inadequate in order that a field may be provided for water services, which at best can, and should be, only supplementary to the railroads.

### Substituting Railroads for Canals

The reason advanced for the development of the St. Lawrence Waterway is cheaper transportation costs to reach foreign markets, particularly for American wheat. Available American farm lands are approaching maximum production and the population is increasing. It is possible that by the time the waterway could be made ready for service there would be no grain to export. If there were a surplus there is no assurance that it would be located sufficiently close to the Great Lakes territory to enable it to use the St. Lawrence Waterway.

It has been estimated[9] that three double-track, fully equipped railroads could be built from Chicago to Boston, Mass., at a cost of $260 000 000 each, the total cost of the three railroads being about the estimated cost of the St. Lawrence Waterway; and that each of these railroads, operating throughout the year to its theoretical maximum capacity, could handle eight times as much freight as the proposed waterway. In other words, the three railways would cost only slightly more than the proposed waterway and combined could carry about twenty-four times as much freight.

The New York State Barge Canal has cost more than $270 000 000. Prior to its construction it was estimated that it would handle 20 000 000 tons of freight per year, but in its best year (1928) it handled a little more than 3 000 000 tons. Any one of the railroads operating between Buffalo and New York could have handled this entire traffic without disturbance of its normal business. The canal costs the people of New York State nearly $11 000 000 per year so that the taxpayers would have saved approximately $4 500 000 if all the freight had been handled by the railroads with the State paying the charges, and the shippers would have saved about $3 000 000.

### Taxes as Affecting Rates

Railroad transportation rates, however, are declining while taxes are increasing. Rates have been lowered until in 1928 they produced an income of $850 000 000 less than if the rates in effect in 1921 had been applicable.

[9] "Economic Features of the Proposed St. Lawrence Waterway," Address by Dr. H. G. Moulton, Pres., Brookings Inst., Washington, D. C., before the Traffic Club of Chicago, on March 21, 1929.

The total earnings of the Class I railroads in the first quarter of the calendar year 1929 were about $8 000 000 greater than in the first quarter of 1926.

Their taxes, however, were more than $7 500 000 greater, the net result being that the public took back in increased taxes almost all that it paid in increased earnings for the handling of a larger freight traffic. The net operating income earned represented an increase of about $37 000 000 over the first quarter of 1926, but it was entirely due to reduction in operating expenses that was secured in spite of advances in wages.

In an address[10] in Washington, President Coolidge issued a warning to the American people regarding the menace to National prosperity that is presented by the enormous increases in expenditures made by the Government and the resulting increases in taxes. He stated that the cost of State and local governments increased from $3 900 000 000 in 1921 to $7 931 000 000 in 1927 and that such a heavy drain on the earnings of the people is the greatest menace to the continuance of prosperity.

The National Industrial Conference Board has emphasized[11] that the Nation's total tax bill in 1923, only five years after the World War, was $7 234 000 000, while in 1928, ten years following the close of the war, it was $9 169 000 000, an increase within the five-year period of 25 per cent. Taxes are increasing faster in proportion than either the population or the National income. In 1923 they were less than $65.00 per capita; in 1927, $76.50 per capita; and in 1928 still more. In 1913 taxes were only 6.4% of the National income. In 1923 they were 10%; in 1927, 12%; and in 1928, 12½ per cent.

## Success without Subsidy?

The railroads as a whole are not opposed to river transportation if it can be successfully conducted without being subsidized. They have co-operated in a constructive manner in the provision of port terminal facilities and in the application of joint rates. They should not be compelled, however, to meet a competition that cannot stand alone. Further expenditures by the Government to extend river transportation will certainly have to come out of revenues received from taxes, which are already burdensome enough.

The present is an era of great and rapid change—of an economic nature—perhaps the greatest the country has ever experienced. It is not confined to any particular section but is nation-wide and varied in character. Many of these changes are occuring faster than corrective formulas can be devised and this warrants unusual and careful consideration of all measures designed for relief.

The people of the United States are optimists, due largely to the fact that for more than 150 years they have had almost continuous growth and prosperity and have developed a sense of confidence and faith that, as a people, they can overcome any critical situation.

[10] Address before the Sixteenth Regular Meeting of the Business Organization of the Government, at Memorial Continental Hall, Washington, D. C., on January 23, 1929.

[11] "Cost of Government in the United States, 1926–1927", pub. in 1928, by the National Industrial Conference Board, Inc., pp. 59 and 82.

With growth in size and strength the Nation must use a proportionately greater effort to comprehend the enlarged scope of economic effects, being not too hasty in applying untried or ill-considered methods of either assistance or control. It must not lose sight of the fact that in the creation and distribution of wealth the public must bear the financial burden caused by every error made in the application of economic theories. The welfare of the whole people must be safeguarded by those in charge of public affairs.

## DISCUSSION

LEWIS C. SORRELL,[12] ESQ. (by letter).—The necessity of some intelligent attempt at forecasting long-run traffic developments, where large capital expenditures for transportation are contemplated, is matched by the extreme difficulty of doing so. The construction of a railway or improved waterway involves the investment of funds for many years; and the wisdom of doing this evidently depends upon the probable demand for such an instrumentality. Any economic unit, such as a nation or a region, is confronted with two questions, namely, how much transportation should be provided, and what instrumentalities should be created to furnish the service? Proceeding from a premise of competition, new facilities might be furnished wherever they could provide a service at less cost than existing agencies; and such generally has been the procedure in the past. A disposition exists to-day, however, to proceed from a premise of co-ordination; and this requires consideration of the effect of new facilities upon the pre-existing ones.

Co-ordination requires, in the case of transportation, a determination of the instrumentality best fitted economically to perform the task; or, otherwise stated, an allocation of the entire task of transportation among the several instrumentalities, so that the aggregate cost will be at a minimum. Considered generally, this viewpoint necessitates a calculation of the entire demand for transportation services, and of the cost of meeting that demand through furnishing different types of facilities. Considered at any given moment of time, the question often becomes that of determining how increasing demand may be most economically satisfied. This is likely to be the case with a dynamic economic system, in which population and wants are increasing possibly at varying rates.

Most transportation facilities, such as highways, railways, and improved waterways, involve heavy outlays of fixed capital, which will be "sunk" for many years. Long-time investments necessitate long-run forecasting of the need therefor. Yet the difficulty of such forecasts cannot be ignored; and the longer the period of time, the greater the difficulty of an accurate forecast. Predicting traffic on American railroads for the next three months, or even for the next year, may be done with considerable accuracy; but attempts to state the probable traffic in 1940 or 1950 involve an appraisal of many elements, some of which are probably unknown to-day. The problem is essentially speculative; almost as much so as it was in the days when the transcontinental railroads were projected. Hence, one must approach such a task with two attitudes, namely, the methods used should be carefully scrutinized for possible errors, and the results even then cannot be accepted too tenaciously. One who essays such a task cannot be held to strict proof of the issues, for such an attitude would probably have prevented the consummation of many improvements in transportation.

Mr. Cornish adopts the method of calculating the probable demand for transportation in the United States in 1950, and then considering whether a

[12] Prof. of Transportation, The School of Commerce and Administration, Univ. of Chicago, Chicago, Ill.

substantial portion of the increment might not be supplied at lower cost by improving the Mississippi River and its tributaries. Obviously, the two most significant terms of this method are demand and comparative cost. Demand he identifies largely with ton-miles, a unit customarily used to express the quantity of service rendered in carrying freight over the railroads. Two relatively minor limitations of this method may be noted. The unit of demand adopted for this study is customarily used, because it readily submits to statistical methods. Quantities carried may readily be combined with distance, in ton-miles and passenger miles; and records of these quantities are available for many years. This permits calculation of trends and the adoption of forecasting equations. It must not be overlooked, however, that the transportation service, which is the subject of demand, is much more than weight and distance; it is also a matter of total cost, frequency, dependability, in-transit service, reliability, financial responsibility, speed (or minimum over-all time), and legal liability. These qualitative aspects, as yet, have not been compounded into any unit. The caution must be injected, that a study of aggregate demand in terms of ton-miles will hardly afford a basis for determining what the apportionment of future demand is likely to be, as between railways and waterways, when that allocation must depend upon the free choice of shippers.

It has been customary, too, in attempting predictions of traffic growth to use railway traffic as evidence of the general development. In the past, when highways and waterways played a less prominent part than they do to-day, probably no large error resulted from the assumption that the general tendency was the same as that manifested in the growth of railway business; but the recent growth of highway and waterway traffic renders railway traffic less accurate as a barometer of total traffic. This consideration, together with the preceding one relating to the unit of demand, does not necessarily invalidate forecasts based upon them; it simply emphasizes the fact that tools heretofore used are somewhat inadequate for the purpose.

More serious is the assumption that underlies the method of measuring future traffic demand. The method used by Mr. Cornish conceives that the growth of demand for railroad transportation is a function of time. Because of the difficulty of forecasting demand, he concludes that the "best solution lies in assuming that the trend of transportation progress in the United States during the past forty years will continue for the next twenty years." A time series of data is charted from 1890 to 1926; and the trend of that series is projected to 1950, at which date it is estimated that American railroads will probably enjoy a freight traffic demand of about 870 000 000 000 ton-miles.

It is instructive to compare these figures with several other attempts at long-range prediction. In 1924 John Balch Blood, Valuation Analyst of the Interstate Commerce Commission, prepared a study and forecast of railroad traffic—passenger and freight. He adopted the premise that such demand is a function of population, rather than of time; and from his study of the trend of population and traffic he concluded[13] "that ton-mileage varies approximately as the third power of population." His forecast provoked much

[13] *Railway Age*, Vol. 76 (1924), pp. 369–371.

criticism, especially as regards statistical methods, which were thought to yield extravagant results. The Bureau of Statistics of the Interstate Commerce Commission prepared a study, based upon the years 1900-1915 (selected to eliminate the extreme fluctuations of the World War and post-war periods), the results of which were utilized by the Commission in the reduced rate cases of 1922.[14] In 1923, the Chamber of Commerce of the United States made a report on the "Probable Freight and Passenger Traffic of the Railways of the United States of 1933". Of course these different attempts at forecasting used somewhat different methods and different terminal years. In 1924, L. A. Abbott, a Statistical Analyst of the Interstate Commerce Commission, discussed the methods used in the several estimates, and supplemented them with an independent estimate of his own, bringing them all down to the same terminal year 1943.[15] The several forecasts yielded the following results:

| Forecast for the year 1943 made by: | Billions of ton-miles. |
|---|---|
| Interstate Commerce Commission | 494 |
| U. S. Chamber of Commerce | 727 |
| L. A. Abbott | 623 |
| J. B. Blood | 1 167 |

So far as concerns the demand for railway transportation, it is unsafe to assume that the trend for the next twenty-five years will be the same as that for the last forty. A careful study of the growth of freight traffic on American railroads shows that a noticeable change in the rate of growth occurred about 1910. Dr. M. O. Lorenz, Director of Statistics of the Interstate Commerce Commission, recently made this statement:[16]

"From 1900 to 1914, freight ton-miles approximately doubled, while the ton-miles of 1928 were only about 50% greater than those of the fiscal year 1914. Furthermore, the passenger traffic and tons of freight have failed to maintain the same absolute amount of increase per annum in the second as compared with the first half of the period 1900-1928. Ton-miles of freight, however, show about the same annual addition in absolute amount from 1900-1914 (fiscal years) as from 1914 (fiscal) to the calendar year 1928, the annual addition having been 10.5 billions in the first period, and in the second 10.2 billions. It is not safe to predict the future solely by the past, because new forces come into action. The development of the motor vehicle was such a force, the effect of which on railroad traffic was not fully appreciated in 1915."

Generally speaking, it would seem as though methods of forecasting the trend of traffic, which are based upon the ratio of demand to population, would be somewhat more valid than those relying upon a time series alone. Mr. Abbott questions this,[17] holding that comparison of the different forecasts suggests that those using population growth as a basis have introduced an unnecessary element. It may be said that the time series does include all existing variables, without assigning weight to any single one. The writer has developed two equations of per capita ton-miles, using 1899-1926 and

[14] Interstate Commerce Comm. Repts., Vol. 68, p. 701.
[15] *Railway Age*, Vol. 77, pp. 243–247 (1924).
[16] As reported in the *United States Daily*, July 15, 1929.
[17] *Railway Age*, Vol. 77 (1924), pp. 243–247.

1910-1926 as periods for the calculation of the trend. Linear equations were used in the following form:

(*a*) Fiscal Years, 1899-1926; Centered, 1912-1913:

$$Y = 2\,849.890 + 36.698X \ldots\ldots (1)$$

(*b*) Fiscal Years, 1910-1926; Centered, 1918:

$$Y = 3\,227.0156 + 50.4473X \ldots\ldots (2)$$

in which, $Y$ is the traffic, in ton-miles per capita; and $X$ is the ratio of demand to population.

Equation (1) gives 4 207 ton-miles per capita, and Equation (2) 4 841 ton-miles per capita, as the expected demand in 1950. Mr. Raymond Pearl gives[18] the expected population of Continental United States at that date as 148 678 000. Applying this estimate to that of expected ton-miles per capita, gives 623 000 000 000 and 716 000 000 000, respectively. Most estimates, except those of Blood, would probably assign a considerably smaller value to the expected ton-miles for 1950 than the figure given by Mr. Cornish.

It is obvious that the actual demand for transportation is a function of many variables. Increasing population, together with an improving standard of living, would ordinarily tend to increase the demand for transportation, as expressed in ton-miles. There are numerous forces, however, that work in the opposite direction. Increasing decentralization of industry, substitution of transmission of energy for transportation of coal, reduction in the amount of coal or other raw material required in production, substitution of materials involving short hauls for those requiring long hauls, and importation of commodities formerly produced at home, are a few instances of factors that must be considered in estimating the probable future traffic on inland transportation facilities.

*Cost of Transportation.*—If the calculation of probable future demand is beset with difficulties, the computation of comparative cost is even more intricate. This is so, not only because cost data are so difficult to secure, but also because agreement may not exist concerning the items that should properly be included. That cost varies with the purpose to be served, and the problem to be solved is well recognized. Where, as with transportation instrumentalities, a large volume of overhead costs exists, questions of policy concerning the apportionment of such overhead may complicate the solution. Likewise, joint expenditures, as for navigation and flood protection, may raise the issue concerning the proper sum to be charged against commerce. Where a long period of time is required to construct the enterprise, interest and operation deficits during such construction period must be considered. Similarly, the period of time required to develop traffic to the point, where the facility enjoys a degree of utilization necessary to realize the economies of its use, may accumulate a considerable burden of "developmental expenses", sometimes capitalized under the expression, "good-will".

The instant problem involves a choice between two alternative methods of meeting an anticipated increase in the demand. Part of this assumed increase may be accommodated by an improved waterway, or by increasing the rail

[18] "Studies in Human Biology," p. 590.

capacity. The choice of alternatives involves an approximation of the total economic outlay required for one instrumentality, as compared with that required for the other.

The method used by Mr. Cornish is reduced to five logical steps: First, he ascertains the probable increase in railroad investment necessary to afford the requisite increase in capacity. Second, he makes a similar estimate for the waterway. These two estimates are reduced to capital costs per ton-mile of capacity. Third, although not expressly so stated, he evidently regards rail operating costs as the present average per ton-mile earnings; this, of course, includes return on investment and taxes. Fourth, he takes the present earnings of the Inland Waterways Corporation as evidence of carrier-operating costs on the waterway. Fifth, he computes the saving to the shipper under the present 20% differential in water rates under the rail, on the assumed tonnage likely to be realized by the waterway, and adds thereto interest on the difference in capital outlay for waterway and railway, respectively. Limitations of space permit only cursory examination.

*Railroad Capital Outlays.*—Without attempting a detailed check on the trends in the capital outlays for the several kinds of railroad property, and without essaying the difficult task of estimating the amount of unused capacity now existing in the railroad plant, it may be said that an estimate of an annual investment of about $400 000 000 per year, to provide better freight-carrying facilities, would probably fall within any competent railroad opinion. The exact amount of such outlays will depend not only on the needs of increasing traffic, but also on the desire to reduce costs by substituting capital for labor, and on the necessity of complying with public demand for terminal improvement and grade separations.

*Waterway Capital Outlays.*—Without checking the estimates of equipment and channel improvement costs, necessary to carry the estimated traffic increase, it may be observed that Mr. Cornish disregards capital outlays already made for river improvement and terminals, except the terminals used by the Federal Barge Line. Doubtless, it is difficult to estimate them, because, in part, they are joint with the cost of flood protection. Where a plant has been built, such that its productive capacity greatly exceeds the market, it may be a justifiable procedure to treat a considerable part of that capital outlay as a sunk cost; "a matter of historical interest but not affected by any subsequent acts of the management".[19] The premise of this argument is not a transportation agency larger than needed, but rather one to be enlarged to meet the demand. The outlays already made for the canalization of the Mississippi will be used to carry that increased traffic, as well as the future capital investment; and it would seem that the annual cost on account of total capital invested should be prorated against the total traffic anticipated in 1950.

*Railway Operating Costs.*—These, of course, are not identical with average freight receipts per ton-mile; but for purposes of rough comparison that is not very material. Mr. Cornish considers that the present average receipts of 11 mills per ton-mile are not fully compensatory to railroad capital; and

[19] "Economics of Overhead Costs," by Clark, p. 180.

assumes that increasing density will probably render the present freight rate level fully so. If railroads now existing in the United States can achieve a density of 1 600 000 ton-miles per mile of all tracks by 1950, assuming no other changes in cost, it is likely that a substantial reduction in rates could take place. This would lessen the savings due to waterway construction.

*Waterway Operating Costs.*—In this calculation Mr. Cornish takes the present ton-mile earnings of the Inland Waterways Corporation as evidence of carrier cost when using this agency. These figures do not include taxes and interest, which a private carrier must meet; possibly, he assumes that expected improvements will take care of these. In order, however, to present figures comparable with the rail carrier's earnings, the taxpayer's contribution should be considered. This would require something added for channel and terminal maintenance and operation, interest on the investment, and taxes foregone by the public on capital thus invested. With the present utilization of that waterway, the inclusion of such costs would probably produce a somewhat unfavorable result; but with the assumption of a much greater utilization in 1950, the added cost per ton-mile because of such overhead costs would be much smaller.

*The Economic Benefits of the Waterway.*—These are calculated by applying the present freight rate differential to the expected traffic in 1950, and adding thereto interest saved by reason of the much smaller investment required to carry 40 000 000 000 railway ton-miles by water than would be needed to carry that traffic by rail. The estimate of an annual saving of about $160 000 000 would not be impossible of attainment, provided the assumed traffic density on the waterway is actually achieved; but the method of demonstrating this seems confused. The present differential of 20% is not based upon differences in operating costs; supposedly, it is based upon the concession to the shipper necessary to induce him to use the waterway in preference to the railway. That is, it is more nearly a measure of the difference in the valuation of the two services; and, at present, that saving to the shipper is offset in part at least by the taxpayer's contribution in the shape of non-taxable and non-interest earning capital. The saving is not a net social gain; but even supposing that this differential by 1950 did come to represent a net social gain, one would question the accuracy of adding interest saved to savings from freight rates in order to measure the total benefits. This is so because the freight rate differential then would be due largely to savings attributable to a smaller capital outlay for the waterway than for the railway.

A clearer procedure would be to ascertain the probable operating costs of the waterway carriers, not including returns on capital in the waterway itself, and to reduce these to a ton-mile basis. Next, calculate the capital investment in channel and terminals necessary to carry the assumed traffic. Compute the maintenance and channel operating costs, interest costs, and taxes that might be assessed against such a waterway itself; reduce these overhead costs to a ton-mile basis. Add this ton-mile toll to the ton-mile operating costs and thus arrive at the probable social cost of a ton-mile of water transportation in 1950 with an assumed utilization of 60 000 000 000 ton-miles per

annum. For purposes of comparison equate waterway and railway ton-miles on the basis of 1½ to 1. The difference between this figure and the average probable railway freight receipts per ton-mile with the density premised for 1950, represents a net social saving due to the use of the waterway instead of the railway.

The remaining issues must be commented upon briefly. Although the expression, "efficiency", commonly means the ratio of output to input in terms of work, and may possibly be used to compare use with capacity to render service, nevertheless it seems preferable to adopt the term, "utilization", for the latter concept, rather than the over-worked term, "efficiency". In calculating the probable growth of waterway traffic on the Mississippi System, it hardly seems wise to include the Panama Canal; as in the comparable case of railway location, traffic studies should be confined to agencies the circumstances of which are not too dissimilar. Should the estimated traffic fail to materialize, the burden of overhead costs per unit of waterway traffic would be considerably increased, and the savings, of course, correspondingly diminished. The same result will follow if the estimate of capital expenditures yet required is considerably below the actual sum needed.

This is in no sense captious criticism. Mr. Cornish has done good service in attempting to give a quantitative expression to the variables in this problem. Transportation must be studied comparatively, with reference both to the service and the cost. Economic, engineering, and accounting methods must all be utilized in the process. The subject bristles with difficulties; and early attempts at solution will of course involve errors. It may not be too much to hope that further studies of this kind will follow; and that as a result something like a general acceptance of general principles may accrue, and that methods of solving these problems of transportation co-ordination may steadily improve.

R. B. KITTREDGE,[20] M. AM. SOC. C. E. (by letter).—At this time, when extravagant claims both for and against inland waterways are being so freely made from numberless platforms, and so widely discussed in the public press, there rise in many minds questions of reasonable doubt as to whether the further development of inland waterways would result in a waste of the taxpayers' money or in a substantial means of relief to a distressed Middle West and to a depressed agricultural industry. The paper by Mr. Cornish presents the opportunity for thoughtful discussion by the profession, which should do much to clarify the situation.

One of the conclusions of this paper is that, after the completion of waterways now authorized, the Mississippi Valley Inland Waterway System by 1950 could produce annually the equivalent of 40 000 000 000 ton-miles of railway transportation at a minimum economic advantage of $160 000 000 per annum. If true, this is important.

Apparently, however, the conclusion has been drawn as the result of an analysis which includes two errors of major importance: First, figures which cover the total cost of railway transportation have been used in comparison

[20] Prof. of Transportation Eng., State Univ. of Iowa, Iowa City, Iowa.

with other figures which include only a part of the cost of waterway transportation; and, second, the railways have in effect been charged not only once but twice with the interest on a substantial part of their investment. When these interest charges are estimated correctly, and when the costs compared are the total costs, the logical conclusions as to the economic advantage of completing this waterway system may of necessity be materially modified.

Mr. Cornish has estimated at $1 880 000 000 the investment required to expand railway facilities for an additional 40 000 000 000 ton-miles of railway traffic. He has also estimated at $600 000 000 the investment necessary to supply an equivalent amount of waterway transportation by the completion of certain partly constructed waterways in the Mississippi Valley. Capital to the amount of $1 280 000 000 is thus assumed to be saved for investment elsewhere if, by the completion of these waterways, the indicated expansion in railway facilities is indeed avoided. At this point, by adding to an estimated $90 000 000 annual saving in freight charges the sum of $73 600 000 to cover the annual interest, at 5¾%, on this additional investment of $1 280 000 000, Mr. Cornish arrives at a figure of $160 000 000—this representing, in round numbers, the minimum yearly economic advantage of waterway transportation on this Mississippi Valley System. In this computation consideration has nowhere been given to a considerable part of the cost of waterway transportation, and interest charges have been handled incorrectly.

The author's $90 000 000 of annual saving in freight charges was estimated by using rail rates of 11 mills per ton-mile, and water rates of 80% of the equivalent rail rates. The rail rates thus used would cover the total cost of the rail transportation, including taxes, all railway maintenance costs, and interest on the total railway investment. On this waterway system, rates fixed at 80% of the equivalent rail rates could not be expected to cover the total cost of the waterway transportation, including an allowance for taxes, the maintenance costs of the waterways, and interest on the additional investment required to complete their construction.

For some time past, the average railway freight rate has been approximately 11 mills per ton-mile, and railway revenues over this period have covered the total cost of railway transportation, including taxes, and all maintenance costs, and whatever interest has been paid on railway investment. On inland rivers and canals, with the exception of a part of the Ohio River System and of the connecting channels of the Great Lakes, water rates at 80% of the equivalent rail rates have not been sufficient to cover the total cost of the waterway transportation. The basis for such rates is what the traffic will bear and is not what the transportation by water actually costs. Low rates on inland rivers and canals have been possible only because the taxpayers have constructed and maintained the waterways and have also waived taxes and interest upon them. If the railways were similarly relieved of maintenance, taxes, and interest, railway rates might well be cut in two. This does not mean that transportation development on inland rivers is never justifiable, but it does mean that, before its economic justification can be established, full consideration must be given to its total cost.

When waterways are constructed and maintained at governmental expense, the saving to the shippers involves a sacrifice by the taxpayers which by no means should be overlooked. Maintenance costs of the waterways, interest on their construction cost, and taxes not assessed, are all matters of more than academic interest and, because this is true, they all deserve careful consideration. Although a part of the cost of waterway transportation may be concealed for a time, in the end it cannot be escaped. The burdens on the taxpayers may be less in evidence than are the savings to the shippers, but, by virtue of their being less apparent, they are in no sense less real.

Instead of deducting from the $90 000 000 estimated annual saving in freight charges the sacrifices required of the taxpayers to make this saving possible, Mr. Cornish has added $73 600 000 as representing 5¾% interest on $1 280 000 000 of the railway investment. This interest has been added in spite of the fact that, when railway rates were estimated at 11 mills per ton-mile, interest on all the railway investment, including this $1 280 000 000, had already been charged once against the railways. Mr. Cornish clearly estimated that railway rates of 11 mills per ton-mile would be sufficient to cover interest on all the railway investment. Interest on a part of this investment should not be charged against the railways again.

If, by constructing waterways, $1 280 000 000 of capital, which would otherwise be invested in railway facilities and earning 5¾% interest, could indeed be released for investment elsewhere, some benefit would undoubtedly result to the credit of the waterways, although such a benefit would not amount to any substantial part of $73 600 000 annually. The benefit of releasing for investment elsewhere capital already earning 5¾% interest would not amount annually to another 5¾% of the capital.

Wherever the saving in freight charges is less than the sacrifice required of the taxpayers, the construction and operation of inland waterways would result in an increase in the total cost of transportation. In the face of this condition, the economic justification of the waterways must be based squarely on some benefit in addition to the saving effected in freight charges.

Other benefits, in addition to the savings in freight charges, and at the same time certain other disadvantages, in addition to the contributions by the taxpayers, would follow the development of an inland waterway system. All these, of course, should be carefully evaluated before drawing any final conclusion as to the economic justification of waterway transportation.

Mr. Cornish has clearly formulated certain definite questions with reference to railway and waterway transportation, and he has courageously given both his own answers to these questions and the process of reasoning which lay behind them. Inevitably some errors will creep into so comprehensive a discussion; and the writer believes that errors have been made which result in over-estimating the value of waterway transportation. Errors which may exist in the paper, however, should not be allowed to obscure all of value which there remains.

The completion of this Mississippi Valley Inland Waterway System may be justifiable; the advantage, however, from a purely economic standpoint, of its

immediate completion and use has not to the present time been convincingly demonstrated.

HENRY A. PALMER,[21] ESQ. (by letter).—An understanding of a few fundamentals should precede any consideration of inland waterway development, or the lines along which such development should proceed. Some of them do not seem to be understood generally.

The movement for the development of inland waterways as an agency for the transportation of freight is due to (1) the passion of the engineer for the utilization of natural waterways; (2) the desire of certain localities and business interests for lower freight rates—no matter at whose expense; and (3) the willingness of demagogic politicians always to be "for" what they think their constituents desire.

Any policy of this sort, however, should be based on something more sound. There is nothing sacred about any kind of transportation and, if it is found that water transportation fills a need that can be supplied in accordance with sound and reasonable economy, it should, of course, be supplied. Indeed, it will be supplied, because capital is constantly on the lookout for such opportunities; but it ought not to be supplied under any form of paternalism or conditions that require support to be furnished by the public in order that those who benefit may prosper.

Thus, wherever there is, on adequate and fair investigation, found to be a reasonable demand for the development of a waterway and a reasonable assurance that traffic will seek it, once it is developed, the Government should undertake to develop that waterway. The development, however, ought to be with the understanding that operators of transportation on it shall be subjected to the same sort of regulation that governs their competitor, the railroad; that rates shall be based on a real cost study, which has never been made; and that operators shall pay into the public treasury a reasonable fee for permission to use the waterway as a place of doing business for profit.

Under present conditions inland waterway operators are permitted to make rates arbitrarily 20% less than rail rates. There is no economic basis for that differential; that is, no one knows just how much less the cost of water transportation is than that of rail transportation, if any. Waterway carriers make their own regulations and do things for shippers that the railroad companies, under strict regulation, are not permitted to do.

Furthermore, whatever else may be permitted, the Government should retire from the transportation business of the Mississippi and Warrior Rivers. Government in business of any sort is not in accord with approved public policy. In this particular case it causes sad complications because the Government corporation that operates this business insists on showing a profit, and that profit is computed with no overhead expense, such as a private operator must set up—no taxes, no insurance, and no cost of capital. For that reason, it is not a fair exhibit of what can be done in waterway transportation, although Government operation on these waterways purports to be an experiment for the purpose of demonstrating to private capital what can be done. Of course,

[21] Editor and Mgr., *The Traffic World*, Chicago, Ill.

private capital will not be fooled, but the public is fooled and has an extremely false idea of the cheapness of water, as compared with rail, transportation. This confused idea prevails even in Congress.

Much is said in favor of developing waterway transportation on the theory that the railroad companies may not be able to take care of the country's growing traffic. There can be little to this if the Government carries out the spirit and even the letter of the Transportation Act of 1920, which is that the railroads shall be enabled to earn a fair return on the money invested in them. If they are permitted to do this they can be counted on, in their own interest, to make the extensions necessary to care for increasing business.

Admit for the sake of the argument, however, that the railroads may not be able to cope with increasing traffic demands, as time goes on, either because they are incompetent or because they are so restricted in earnings as not to be able to do the things that ought to be done and that they would like to do. Inland waterway development might then become advisable; but why develop the waterways under unfair conditions, even then? Why not place them on a sound economic basis at once, instead of providing here and there facilities for those who can use them at the expense, in part, of the people as a whole? Why not make those who use them pay for what they get? Certainly, no one in his senses has ever advocated such a system with respect to rail transportation; but, when the subject is carefully thought out, if the Government concludes that it must provide cheaper and more transportation facilities, why should it not build a railroad, for instance, between Chicago, Ill., and New Orleans, La., charge rates 20% less than the rates it permits privately owned railroads to charge, pay the deficit out of the public treasury, and then tell the people not only that it is giving them low rates, but that the operation is profitable? Any one capable of thinking can see that such a thing would be unfair to the railroad companies, subversive of sound transportation policy, and indefensible in economics. Yet what is the difference, in principle, between such a course and the one that is being pursued?

Selfish and unsound views with respect to this question may be expected from those who have interests at stake—the railroad companies, on the one hand, who do not want this competition, and shippers, on the other hand, who can use waterways and can profit by the low rates offered. Engineers, economists, and statesmen, on the other hand, ought to clarify their views and act in accordance with common honesty and sound practice.

J. Parker Snow,[22] M. Am. Soc. C. E. (by letter).—The Symposium sets forth an imposing array of data on various types of transportation as well as many valuable comments on the ethics of Government improvement of public ways by land and water. The discussion here concerns the paths or ways of transportation rather than the substance carried or the commercial aspects of the great subject; and railroads and waterways are the special ways in question. Passenger traffic on these ways seems to be a decreasing factor at present, and freight traffic only will be discussed herein.

[22] Cons. Engr., Boston, Mass.

To treat the subject rationally it must be recognized that there are two fundamentally different classes into which these ways naturally divide. Railroads are economically essential monopolies, privately owned and operated, while waterways are of two kinds. Artificial canals, whether owned privately or by the Government, are properly, like railroads, essential monopolies; while the sea, lakes, and navigable streams are, like highways, properly free for all who furnish the vehicles which they use. Ways of the first kind are common carriers and should be under public regulation. They are commercial ventures; no one but their owners can use them, and the traffic they carry must pay rates for the service. On the other hand highways and natural waterways are open to free competition to all proper use. They are not, speaking broadly, well adapted for use by common carriers. General Ashburn intimates this as applying to waterways. His Table 1 shows a slight net income in common carrier service on waterways for 1928; but, if a fair return on cost of equipment and for depreciation had been included, the net would have been in red type. If freight rates were computed on a rational basis, a just comparison of them could be made which is impossible under the present American method. The German method for a generation or more has been to fix the rate on the sum of the costs at each end of the run and that of the line haul. If this method were in use in the United States much fairer comparison could be made than with the rates now existing. Street-car lines occupy highways and are common carriers, but they furnish their own track and vehicles and are necessarily in the first classification. Even buses must be so classed if used as constituent parts of car lines or railroads, but sound judgment is needed in granting or denying permits for competing bus lines.

Ways of the second class must be adapted and maintained by the public. Municipalities, with assistance from the State and Nation, handle highways, while the Federal Government maintains the waterways. Proper maintenance means improvement to keep step with advancing means of transport. The sums spent to make and keep harbors and navigable rivers properly usable seem enormous, but they are small compared with the vast aggregate sum spent on highways. The cost of improving highways can happily be kept reasonably low to the common taxpayer by means of the gasoline excise. Improvement of natural waterways must be done by the Government; it is not subsidy; it is justifiable improvement, and there seems to be no way to pay for it except by appropriations from the Treasury. Unhappily, the securing of such appropriations sometimes leads to "log-rolling bees" in Congress. Whatever the difficulties may be, however, public ways must be kept abreast with the march of progress.

Railroads are old; vast progress has been made in developing means of transport since their inception. Naturally, these new means encroach on the business that the railroads would like to handle, but, if the railroads cannot do the work better or cheaper than the new means, they will be passed by just like the canal-boat, the freight wagon, and the stage coach a century ago. The railroads, however, are still the backbone of this country's interchange of goods. They should be free to use public ways by land or water

if they can compete with the open competition naturally inherent to such ways. For instance: If a train-load of goods stands at St. Louis, consigned to New Orleans for export or for domestic distribution; and if waterway transport by means of the magnificent channel maintained for the public by the Government is enough cheaper than rail transport to pay a railroad for installing appliances at both ends of the route to transfer cars between land rails and rails on car-floats, said floats and their propelling power being the property of the said railroad, then, the railroad should be allowed to establish such facilities, not as a monopoly, but on the same basis as railroad trucks are now allowed to distribute goods *via* city streets. If this type of transport is cheaper than the established rate by rail, it should be the base for the standard rate to be applied to goods of the class that can admit the slower rate of movement. A rate of 80% of the rail rates is unscientific and absurd.

Motor vehicles adapted for use on highways have changed the present business status. This may be called an oil-traction age. If railroad heads would give more effort to develop oil-electric locomotives to replace steam traction instead of expending their energies in the contest to be the "big boss" in the preparation for consolidation by straw corporations and other means, the case of the railroads might look better.

BAXTER L. BROWN,[23] M. AM. SOC. C. E. (by letter).—In accepting the Hoover Medal on April 8, 1930, President Hoover stated:[24]

"With the development of our great national tools, our engines, our railways, our automobiles, our steamships, our electric power and a score of other great implements, together with the supplies of material upon which they depend, the engineer has added vastly to the problem of government, for government must see that the control of these tools and these materials are not misused to limit liberty and freedom, that they advance and do not retard equality of opportunity amongst all our citizens. * * * But when the problems which these great tools create come to the door of government, they are at once emotional problems, * * *. Our greatest difficulty in dealing with these problems of government is when the emotion comes first. Facts and the technical knowledge come but slowly or are often lost in a sea of embittered controversy."

Transportation has been one of the greatest problems of mankind since the earliest days and will so continue until the end of time. Competition of the various methods of transportation is the best incentive for its constant improvement, but such competition must be along fair and just lines, or it will be "misused to limit liberty and freedom" and "retard equality of opportunity amongst all our citizens." It was this thought that caused the passage of the Sherman Act.

Owners of the best and shortest routes, where the cost of transportation is naturally less than by any other route, should be protected in their advantage and allowed to profit by their foresight, in being the first in the field, or, by their sagacity, in securing the best available facilities. Obviously, they will get the "cream" of the business, and competing lines must be satisfied with the less desirable class of business, and they must handle it for a smaller

[23] Cons. Engr., St. Louis, Mo.
[24] *Mechanical Engineering*, May, 1930, p. 528.

margin of profit. It would be palpably unjust for the Government to interfere and endeavor to reduce or remove the natural advantage enjoyed by the owner of the best system, so that others could continue in operation.

"Equality of opportunity" does not mean that any individual should refrain from exercising his talents for his own benefit, in order that another person less fortunate in ability should have a better chance to acquire the desirable things in life; nor, having possession of these better things, whether acquired through his own exertion or by inheritance, is it necessary for an individual to relinquish these advantages, for the benefit of others less energetic or less far-sighted than himself or than those who have gone before him.

The daily newspapers of April 26, 1930, reported that the House of Representatives had passed the River and Harbor Bill, carrying $15 000 000 for improvement of the Missouri River between Kansas City, Mo., and Sioux City, Iowa. It is questionable whether all the freight carried on the river between these two points during the period, 1930 to 1950, will be worth that much. Does any one believe that a proposition to spend that amount of money on that stretch of river for the purpose of putting it into condition to carry freight in competition with the railroads could be put before any group of financiers or bankers with the slightest hope of getting any favorable consideration?

There seems to be a disposition to bolster up unprofitable enterprises by subsidizing them by the Government, State, or city. From the standpoint of economical and efficient management, there is no reason for the existence of any institution, outside those classed as charitable, which is not self-sustaining.

Upon whether one views the relation between rail and Mississippi River transportation from the emotional or from the clearly commercial standpoint, depends the answer as to whether river transportation, as exemplified by the Government's experiment under the name of the Inland Waterways Corporation, is a success or a failure.

This governmental agency is engaging in unfair competition in the attempt to demonstrate that it is a commercially profitable enterprise. In the preparation of financial statements to be used in support of this argument, no consideration is given to certain expenditures which would necessarily be included by a privately owned enterprise, such as interest on investment, and taxes. The enterprise is profitable only to those who are so fortunately situated as to be able to take advantage of its arbitrary rate of 80% of the rail rate.

An examination of the published records of the Corporation shows that 1928 was apparently the best year, when a net income of $327 712 is indicated. If, in this year, the Corporation had been required to pay taxes in the same ratio as the railroads (6.37% of their gross revenues) its expenses would have been increased $427 272. If interest at 5% had been charged on the depreciated value of its equipment, there would have been an additional charge, to expenses, of $785,647, making a total of $1 212 919. This indicates an actual loss of nearly $900 000.

The Corporation's annual report for 1923 states that Congress had appropriated, up to 1923, nearly $750 000 000 to create navigable streams and canals.

It is not stated what portion of this could properly be allocated to the channels used by the Corporation. Interest on this sum at 5% is $37 500 000, a substantial part of which is properly chargeable to the Corporation's operation and enters into the cost of transportation furnished. It is paid by the taxpayers as a whole and not by the shippers using the service.

No part of the maintenance of the channels used is charged against the Corporation. This expense is unknown, but if it is assumed that a proper charge for this feature would be in the same ratio as the Maintenance of Way and Structures expenditures for Class I railroads for 1928 (13.71% of gross revenues), the Corporation's expense would be increased $919 608.

Attention is called to the loan of $880 000 to municipalities and the fact that the terminals of the Corporation have been in large part furnished by the municipalities served. The Corporation's Chairman, before the Appropriations Committee, mentions fourteen cities that have expended a total of $24 000 000 in providing terminals.

It is evident, therefore, that the actual costs of operating the Corporation for 1928 are under-stated to the extent of at least $1 800 000. If the traffic had been handled by rail at charges 25% in excess of those of the Corporation, the increase in cost would have been $1 677 000, or a net saving to the public of $123 000, exclusive of interest charges on funds used to provide channels.

The public, not the shipper, assumes these omitted costs, and, on a commercial basis, they must be considered in determining the cost of transportation furnished. As nothing is included for profit in this comparison, the prospect of persuading a private corporation to undertake the operation is not encouraging.

There has been a growing tendency to put the Government into business, from the operation of railroads to the introduction, in the Seventy-first Congress, of an Act to permit engineers of the Bureau of Public Roads to serve Latin-American Governments while remaining under full pay by the United States Government. This is a case of proposed subsidizing of engineers in direct competition with legitimate business and is parallel with the Government's subsidizing of waterway transportation.

The Government's experiment in river transportation has reached a point that changes the problem from one of transportation to the larger and broader one of the Government's engaging in business in direct competition with private enterprise. Is the foundation being laid for the Nation to become another Russia, with all that the name implies, or is the United States Government to continue dedicated to the protection of "life, liberty, and the pursuit of happiness?"

THEODORE BRENT,[25] ESQ. (by letter).—The general impression gained from the paper by Mr. Cornish is that the entire subject has been viewed by him with conservatism.

Concerning the demands of the country for transportation, the general rule of calculation has been that traffic demands double every twenty years,

[25] Pres., Redwood Line, Inc., New Orleans, La.

on the basis of the present growth of the United States. This only calls for a sustained increase of 3.5% annually. Despite the dislocation and inequality of the World War period, this rule has been quite well justified in the elapsed period of the decades, 1910 to 1930, and there are no present signs of a cessation of normal National growth.

The calculations of a public requirement of 870 000 000 000 ton-miles of transportation by 1950 will probably be exceeded if the facilities are provided in time to permit traffic to expand normally. If the demand is not promptly met, then business must inevitably turn in upon itself and by a marked redistribution of industry and manufacture permit of such growth by a lessening of the volume of transportation between producer and consumer. The dislocation and capital expenditure involved in such redistribution must inevitably be greater than that necessary to enable transportation to keep pace.

The estimated cost of new railroad facilities to meet these requirements seems ultra-conservative. In its final form the paper calls for the production of about 50 000 additional miles of main track with yards, sidings, equipment, power, and permanent structures necessary to enable this and the existing railroad plant to carry the increased load. The estimated capital cost is in excess of $11 000 000 000, or slightly in excess of $220 000 per mile of new railroad, equipped. The average investment in the 240 000 miles of main-line railroad in use to-day (1930) is $125 000 per mile. The present average traffic density is 1 800 000 ton-miles per mile of road. With the addition of the 50 000 miles of new main track, the then existing plant of 290 000 miles of main line, equipped, has to support a traffic density of 3 000 000 ton-miles per mile. Obviously, this new construction will not be an average railroad. A cost of $300 000 per mile, or a total expenditure, equipped, of $15 000 000 000 will be more in keeping. The Pittsburgh and Lake Erie Railroad, which is the road of greatest density per mile in the country (10 700 000 ton-miles per mile), has cost $586 000 per mile. Making allowance for surplus equipment, the actual plant producing these results has cost about $400 000 per mile.

The new construction will not be where construction is cheap, but where it is most expensive, and freight traffic will have to bear the brunt of it. Other forms of transportation will increasingly drain away the passenger traffic and that which remains must become more and more expensive, without creating the ability to increase fares or service charges materially. An estimate of $15 000 000 000 is nearer the mark than $11 000 000 000 in the writer's survey of the situation.

The increase of 10% annually for river traffic for the twenty-five years following 1930 is conservative. The relatively small growth of traffic on the Lower Mississippi River during the operation of the Federal Barge Line in the three years, 1926 to 1929, is due solely to the delay of the Government in providing needed facilities and the relatively meager power of its incomplete joint relations to attract traffic. Both these handicaps have recently been remedied and the country is due to see a marked upward trend of ton-miles at least for the 10-year period (1930 to 1940).

It is possible to measure the maximum capacity of a waterway which has limiting physical features, such as locks; but who can measure the capacity of a well-regulated river, such as the Lower Mississippi? Three tows per week in each direction between New Orleans, La., and St. Louis, Mo., produced about 1 338 000 000 ton-miles of transportation in 1928. Loaded to capacity both ways, these tows could as readily have produced 3 000 000 000 ton-miles. Tows of this size could be dispatched at half-hour intervals and be less noted than the daily parade of lake freighters in front of Detroit, Mich. Such service would produce 300 000 000 000 ton-miles of transportation twice the estimate given by Mr. Cornish and still the capacity of the river would in no manner be taxed. The estimate of the carrying capacity of this river, at least, is conservative.

The cost figures on most inland waterways are still experimental. Projecting present known costs on the Lower Mississippi to a basis of 2 500 000 000 ton-miles, the cost of operation, including depreciation of plant and terminals, is 3.27 mills per ton-mile. Profitable operation in the carriage of bulk commodities at 1 mill per ton-mile on the Lower Mississippi River will be reached some years before the inland waterways are called upon to carry burdens comparable with the 60 000 000 000 ton-miles which this study forecasts.

The day of cheap railroad transportation is past. Sweeping increases in rates are being made in all important territories to bring railroad revenues to the mark fixed upon as necessary to support and expand the plant.

Shippers are only beginning to realize at what low costs good transportation by water can be performed at a profit. The cleavage between the relative cost and the value of the service increases year by year. The very force of necessity is bringing the entire rail-water transportation problem rapidly from the academic to the experimental stage. There will always be a field for controversy, but with growing appreciation of an informed public the assertions which to-day require "damnable iteration" will take the form of truisms. For the time being, however, it is necessary to go on proving, over and over again, that water transportation is cheap and rail transportation is very expensive. Mr. Cornish does this in a masterly way. This research proves the old truth in a new way and is a valuable reference work.

SAMUEL O. DUNN,[26] ESQ. (by letter).—The National Administration has proposed, as one of its major activities, the widespread development of inland water transportation. In view of the importance to the United States of adequate, dependable, and efficient transportation service furnished at the lowest possible cost, of the magnitude of the proposed waterway development, and of the vast expenditure of public funds which such development would entail, some analysis of the general waterway situation, based upon the facts as disclosed by past experience, may very well be made.

*Inland Waterway Development.*—The Great Lakes are inland waterways, but it should be understood that in the following discussion the words "inland waterways", are used only in reference to improved rivers and canals. The Great Lakes were made deep and large by Nature, and nobody questions that transportation on them is much cheaper than by rail.

[26] Editor *The Railway Age*, Chicago, Ill.

At Louisville, Ky., on October 23, 1929, President Hoover, in connection with the celebration of the completion of a 9-ft. channel in the Ohio River, outlined the general policy of his Administration to continue "the modernizing of every part of our waterways which will show economic justification in aid of our farmers and industries." No elaboration was made of the phrase "economic justification."

There are many waterway advocates who subscribe wholeheartedly to this program and who support it with optimistic opinion, theory, belief, and prophecy. Yet in fairness to the waterways, which in the past have been embarrassed by the too optimistic predictions of their friends, in fairness to the railways with which these waterways will compete, but most of all in fairness to the general public which will "foot the bill," the basis of actual fact is the criterion by which the program should be judged.

Chief among the claims advanced in support of waterway development, and hence presumably closely linked to "economic justification", is the statement that such development will "cheapen" transportation. What is meant by "cheaper" transportation? Do the advocates of waterway development mean that waterway conveyance charges alone will be lower than the corresponding rail rates, or that total waterway costs, including both charges for carriage and the burden of capital charges, maintenance, and operating expenses borne by the taxpayers, will be less than the railway rates? These questions thus far remain officially unanswered.

In an Interim Report issued in 1927 by the Board of Engineers for Rivers and Harbors and the Shipping Board, "to render immediately available data showing the importance to the country of the improvements completed and in progress in the Ohio Valley," the following statement was made:

"The primary measure of the economic value of any waterway system is the savings in transportation costs which it affords. Usually this saving is shown by comparing the water transportation costs with the rates for moving the same goods between the same points by rail. Included in this cost of water transportation should be the charges for interest on capital investment in waterway improvements plus annual cost of operation and maintenance."

An exactly opposite position is taken by Maj.-Gen. T. Q. Ashburn, U. S. A., Chairman and Executive of the Inland Waterways Corporation, who states, in the 1929 Annual Report of that Corporation, that,

"Because hundreds of millions of dollars have been spent in making streams navigable is absolutely no reason why the upkeep of these rivers or the cost of their maintenance should be charged to this corporation or any other corporation operating fleets on these water 'rights-of-way'."

Finally, a middle ground also appears to be taken in the Interim Report mentioned, which claims—although with little convincing evidence—that certain waterway expenditures have already paid for themselves. In a report entitled "Inland Water Transportation in the United States", the Transportation Division of the U. S. Department of Commerce advances a theory, subscribed to by many, that much of the past expenditures for river improvements should simply be charged off and forgotten. Furthermore, it states that "for services on channels already made navigable or on canals already built the returns

need cover only current operating expenses and necessary maintenance of channel, terminals, and floating equipment in order to justify continuance."

So far, search for an interpretation of "cheaper" transportation and its relationship to "economic justification" has brought to light only conflicting Government opinions. In order to obtain official information, inquiry as to the meaning of this phrase was made of the Hon. Patrick J. Hurley, Secretary of War, under whose authority and jurisdiction National waterway improvements are carried out. Mr. Hurley's only reply was that "The War Department has no intention of inviting controversial discussion as to the relative merits of various forms of transportation."

In the face of this official attitude, one must draw his own conclusions. It would appear that the only logical interpretation to be put upon the claim of "cheaper" water transportation is that it means that total waterway costs, regardless of who pays them, will be less than the corresponding rail charges. Total cost is the crucial test.

The only cost paid for the transportation of freight by rail is the freight rate charged. The cost of transportation by inland waterway is divisible into two parts. The first is paid by the public, and consists of interest upon the investment made in improving the waterway and building terminals, the expenses of maintenance, and certain operating costs, particularly in the case of canals or canalized streams. This public payment represents a subsidy to the waterways that results in an increase in taxes. The second part of the cost of water transportation is that incurred in the actual movement of freight.

Now, on sound principles of economics, what should be the objective? Should it be to reduce freight rates entirely regardless of the effect upon taxes? Plainly, if the development of waterways will result in reductions of freight rates, it will also result in increases in taxes. Total taxes in the United States increased 30% between 1923 and 1928, and amounted to twice as much as the total freight earnings of the railways. Can it be contended that taxes are so unimportant, and freight rates so important, that the National prosperity would be promoted by securing a saving in freight rates at the cost of an increase in taxes that would exceed the saving in freight rates?

Furthermore, the development of waterways is not the only way available in which taxes can be used to reduce freight rates. Recently, the British Government actually has secured reductions in freight rates on agricultural products by giving the railways equivalent direct subsidies from the Public Treasury. The railways of Canada receive subsidies from the Government for making low rates. This is not pointed out in advocacy of similar subsidies for the railways of the United States, but it is surely pertinent to call attention to the fact that if the total cost of inland water transportation, including the part paid in taxes, is or will be greater in this country than the total cost of providing similar transportation by rail, then any desired reduction of freight rates, either on certain commodities, or in certain parts of the country, or even on all traffic throughout the United States, obviously could be secured at a lower cost to the taxpayers by having the Government subsidize the railroads than by having it develop and maintain waterways. As regards the total cost of carrying all freight there is this further fact to con-

sider: The greater the density of railway traffic, the cheaper the railways can handle each unit of this traffic. Therefore, any policy that hinders the increase of railway traffic also hinders the reduction of the cost of transportation by rail.

The situation thus narrows down, primarily, to a question of relative costs. How, then, do the total costs of transportation by inland waterway and by railway in this country compare, and how may they be expected to compare in the future? Actual experience can never be intelligently or safely disregarded. For many years the Government has been improving inland waterways and the country has actually had transportation by both water and rail. There is an abundance of information regarding the costs to the public of rail transportation, but lamentably little reliable and satisfactory information regarding costs of inland water transportation. For many years the Army Board of Engineers for Rivers and Harbors and others have been giving estimates to Congress and the public regarding proposed waterway improvements, including the traffic that would be handled, the expense of improving and maintaining the waterways, and the savings in transportation costs that would result. Those who have made these estimates seldom have come forward after the improvements have been made with figures showing the extent to which results have or have not justified their estimates and expenditures.

There are three great inland waterways in the United States upon which transportation operations are now being conducted. These are the New York State Barge Canal, the Ohio River System, and the Mississippi. What does the record show?

In 1929, the New York State Barge Canal handled a freight traffic amounting to 715 551 472 ton-miles. Cost of canal maintenance and repairs amounted to $3 390 432, while interest on the investment, at 5%, amounted to $8 811 061 in that same year. On a ton-mile basis, maintenance and repair costs were 0.474 cent, and capital costs, 1.231 cents, a total "hidden" cost of 1.705 cents per ton-mile which was paid in taxes by the people of New York State. The average actual waterway conveyance charge on the Barge Canal—a figure which far too often is considered by the waterway advocate as the total cost of water transportation—is conservatively estimated at 0.450 cent per ton-mile, making the total cost of transportation on the New York State Barge Canal 2.155 cents per ton-mile. The corresponding average ton-mile revenue of the Class I railways in the Eastern District in 1929 was 1.090 cents. Frederick Stuart Greene, M. Am. Soc. C. E., Superintendent of Public Works of New York State, has said that in 1925 it cost the State $4.51 per ton for all freight loaded on the canal, regardless of length of haul, and that it would have been cheaper for the State if all the freight carried on the canal had been put in railroad cars and the State had paid the freight bills. Is this "cheaper" transportation, or economic justification?

What of the Ohio River System? It is conceded even by some of the principal advocates of waterway development that the bulk of the very large expenditures heretofore made on waterways has been wasted, because it has not resulted in the increase of water traffic and the reduction of transportation costs which it was intended to accomplish. It is stated, however, that future

expenditures will be made more wisely and that it is entirely beyond question that they will result in cheapening transportation. In other words, the public is asked to do what is always unintelligent and unsafe, namely, to disregard experience. Surely, however, it cannot reasonably be asked to disregard very recent experience. The completion of the improvement of the Ohio River System is so recent that it was celebrated within the past year (1929). What does this waterway show on a cost basis?

Some very interesting figures of "savings" to the public resulting from water-transportation operations on the Ohio River System are contained in a report entitled "Transportation in the Mississippi and Ohio Valleys", issued in 1929, by the War Department Board of Engineers for Rivers and Harbors and the Bureau of Operations of the U. S. Shipping Board. In this report the following statement is made: "Based upon a ton-mileage of 2 649 000 000 on the Ohio River System in 1926, the savings in transportation costs amounted to about $25 000 000."

From the foregoing figures, the "savings" claimed appear to amount to 0.944 cent per ton-mile. Disregarding the fact that the ton-mile basis of comparison is peculiarly favorable to the waterways because of the fact that water routes, over any material distance, are almost invariably much more circuitous than the corresponding rail routes, it is interesting to note that in the same year (1926), the average ton-mile revenue of the eight principal Class I railroads operating in the Ohio Valley was only 0.883 cent. In other words, the waterway "savings" claimed amounted to 107% of the corresponding average rail revenue per ton-mile. At their average ton-mile rate of 0.883 cent, the adjacent railways would have carried the entire traffic moved on the Ohio River System for less than $23 400 000, or for about $1 600 000 less than the saving in transportation costs claimed.

This average of 0.883 cent per ton-mile for the adjacent railways covers all classes of traffic and is thus increased by the inclusion of much high-grade traffic which the waterway does not handle. The greater circuity of river routes also distorts the figures in favor of the waterway. On the other hand, average hauls on the Ohio River System are relatively short and, on corresponding rail hauls, average ton-mile revenue would be affected by the relatively large part of terminal expense it would have to bear. These three factors cannot be evaluated statistically. Despite this fact, it seems pardonable to view with some skepticism statistics which indicate that the transportation of freight on the Ohio River System resulted in savings to those for whom the freight was carried actually exceeding the total amount that the railways, at their average revenue per ton-mile, would have received for handling it.

From the report of the Board of Engineers previously mentioned, the total investment of the public's money in the Ohio River System appears to be about $240 000 000. A study of all the available data indicates that for every ton of freight carried 1 mile on the Ohio River System the taxpayers are paying a cost of about 5 mills; and those whose freight is carried are paying a cost of about 5.5 mills, or a total of more than 1 cent, as compared with an average ton-mile revenue of less than 9 mills on the adjacent railways. Approximately 90% of the traffic handled on the Ohio River System consists of

such low-grade commodities as coal, sand, and gravel. The average revenue per ton-mile of the Chesapeake and Ohio and the Norfolk and Western Railroads, which operate in the same territory and the traffic of which consists mainly of low-grade commodities, especially coal, is only about 6.5 mills, or 40% less than the average total cost of transportation on the Ohio River System. Does this show "cheaper" water transportation, or economic justification for further waterway development?

Finally, what is the situation on the Mississippi River, the third of the Nation's great waterways? It is impossible to obtain detailed statistics regarding the Government's investments in the Mississippi for navigation purposes, or detailed figures regarding operating costs, but the situation seems very aptly summed up in the report of the Inland Waterways Corporation for 1929, wherein General Ashburn states:

"If the cost of their [the rivers'] upkeep be charged to the few operators thereon, the only result would be to destroy their value as water 'rights-of-way' by raising the cost of transportation *via* water so high that no carrier could operate and the whole policy of Congress would be defeated."

Clearly, if the imposition upon carriers by water of charges merely to defray the cost of maintaining the waterways would make the cost of water transportation so high that the water carriers could not compete with the railways, it must be that the total cost of transportation by inland waterways is, and will be, greater than the cost of transportation by rail. In other words, water transportation is made possible only through large Government subsidies, paid, in turn, by the people at large in the form of taxes.

So much for cost! What about certain other requisites essential in an efficient transportation machine? To be specific, what about adequate and reliable service?

The following quotations from the 1929 report of the Inland Waterways Corporation are highly illuminative as to the ability of waterways to furnish adequate and dependable service.

Regarding the Upper Mississippi, the report states:

"The rainfall during the months of May and June was very deficient and by mid-June we were beginning to have trouble on account of low water. * * * Our greatest misfortune during the month of August occurred when the lower gates of the lock at the high dam between the cities of St. Paul and Minneapolis gave way, permitting the water above the dam to escape and leaving the steamer *Altair* and six barges hopelessly stranded at the Minneapolis terminal."

Similar misfortunes visited the Lower Mississippi. Witness the report:

"Within the last five months of 1929 we encountered every detrimental navigating element presented in the almost eleven earlier years of operation and in an aggravated degree, resulting in serious interruptions to schedules and revival of the service complaints which had been almost entirely eliminated. The inadequate channel was comparable to 1922 with the exception that in 1929 a far greater area was involved and the duration of the low-water period was almost twice as great. In 1929 the detention to line vessels in active service directly chargeable to fog and unavoidable channel obstructions was as follows: August, 1 913 hours; September, 3 356 hours; October, 3 323 hours; November, 743 hours; and December, 2 047 hours. Ice closed the St. Louis harbor almost an entire month earlier than usual."

As to the third operating division of the Inland Waterways Corporation, the report continues:

"On the Warrior River we experienced the greatest flood period in our career, considerably slowing up operations. Normal tows of seven barges had to be reduced to two and three barges, in order that the power might carry them up stream."

As regards the Ohio River, the following Associated Press dispatch was sent from Portsmouth, Ohio, on June 5, 1930:

"Boat traffic on the Ohio River between Pittsburgh and Cincinnati was abandoned temporarily to-day when the water dropped so low as to make navigation impossible. Lack of rainfall during the past several weeks was blamed. The *Chris Greene* went aground on a sand-bar above here last night, but succeeded in breaking loose and later attempted to return down stream to Cincinnati. A number of boats and packets tied up here rather than attempt passage through the sand-bars. The navigable stage here is 9 ft., but the level had dropped to 6.5 ft. to-day and was dropping rapidly. Above Portsmouth the water became so shallow that persons could wade across the river. The water dropped below the navigable stage at Dam 30, Greenup, Ky., and Dam 32, Vanceburg, Ky. Dam 31, near here, was of no use to river traffic as wickets had been raised several days ago to make repairs which will require three weeks. The *Senator Cordell*, bound from Cincinnati to Pittsburgh, tied up here because of the low water. Boats that stopped here were the *Ed Kenna*, pulling empty barges from Cincinnati to Huntington; the *Otto Market* and the *A. C. Ingersoll*, both bound to Cincinnati with tows of coal."

No further evidence is needed, beyond these official statements, to indicate the weakness inherent in waterways when it comes to providing adequate and dependable transportation. Whether from ice, from low water, or from high water, streams are affected by natural forces beyond the control of the engineer, be he ever so skilled. Reliable and adequate transportation service is essential to National life, in its present highly developed industrial stage. Such service the railways give to every section of the country. Such service the waterways do not, and cannot, give.

The increase which has been made in the past decade in the efficiency of railway operation—marked by cheaper service, faster service, more adequate service, and more dependable service—has been characterized as one of the outstanding achievements of the post-war era. Business leaders of the Nation have testified at length as to the value of this improved rail service, both to their own industries and to the Nation at large. This testimony is a matter of common knowledge, including in its list of benefits such factors as greatly reduced inventories; release of capital frozen in transit; reduction of factory operating expense, and stabilization of labor forces; reduction of demurrage charges; receipt of shipments in better condition; increased volume of sales; and the widening of potential markets. In fact, it has been reliably estimated that the benefits derived by general business from the improvements made in railway service since 1922 are equivalent in annual value to a reduction of at least 30% in present railway freight rates. Do the waterways offer any such service benefits to the Nation? They do not and, from their natural characteristics, they can not.

In determining "economic justification" the fact cannot be disregarded that rail service is faster, more dependable, and better in other respects than is the transportation service offered on inland waterways. Therefore, to put the water service on an economic parity with rail service, the total cost of transportation by water must be enough less than the cost by rail to offset this difference in the character and value of the service rendered. It has often been stated—and, indeed, used as a basis for calculating water rates—that rail service is at least 25% more valuable than water service and that, therefore, the costs by water must be at least 20% less than by rail to offset this difference in the quality of service.

The available facts regarding the three principal inland waterways indicate that the total costs of transportation thereon are actually greater than the corresponding rail charges. They are thus in the position of furnishing poorer service at higher costs. Is this "economic justification" for further waterway development?

Finally, there is one further point upon which question may be raised as to the advisability of further waterway development. In the first place, these proposed improved waterways, if developed, either will or will not handle a material tonnage. If they will not, there is no legitimate reason for spending vast sums of public money on their improvement. If they will handle a material tonnage, this, of necessity, must be taken in large part from the railways. That the waterways, as their advocates claim, will develop any considerable volume of "new" tonnage is hardly susceptible of proof. This is not to deny that the development of new waterways, under some conditions, may result in increased traffic for certain railways adjacent thereto; but in the main it appears that such problematical increases in traffic on certain railways may result only through the relocation of industries, to take advantage of the possible lower water conveyance charge and to profit from the public transportation subsidy financed by the taxpayers. Under such circumstances, traffic gained by one group of railways will be traffic lost by another rail group. It is impossible to avoid the conclusion that if improved inland waterways attract the traffic which their advocates foresee, there will be a material reduction in the tonnage that would otherwise be offered to the railways for transportation.

What will this mean to rail costs and rail service? The inability of inland waterways to furnish adequate and dependable service has already been mentioned. This inability means that the railroads, as an economic necessity, must maintain surplus transportation capacity to be able to handle adequately, dependably, and efficiently the waterway traffic (or a considerable part of it) at those periods when the waterways, from causes beyond human control, cannot furnish adequate and dependable service. Such periods have occurred times without number in the past. That they will recur is beyond question.

Meanwhile, what of the railways in those years in which the waterways are able to furnish their service and in which traffic is attracted from the rail lines because of the lower direct conveyance charge to the shipper? What of the capital costs on the railway plant? How will their properties, necessary in time of waterway failure, be supported under a reduced tonnage? It is

obvious that this remaining rail tonnage must either bear higher rail charges or else suffer impaired rail service. In either case the same practical effect is produced—the cost of rail transportation is increased.

This economic necessity for railroad transportation capacity to assume the carriage of water traffic in those inevitable periods when the waterways cannot function satisfactorily is in striking contrast to the second argument advanced by the waterways advocate—that further waterway development is required to "relieve" the railways, either of current or of probable future traffic demands upon them. This argument, at least in part, was made by Mr. Cornish. Without attempting any detailed analysis of his paper, some observations upon his conclusions, as viewed in the light of actual traffic changes on the railways in the forty years since 1890, may pertinently apply not only to his arguments, but to those of others who foresee a railway need for "relief" from an overwhelming traffic.

His conclusions are predicated upon a forecast that in 1950 railway freight traffic will reach the staggering total of 870 000 000 000 ton-miles. Revenue ton-mileage in 1929, the highest figure ever reached, was approximately 450 000 000 000; so Mr. Cornish apparently foresees an increase of 420 000 000 000 ton-miles in the next 21 years. What in the record of the past justifies such a belief? What are the facts?

Statistics of railway revenue ton-mileage are available for the past forty years. From 1890 to 1929 (39 years) the increase in railway freight traffic was 374 000 000 000 ton-miles. Mr. Cornish's estimate for the next 21 years is, therefore, 12% in excess of the actual increase in the entire last 39 years. The increase in the 21 years from 1908 to 1929 was 232 000 000 000 ton-miles. Mr. Cornish's anticipated increase is, therefore, approximately 80% in excess of the increase that actually occurred within the last 21 years.

Even more significant is the marked change which has occurred since 1920 in the trend of railway freight traffic, a change characterized not by an increasing growth, but by a rapidly declining rate of growth. From 1890 to 1900 there was an annual average increase in railway ton-mileage amounting to 6 500 000 000. In subsequent periods the average annual increase was as follows: 1900-1910, 11 500 000 000; 1910-1920, almost 16 000 000 000; 1920-1929, only 4 000 000 000. Thus, during the last nine years, the average annual increase in railway ton-mileage was only about one-fourth as great as in 1910-1920, only about one-third as great as in 1900-1910, and only about two-thirds as great as in 1890-1900. In the light of this marked retardation since 1920 in the rate of growth of railway freight traffic, it seems extremely doubtful whether the increase within the next 21 years will exceed 125 000 000 000 ton-miles, which would make the total freight traffic available for the railways in 1950 only 575 000 000 000 ton-miles. Mr. Cornish estimates that "railroad renewals and increased operating efficiency may provide" for the handling of about 650 000 000 000 ton-miles in 1950. It would appear, therefore, from the actual experience of the past decade, and Mr. Cornish's own estimate of the amount of traffic that can be handled by rail in 1950, that the railways not only will not need any "relief" by waterways in 1950, but will be able then, as they are now, to handle much more traffic than is available for them.

The railways have no fear of an overwhelming increase in traffic, in view of the experience of the last decade. On the contrary they fear, and with reason, that the retardation in the rate of increase in their freight traffic, caused at least in part by the loss of business to their subsidized competitors, may result in a situation wherein it may be difficult to support their properties. Already retrenchments in capacity have been made in various parts of the railway plant. On the Class I lines the number of passenger-train cars has been reduced from 55 040 in 1924 to 53 097 in 1928; the number of locomotives, from 65 358 in 1924 to 59 391 in 1928; total locomotive tractive power, from 2 611 000 000 lb. in 1926 to 2 580 000 000 lb. in 1928; the number of freight-carrying cars, from 2 357 234 in 1925 to 2 297 677 in 1928; and the total carrying capacity of freight cars, from 105 953 000 tons in 1926 to 105 327 000 tons in 1928. Further, in the peak year of 1929, the average daily freight-car surplus at no time fell below 107 000. In the face of these figures it seems obvious that the railways' imperative need is not for "relief" from traffic, but for more traffic. Every ton taken from the railways increases the unit cost of rail transportation; every ton gained by them reduces this unit cost.

It thus appears from the available evidence that on the three great inland waterways the cost of transportation is greater than by rail; it appears that inland waterways are physically incapable of furnishing adequate and dependable transportation service; it appears that if the proposed development of inland waterways attracts to those waterways the volume of traffic which is predicted, there will be a material loss in the volume of tonnage which otherwise would move by rail, while at the same time the railways must maintain surplus transportation capacity against the inevitable waterway breakdowns; it appears that there is no necessity for waterway development to "relieve" the railways. In consequence, waterway development will mean that the traffic which these waterways may attract will be handled at a higher cost to the Nation in general than if it were carried by rail; that this service will be inferior to rail service; and that either railway rates will have to be increased on the remaining rail traffic or the quality of rail service reduced. In other words, the only results of further inland waterway development seem to be increased National transportation costs and impaired National transportation service.

Those who favor the development of waterways doubtless will answer that the facts presented herein do not prove the greater cost of water transportation as compared with rail transportation. If so, let them come forward with better data—data such as would be convincing to any trained student of business and economic problems. The most outstanding fact regarding this controversy concerning the comparative costs of water and rail transportation is the lack of credible and convincing evidence in support of the claims made as to the low and prospective costs of transportation on inland waterways. The public is being asked to invest hundreds of millions of dollars in waterway improvements, and in behalf of this expenditure claims as to the cheapening of transportation that will result are being made, which are not supported either by the facts derived from past experience or adequate data as to future probabilities.

The Nation has to-day a railway system which is being operated efficiently and is more than adequate to all the demands being made upon it. When it is proposed to develop another system of transportation by the expenditure of public money, which, it is claimed, will carry freight at less cost than the existing means of transportation, the burden of proving that claim obviously rests upon those who make it. As this means of transportation is to be provided by increasing the taxes of the public, it is obvious that its development cannot be economically justified except by showing that it will probably, and, indeed, almost certainly, cause a reduction in what the public must pay for freight transportation that will exceed the increases in taxes it must pay.

To say that the development of waterways will "cheapen" transportation because it will cause part of the Nation's freight to be carried for lower rates than it would be carried by rail simply evades the real issue. The cost of transportation, whether by airway, highway, waterway, or railway, is the total amount that has to be paid to provide such transportation, regardless of who pays all or any part of this cost. All the people directly or indirectly pay both taxes and freight charges. The question of the expediency of developing any inland waterway always, therefore, is a question of taxation as well as of freight charges. It always involves the questions, first, as to whether the increase in taxes will or will not exceed the savings in freight charges directly effected by the development of the waterway; second, as to whether there will not result a diversion of traffic from the railways that will make it necessary for them to charge higher rates on their remaining traffic than would otherwise be necessary; and, third, as to whether, if there actually is a net reduction in the total amount that must be paid for transportation by both rail and water, those who pay the increased taxes will be the beneficiaries of the reduction in freight rates.

Not until the advocates of inland waterway development squarely meet these questions with data such as would be convincing to private capitalists who were being solicited to invest their own money, will inland waterway development be discussed on its merits as a National economic and business problem. The American public is being urged to invest a large amount of its capital in inland waterways to increase the prosperity of the Nation, and not merely that of certain shippers, communities, or territories. It ought not to invest it, or be asked to invest it, on the basis of information any less complete and convincing as to probable costs and savings than that which would be demanded by business men who were being asked to invest their own capital.

This country has had more than a hundred years of experience with inland water transportation. Would a private business, after a hundred years of experience in its own field, spend a dollar for development on prophecy? Would it not search the records of the past for a guide to the future? Is it unreasonable to ask similar prudence in Government expenditures?

"Economic justification" is an adequate reason for future waterway development in the United States; but in accepting this reason it would appear, first, that the term should be interpreted as a reduction in total National transportation costs; and, second, that it be supported not by belief, opinion, theory, or prophecy, but by facts and facts alone.

HENRY W. HOBBS,[27] M. AM. SOC. C. E. (by letter).—The discussion of this subject has raised the question of the economic justification of inland waterway improvement at Federal expense. Before the construction of railways, rivers and canals provided the best, and in many cases the only, means of transportation. They continued to be the primary means of transportation up to about 1860, the early railroads acting mainly as feeders to the waterways. With the extension of the railroads severe competition developed between them and the waterways, as well as among the different rail lines. The effect of this competition is still seen in the rail rate structure of the country, with its marked discrimination in favor of points with water competition. The improvement of these earlier waterways was fully justified, as they formed the primary means of transportation and were important factors in the development of the United States.

In the latter half of the Nineteenth Century there was a period when many waterway improvements were authorized, some of which were of questionable value. To-day, waterway legislation is probably subjected to more careful study than any other question coming before Congress. In 1902, Congress created the Board of Engineers for Rivers and Harbors, to which all projected waterway improvements are referred for study and recommendation. Each project is now submitted for study to an officer of the Corps of Engineers who is stationed in the general locality, where a district office is maintained. He first submits a preliminary examination report, which contains such economic data as he is able to collect, with a general description of the locality and the details of the improvement desired. This report is then acted upon by another officer of the Corps of Engineers, who, as Division Engineer, has charge of a number of districts. The District Engineer's report, with the comments of the Division Engineer, is next studied by the Board of Engineers for Rivers and Harbors. If it finds that the proposed improvement appears economically justified, a field survey is made to determine the cost of the work and such other features as appear necessary in reaching a final conclusion. The survey report is made by the District Engineer, receives the comment of the Division Engineer, and the case is again considered by the Board of Engineers for Rivers and Harbors.

In the office of the Board, engineers, statisticians, economists, and rate clerks assist in working up the information received from the District Engineer and from other sources. This includes data concerning the potential commerce and the points of origin and destination of the several commodities. Much information of this character is obtained from the Department of Commerce. The practicability of the expected movements is studied, together with the available means of shipment and the transportation costs. The prospective savings in transportation costs are the differences between the existing rates on the same commodities, between the same or equivalent points, and the cost by an improved channel. The transportation costs by water include all terminal and transfer charges. An unfavorable report is indicated if these savings are not sufficient to show a considerable margin above the annual carrying charges on the proposed improvement. These charges include interest

[27] Executive Secy., Board of Engrs. for Rivers and Harbors, Washington, D. C.

and amortization on the investment in channel improvement, and the maintenance cost, including the operating cost of locks and dams if such works form part of the project. No account is taken of savings to the public resulting from any possible rail-rate reduction to water competitive points. The principal traffic of the waterways is made up of bulk commodities, and little consideration is given in the Board's studies to the movement of high-grade general freight. About two-thirds of the recommendations made by the Board to Congress are unfavorable.

The claim that water transportation is more expensive than rail appears to be based on a comparison of water-haulage costs, including carrying charges on the improvement, with the average revenue per ton-mile of the railroads serving the territory. Taking into consideration the difference in the character of the shipments by water and by rail, and particularly taking account of the many peculiarities of the rail rate structure, it is apparent that such a comparison does not give a correct result. It appears that the only fair way to arrive at the saving in moving a particular commodity by water rather than by other means is by a direct comparison of the rates on that particular commodity between the same or equivalent points. To illustrate this, the average cost of moving coal on the Monongahela River is about 3 mills per ton-mile, while the rail rate on coal on parallel roads, for the same average haul, is 19 mills per ton-mile. This ton-mile cost on the Monongahela River cannot be used on another stream without making corrections for channel dimensions, current velocity, distances between the origin and destination of the commodity, size of cargoes, regularity of shipments, back haul, and other conditions peculiar to the river under consideration. Wheat is moved by the Inland Waterways Corporation from St. Louis, Mo., to New Orleans, La., at a rate of 2 mills per ton-mile, or $1.30 per ton under the rail rate.

The cost to the people of the United States of making waterway transportation possible is covered by taxation. While the total taxes in the United States have increased greatly since 1923, Federal rates of taxation have been several times reduced during the same period. The returns which the people receive from this taxation for waterways come in the form of reduced commodity prices. The savings to industries, due to the lower cost of transporting raw materials by water, make possible the marketing at lower prices of the products of the industries affected. The iron and steel industry may be noted as one of those affected. These commodities enter into the construction of many things in general use, such as household utensils and equipment, thereby distributing the benefits to the entire population.

The cost of moving coal on the Monongahela River has been cited. The annual carrying charges on the improvement of the Monongahela River, based on the ton-mileage of 1929, are less than 1¼ mills per ton-mile. The carrying charges on the improvement of the Ohio River are greater than this at the present time, but will decrease as the traffic increases. Taking the Ohio River System as a whole, the total ton-mile movement in 1929 was 2 886 436 000. The savings on the Monongahela River alone are in excess of the annual charges for the entire Ohio River System. The Ohio River improvement, although only recently completed, already shows returns slightly in excess of the annual costs.

The traffic on the system in 1929 totaled 59 537 000 tons, an increase of about 10 000 000 tons over that for 1925. The activities of large concerns, which have expended many millions of dollars in building towboats and barges, indicate that the movement of commerce on the Ohio River System will continue to increase. The total commerce on rivers and canals in 1929, exclusive of the Great Lakes and not including rafted timber, was 170 688 000 tons, an increase of about 35 000 000 tons over 1925. The ton-mileage was 9 446 712 000; in 1925, it was 8 417 052 000.

After a waterway has been completed and has been in operation a sufficient length of time to indicate its value as a part of the transportation system of the country, careful studies are made to determine the justification for the expenditures made by the Federal Government. In a few cases negative results have been shown. The Cape Fear River above Wilmington, N. C., has not shown a profit, as the improvement does not extend far enough up the river to give adequate depth at Fayetteville, the center of the principal tributary area. The St. Johns River, in Florida, between Jacksonville and Palatka, shows a small deficit, although the section of the same river between Palatka and Lake Harney shows a large profit. The only stream on which a considerable deficit has been shown is the Warrior River, in Alabama. Water transportation on this stream was handicapped for a number of years by an unfair division of rates between the rail and water carriers. Considered as a whole, the waterways of the country return each year, in reduced transportation costs, a sum much greater than the carrying charges on the improvements.

Dependability of service is an important matter. The length of the navigable season on the Great Lakes is about eight months. During the closed season it has not been found necessary to continue shipments of the principal commodities by rail. Large quantities of these bulk commodities are stored during the navigation season to preclude the necessity for such movements at higher cost during the closed season. The Ohio River is now open to navigation throughout the year, being subject in general to unimportant delays averaging not to exceed ten days annually. Such delays are not of serious importance on transportation lanes carrying principally bulk commodities, and instances can be cited where delivery is made more promptly by water than by rail.

Some classes of freight move most cheaply by water, others by rail, and others by motor truck. The greatest economy of transportation can be obtained by a proper co-ordination of these various means of transportation. It would be an economic loss to do away with the cheaper forms of transportation, whether they be by waterway, by railroad, or by truck, in favor of movement at higher cost over any other of these facilities. An ideal condition would provide for shipments, by the various routes, of the particular commodities best suited for transportation over each.

C. W. KUTZ,[28] M. AM. SOC. C. E. (by letter).—In 1925, the writer prepared a paper on the "Relation of the Ohio River and Its Tributaries to Transportation in the United States."[29] At that time, the 9-ft. project was incom-

[28] Brig.-Gen., U. S. A. (*Retired*), Washington, D. C.
[29] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1105.

plete, and the tonnage moving on the Ohio River itself, exclusive of tributaries, was 15 725 849. To determine the water-haulage cost of moving this tonnage and its relation to published rail rates on like commodities that have the same points of origin and destination, a comprehensive analysis was made of the 1925 tonnage.[30]

Nineteen separate movements were studied and for each is shown the rail rate and the water-haulage cost as secured from the principal users of the river. Some of these users were common carriers and some contract carriers, but the large majority were private carriers. In the first two classes the water-haulage cost included an item of profit to the owner. In the third class the water-haulage cost included a 6% return on the investment in floating plant and on the privately owned terminal facilities, a return which is comparable to that which the railroads of the United States are permitted, under the Transportation Act, to earn on their investments,

As most water movements involve higher terminal charges than corresponding rail movements, the difference between the rail rates and the water-haulage costs was reduced by the estimated terminal differential. This method of determining economic justification is superior to a comparison of cost per ton-mile, as it eliminates differences due to the generally greater length of the water route, and it also avoids the faulty comparison of a long-haul rail rate with a short-haul water rate. In 1925, the average length of haul on railways was in excess of 200 miles, whereas that on the Ohio River was less than 90 miles.

It may be noted that this table (Table 23[30]) dealt only with the Ohio River, excluding all its tributaries, some of which, such as the Monongahela River, are enormously profitable, while others are economic failures. When the movement involved the use of a tributary, as well as the Ohio River, the difference between the rail rate and the water-haulage cost was prorated between the two streams on the basis of the mileage of each involved in the movement. The table showed that the differences between rail rates and water-haulage costs, when applied to the 1925 tonnage, resulted in a saving to the shippers for that year of $5 328 594, which was about 87% of the annual charges for 1925.

TABLE 9.—Comparisons Between Tonnage, Ton-Mileage, and Savings

| Year | Tonnage | Ton-Mileage | Savings |
|---|---|---|---|
| 1925 | 15 725 849 | 849 195 846 | $5 328 894 |
| 1926 | 19 754 978 | 1 101 629 085 | 6 911 600 |
| 1927 | 20 128 518 | 1 214 490 565 | 7 098 600 |
| 1928 | 20 938 267 | 1 344 687 000 | 7 796 000 |
| 1929 | 21 955 000 | 1 512 584 000 | 8 174 106* |

* Estimated, increase being proportioned to the increase in tonnage.

The project was completed in 1929 at a capital cost of about $115 000 000. The annual cost of operation and maintenance was then estimated at $2 350 000.

[30] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), Table 23, p. 1178.

If interest at 4% and a depreciation or obsolescence factor based on an assumed life of 50 years (sinking-fund basis, 4%), is added, the annual charges of the completed project will be equal to $7 703 000.

Table 9 shows how the commerce and the savings, based on similar analyses, have increased since 1925. From this table and from the estimated annual charges, it appears that the canalized Ohio River, although just completed, is already yielding savings to shippers in excess of the annual charges. As its capacity is many times greater than the present tonnage, the economic justification of the investment seems to be assured.

T. Q. ASHBURN, ESQ. (by letter).—Too much has been said in the various discussions of this paper about the relative merits of rail, water, and motor transportation and the effect of such competition upon the revenues of the various carriers, and far too little about the interest of the public in securing the best transportation at the cheapest possible rate. Every citizen is vitally interested in the cost of transportation because it is concealed in the price of every article he utilizes, the food he eats, and the clothes he wears.

Every new country passes through four stages of transportation: Water; paths and roads; rail; and, finally, the one through which this country is now passing—that of co-ordination and co-operation.

Each of these stages follows as naturally as day follows night; each performs its function satisfactorily considering the condition involved; and each, in the order named, inevitably leads to the other. As soon as a better and cheaper, and more satisfactory, form appears, the less satisfactory, and the more expensive, form fights constantly to prevent the people of the United States from enjoying such transportation, and always on the ground that:

"The existing forms of transportation fill all our needs, and if you allow competition it will destroy our revenue. We are too important to be destroyed or hurt; we have expanded at the peoples' demand, and it is unfair competition to subsidize some other form of transportation to our disadvantage."

It will be observed that there is no thought anywhere, in this argument, that the people who have "paid and paid" to get transportation, who have allowed one form to supersede another (and always by subsidies), have any legal, moral, or ethical right to patronize that form of transportation which is of most value to them.

The problem confronting the people of the United States is this: They have nearly $1 500 000 000 invested in harbors and navigable waterways, and they have been appropriating annually vast sums of money to continue making navigable streams, in the hope that a cheaper means of transportation will be created whereby the entire country will profit. This vast scheme has only been partly completed, and it will require a comparatively small sum to finish that part of it which has been found to be in accordance with sound economics and sound engineering principles. On its completion the people may look with certainty to the fact that cheaper and better co-ordinated water-rail-motor service will result in a system of transportation superior to any single system, affording every one a real return on the money which he has invested in the form of taxes.

These savings inherent in water transportation will not only be available to those communities fortunately located on navigable streams, because when this co-ordinated system of joint routes and rates is fully developed in accordance with the Denison Act, the shipper in the interior will receive the same savings in cents per hundred pounds through joint rates, as the man who lives near the river. The general principle of determining rates is to apply the water saving between the river ports to the all-rail rate between the points of origin and of destination, and then to establish a joint route, *via* the Federal Barge Lines, by rail and water, or by motor and water, cheaper than the all-rail or all-motor rate. For example, if the all-rail rate on a given commodity from Dubuque, Iowa, to New Orleans, La., were $6.00 per ton, the all-water rate normally would be $4.80 per ton (80% of the all-rail rate), a saving of $1.20. Now, if the all-rail rate from Wightman, Iowa, to New Orleans, for example, were $7.00 per ton, a joint route and rate would be established by rail from Wightman to Dubuque, by water to New Orleans, and the joint rate from Wightman to New Orleans would be $7.00 minus $1.20 (the water saving), which equals $5.80 per ton. The Wightman shipper would thus receive exactly the same savings in cents per hundred pounds as the Dubuque shipper.

This is exactly what the Inland Waterways Corporation proposes to do for every interior shipper; and yet the opponents of waterway development and of the operations of the Federal Barge Lines propose to abandon this vast network of waterways already partly completed, charge it to profit and loss, and admit that the entire policy of 110 years has been a colossal failure, instead of spending the money necessary to complete the system. It is submitted that no business organization, no combination of capital, would abandon any such sum as the $1 500 000 000 already spent to finish seven-eighths of a project which, until completion, is of little value, when by the appropriation of the additional 12½%, a reasonable return on the investment would become available.

In an endeavor to becloud the issue, and by using the same tactics that administrators of canals and highways used against railways in their early pioneering, a concerted attack is being made on the plan of the Federal Barge Lines to utilize streams, on the grounds that this organization is subsidized. It is an agency created by Congress to demonstrate that water transportation is feasible, and economically sound, and it is the only agency available for such demonstration.

Although the Federal Barge Lines have had a net operating income since the inception of the Inland Waterways Corporation, although no money has been appropriated for anything except expansions of the line, although the Corporation could exist and operate and furnish cheap transportation indefinitely on its net operating income, tables such as that in Fig. 10[21] are constantly being published to lead the public to believe that it is being mulcted. It is well to note that the Inland Waterways Corporation has existed only since the latter part of 1924; yet these charges apply to the total expenditures on the waterways on which the Corporation operates, or expects to operate.

[21] From *New York Times*, December 28, 1930.

These attempts to prove that there are certain "hidden charges" which the citizen pays when he ships by the Federal Barge Lines, are only efforts to detract the shipper's attention from one important fact; namely, that he is actually getting cheaper transportation by water.

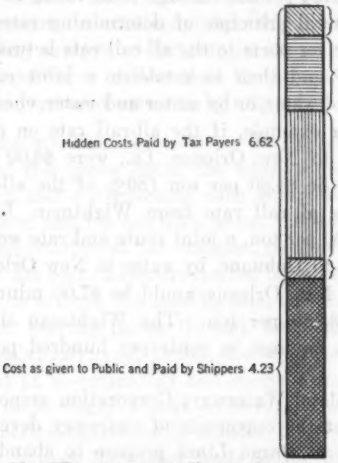

FIG. 10.—"DISCLOSED AND HIDDEN COSTS," IN MILLS PER TON-MILE, OF INLAND WATERWAYS CORPORATION'S OPERATIONS

Certainly the people have been taxed to create and maintain their navigable streams, harbors, lighthouses, etc., to accomplish a certain definite purpose; and since they have been taxed once to create them, why, in order to bolster up a case of "hidden costs", should they be charged again with "tax exemption," "maintenance of waterway," "interest and sinking fund on waterway," and "interest on the Corporation [their own] property?"

The Inland Waterways Corporation is the agent created by Congress to prove that having thus taxed themselves, the people can get that for which they have been taxed, namely, cheaper transportation by water. This is something they had been unable to secure for years, because water transportation has been destroyed by the railroads; and to tax the Corporation, in its pioneering, demonstrative work with a preposterous system of charges which do not exist, and which the people have willed should not exist, is to deny to the people the right to reap the benefit of the investment made.

Assuming, however, that what opponents claim should be charged against water transportation in Fig. 10, are actually things which should be considered, certain errors and discrepancies may be pointed out so that the reader may judge whether or not they make a legitimate case.

The diagram (Fig. 10) was evidently prepared from data contained in the annual report submitted by the writer in 1928. It claims a "hidden cost" to the taxpayer of 0.7 mill per ton-mile on the ground of "tax exemption." The distance from Minneapolis, Minn., to New Orleans is 1 839 miles. According

to Fig. 10 the hidden cost, "tax exemption" on a ton of freight transported from St. Louis, Mo., to New Orleans, is $0.8078. Since the freight charged on a ton of grain from St. Louis to New Orleans is $1.60, the "hidden tax exemption" is 50% as great as the cost, if the diagram is correct.

The total corporation "tax exemption," hidden cost, given in this diagram for 1928, would amount to $1 066 741.90; or (since the freight revenue for the year was $6 445 353.70) more than 16% of the total revenue. According to statistics of railways in the United States, published by the Interstate Commerce Commission for 1928, taxes of Class I steam railways were equal to 6.37% of the total operating revenues. Why charge the Inland Waterways Corporation 16 + %, or three times as much as the railways? On the same basis that railroad taxes are calculated, this "hidden cost" would be 0.23 mill per ton-mile.

On the same basis, the "hidden cost," as given by the diagram of "maintenance of waterways," would be $2 773 528.94; "interest and sinking fund," $5 409 905.35; and "interest on corporation property," $838 154.35 (a total of $10 088 330.54), while the total freight revenue received by the Corporation actually amounted to $6 445 353.70.

Why is this item, "maintenance of waterways," charged to the Inland Waterways Corporation? According to a pamphlet issued by the U. S. Department of Commerce there are 200 common carriers, 98 contract carriers, and 187 private carriers, with a total value of $150 000 000, operating on the inland waterways of the United States. In 1928, to which year Fig. 10 evidently referred, the value of the Inland Waterways Corporation was approximately $16 000 000, or 10.66% of the total invested on inland waterways. A proportionate share, therefore (if such charge is legitimate), would be 0.19 mill per ton-mile for maintenance of waterways, instead of 1.82 mills per ton-mile. The interest and sinking fund on waterways (if such charge be legitimate) would be 0.378 mill per ton-mile.

"Interest on the corporation property" is here computed at 5.5% of the actual value at the time. As a matter of fact the Government can get all the money it wants at 4%, so that the interest would amount to only 0.4 mill per ton-mile. Now, add to the actual items, the "disclosed costs" (which included a net income of $327 712.30), and all that Fig. 10 purports to give as hidden costs, in order to obtain the final cost per ton-mile. Then the results are, as follows:

| Item | Mills per ton-mile |
|---|---|
| Tax exemption | 0.26 |
| Maintenance of waterway | 0.19 |
| Interest on sinking fund, etc. | 0.38 |
| Interest on Corporation property | 0.4 |
| Cost paid for transportation | 4.23 |
| Total | 5.46 |

This may be compared with the 10.85 mills per ton-mile in Fig. 10. In comparison, the actual operating cost of the railroads equals almost exactly 10 mills per ton-mile, without considering any "hidden costs" in the form of land

grants to the railways since 1850, amounting to 132 173 224 acres, or of the subsidy of the $40 000 000 per annum received through Pullman surcharges, or other items.

This "land grant" by the Government to the railroads is a continuing subsidy, since in the fiscal year, 1930, there were 62 249.29 acres of land certified or patented on account of railroad grants by the United States to the railroads precisely as they were certified or patented (or granted) in the early days. One cannot be certain exactly what these 132 000 000 acres, more or less, were sold for, but according to an advertisement issued by the Northern Pacific Railroad Company in 1871, the lands granted to the Union Pacific sold for $4.46 per acre; the school lands of Minnesota, $6.30 per acre; and the lands of the Illinois Central grant at $11.00 per acre, and the advertisement quotes an "average of $4.00 per acre." The Government price per acre at this time was given as $2.50, so that, taking this extremely low price, there is a "hidden cost" to the people of the United States of 132 000 000 acres at $2.50 per acre, or $330 000 000, given to the railroads to secure a "right of way," just as the money spent for rivers was given by the people to the people themselves to secure a "river right of way." Furthermore, the rights of way thus given to the railroads by the Government are carried in the value of the railroads, on which the people are requested to pay an additional 5½% return.

The United States Government spends millions of dollars on harbor improvements, lighthouse service and construction, building jetties, dredging bars, and keeping channels clear and open, in order to aid ocean transportation and make possible the delivery by the railroads of multiplied train loads of freight and passengers. Without this expenditure the seaport terminals of the railroads would be dead ends and would soon become worthless. Of course, the Government is not meeting this great annual outlay specifically for the railroads, but as a means to an end, and to build up, protect, and stimulate the transportation service of the entire country and, also, in the interest of all the people, and it is manifestly a good policy. The people need transportation and they develop it through one form or another of subsidy.

They are entitled to the best form of transportation available at the cheapest possible rate, and if they desire to pay a part of the cost of transportation by highway, or by inland waterways, or by granting to the railways the present existing $40 000 000 subsidy of a surcharge on a Pullman ticket, they have a perfect right so to do. It would appear to be a much better policy on the part of all concerned not to attempt to mislead the people about hidden costs, but to furnish the best and cheapest possible transportation, in fair competition; and that system will come about through proper co-ordination and co-operation of all forms of transportation. It cannot be brought about by crying aloud that one form of transportation will destroy another, or by bickerings, evasions of self-evident truths, or unfair propaganda.

L. D. Cornish, M. Am. Soc. C. E. (by letter).—The writer wishes to record his appreciation of the very able discussion accorded his paper. Mr. Hadley's argument that inland waterway operation will not lower rail rates because of the fixed differential, is true only with respect to waterway common

carriers regulated by the Interstate Commerce Commission. The competition of contract and private carriers on the Ohio and Mississippi Rivers has resulted, during 1930, in certain railroads applying for reduced rates on steel products from the Pittsburgh District. Contract and private carriers unregulated as to rates also constitute a real menace to the development and existence of the waterway common carrier because of their rate-cutting methods.

Professor Sorrell's discussion the writer considers as a conspicuous accomplishment of the main purpose of his paper, namely, to invite or provoke discussions of the subject by trained and experienced students of the transportation problem. His discussion of the various forecasts of future traffic demand and the methods used should be valuable to those interested in that phase of the subject. It appears that the writer's forecast of 870 000 000 000 ton-miles is too large even if it be considered as the shippers' demand on rail, truck, and inland water transportation agencies exclusive of the Great Lakes. This consideration becomes necessary on account of the phenomenal growth of truck traffic since 1925. Truck traffic constitutes a serious menace to the future welfare of the railroads. They must meet this competition by reducing their short-haul and terminal costs and the consequential freight rates and must provide store-door delivery for L. C. L. freight.

Railroad officials and railroad periodicals lay much emphasis on the fact that railroad companies pay property taxes while truck carriers have the tax-free use of highways built and maintained at public expense. It is surprising, indeed, that they apparently overlook the tax on gasoline and its effect on truck operation costs. Every State in the Union taxes gasoline for motor vehicle consumption. The tax ranges from 2 to 7 cents per gal., and probably averages about 4 cents. Heavy motor trucks consume about 0.06 gal. per cargo ton-mile, and hence their gasoline tax for use of highways is about 2.4 mills per ton-mile, which is 3 times the property tax and about 1.6 times the maintenance cost paid by the railroad companies.

The suggestion of Professor Sorrell of a method of arriving at the probable social cost of a ton-mile of waterway transportation and the net social saving is very interesting. The writer feels indebted to Professor Sorrell for his splendid contribution to the subject and especially for his constructive criticism and discussion of the writer's paper.

Professor Kittredge charges the writer with two errors of major importance. First, that "figures which cover the total cost of railway transportation have been used in comparison with other figures which include only a part of the cost of waterway transportation".

This should not be charged as an error for the reason that the writer made no pretension of drawing a comparison between the respective total costs, including past expenditures, for either railways or waterways. To have attempted that would have been futile and the results of only academic interest. Why be concerned about the economic wisdom of past expenditures, or interest charges on them? The writer's comparisons and conclusions refer only to the Mississippi Valley systems. Federal appropriations therefor were provided by taxes, not bond issues, and the public is not paying interest on them. If

one must consider all this water (which is "over the dam" with respect to waterways), why not then, give similar consideration to the millions and possibly billions of dollars of capital which has been lost by investors in the re-organization of bankrupt railroads?

The writer specifically limited his discussion to future costs for railroad extensions and to the completion of Mississippi Valley waterway improvements which, at that time, had been approved and authorized by Congress.

The second error charged by Professor Kittredge is to the effect that the writer claimed as an economic advantage of the waterways an annual amount of $73 600 000 to cover interest on railway capital expenditures saved by the completion and utilization of the Mississippi Valley waterways.

The writer realized that the amount of this claimed advantage was highly questionable and so pointed out in his paper. Professor Kittredge and others called this to the attention of the writer previous to the publication of the paper. All these critics admitted there was justification for some claim of this kind, but did not suggest a method of evaluating it. After due consideration the writer decided to let the claim stand as originally made in the hope that the subject would be clarified in the discussions and that it would serve as a target to invite discussion of the entire paper, particularly by railroad officials and economists.

*The Traffic World,* of which Mr. Palmer is Editor and Manager, is severely critical of the development of inland waterway transportation. While undoubtedly he is well qualified to discuss or challenge statements made by the writer and others who prepared the papers of this Symposium, Mr. Palmer has not (in so far as the writer can determine) chosen to do so. His discussion is apparently only a presentation of his personal opinion on a few of the general phases of the subject.

Mr. Palmer admits that "if it is found that water transportation fills a need that can be supplied in accordance with sound and reasonable economy it should, of course, be supplied", but he refuses to accord to water transportation the right to any form of paternalism or public support during its development period, although the preliminary development of railroads was due to this same form of paternalism.

The discussion by Mr. Brent is confined to the writer's paper and is principally devoted to showing its conservatism. This is, indeed, gratifying to the writer, particularly in view of Mr. Brent's broad knowledge of the subject gained from many years' experience with the Federal Barge Line and other transportation agencies, both water and rail.

It should be noted, however, that Mr. Brent discusses rail costs and traffic densities on the basis of miles of road, whereas the writer discusses them and presents figures on the basis of miles of track. By the latter method costs and efficiency are reduced to a basis common to all railroads, whether of single or multiple-track construction. The Pittsburgh and Lake Erie Railroad mentioned by Mr. Brent has 231.46 miles of road, but it has 1 200 miles of main track. Hence, while its road-mile traffic density (10 700 000 ton-miles) is the greatest, its track-mile density—the true measure of efficiency—is 2 060 000 ton-miles. The Virginian Railroad has the greatest track-mile density

(3 400 000 ton-miles) of any railroad in the United States. Mr. Brent's statements and arguments based on miles of road are correct and would be equally applicable and forceful if reduced to a miles-of-track basis.

The railroad point of view in this controversy has been so seldom presented, except in generalities, that the discussion by Mr. Dunn, who is Editor of *The Railway Age*, stands out as a most valuable contribution to this Symposium. Mr. Dunn presents his data and arguments and conclusions in sufficient detail so as to invite specific definite argument in rebuttal. His views, however, are based upon certain fundamentals which are really the points in controversy. He denies the economic soundness of any form of public subsidy to waterways which is not fully reflected in the cost of water transportation. Recurring annual subsidies should be so reflected, but why should interest on accumulated construction costs provided by the public for channel improvement be added to operating costs when the public is not being taxed for them? There is no more reason for adding such a theoretical interest charge to waterway operation costs than there would be in adding to rail rates a fair return on the billions of dollars of capital which has been lost by investors in the re-organization of bankrupt railroads.

While Mr. Dunn separates the cost of inland waterway transportation into two parts, namely, subsidy cost and the cost of the actual movement of freight, he insists on combining the two for comparison with rail rates, in order to show that the cost of water transportation is greater than rail freight rates. It is true that the public will "foot the bill", but as National or sectional prosperity depends more on the actual moving of the freight than it does on the amount of the freight bill, it is evident that it is the freight rate which must be the governing factor, and that this rate must not be greater than the traffic will bear. For two decades the agricultural and manufacturing industries of the Middle West have been slowly "strangulating" under freight rates which the traffic could not bear, at the same time permitting the industries to prosper. The public in the Middle West at last has realized this condition and believes that in inland waterway transportation lies the solution of the problem. Waterways are Nature's God-given free highways to Man and the laws of all great nations, including those of this country, recognize them as such. Therefore, it is an obligation of the Federal Government to maintain such of these channels as may be used to the economic benefit of the sections where they exist. The extent to which such channels will be used will depend upon the terminal and operating costs of waterway movement plus the profit required to secure the necessary capital. If the resulting freight rates attract commerce in considerable volume, the community will benefit. Some railroads may suffer for a time; but such incidents are only passing events in the march of progress, which cannot be stopped in a nation of free people. A far greater menace to present railway operations exists in the remarkable growth of truck and bus traffic. The haulage costs of truck traffic greatly exceed rail costs. This is a basic economic advantage possessed by the railroads, and hence they should be able to recapture that business.

From his viewpoint of the subsidy question Mr. Dunn correctly shows the present status of costs on the New York Barge Canal, although better authori-

ties than the one he quotes have repeatedly asserted hidden public benefits to an amount greatly in excess of the "hidden" cost mentioned by Mr. Dunn.

The part of Mr. Dunn's discussion relative to the Ohio River System costs is answered in the discussions by Colonel Kutz and Mr. Hobbs, both of whom (as U. S. War Department officials) possessed authoritative knowledge of traffic and costs on that System.

Mr. Dunn's criticism of the writer's forecast of rail ton-mileage for 1950 is well founded. It is probably from 10 to 15% too high. This forecast (Curve *B*, Fig. 5) was derived in 1925 from railway records to 1924. Truck traffic was not considered because its importance was not realized. Authorities now state that the present truck traffic is about 10% as great as rail traffic. If this is true it would indicate that truck traffic in 1929 amounted to 45 000 000 000 ton-miles. Adding this to the rail traffic gives a combined total of 495 000 000 000 ton-miles which is exactly 1% less than the ton-miles shown for 1929 on the forecast curve, *B*, in Fig. 5 of the writer's paper. It is evident, therefore, that the forecast portion of Curve *B* should be considered as indicating the combined public demand for rail and truck traffic inclusive of such water traffic as may be diverted from those two agencies of transportation by the increase over the present volume of inland waterway transportation. Such a correction would require a downward revision in all the writer's forecasts of future railway development expenditures. This revision would not be nearly as extensive as indicated by Mr. Dunn, and to make it now would serve no useful purpose.

The writer is too firm a believer in the industrial future of the United States to accept Mr. Dunn's forecast of 575 000 000 000 ton-miles for rail traffic alone. To accept such a figure requires one to agree that the future rate of industrial progress of this nation not only will not equal the rate of the past forty years, but will progressively decline. If no greater traffic than this may be expected, then, as noted by Mr. Dunn, the writer's analysis shows that no additional trackage or equipment will be required. However, while equipment capacity has fallen off, track construction has continued, and capital investments of the Class I roads since 1924 have increased at a rate 50% in excess of the writer's estimate for freight traffic growth.

As a closure to this discussion, attention is invited to the publication in October, 1930, by the "Bureau of Railway Economics", of a 238-page report entitled "An Economic Survey of Inland Waterway Transportation in the United States". This work contains all authoritative facts and references on the subject and their analyses from the railroad point of view, as to present and past conditions only.

Certain cost data from this report have been widely quoted as proof that the cost of water transportation is greater than existing rail rates and that, therefore, waterway improvement is uneconomic. The report contains (pages 193 to 198) a summarized review of Mississippi and Ohio River costs for the year 1928. The facts are probably correct, but if intelligently and fairly used they offer all the proof required to demonstrate the economic benefit of water transportation on the Mississippi River System. It is needless to say that the so-called subsidy items of channel maintenance and annual interest

on accumulated construction capital cost for the past 100 years are included. The writer offers no protest at the inclusion of these items because the waterway traffic can stand it. The tabulations show the cost of these items per ton-mile of traffic in 1928, but the ton-mileage of that year is only a small fraction of the waterway capacity or the traffic reasonably to be expected within the next twenty years.

The ton-mile costs shown in Column (3) of Table 10 are exactly as they appear in the report (page 196) but Column (4) shows the costs based on a traffic of 45 000 000 000 ton-miles, and the total capital cost is assumed at $270 000 000 to cover the cost of completion of the project. Annual maintenance is increased to $6 000 000 for the same reason. Column (3) clearly shows the economic soundness of water transportation provided it can be developed to a satisfactory volume.

TABLE 10.—STUDY OF TON-MILE COSTS, MISSISSIPPI RIVER

| Item | No. | 1928 | 1938 to 1950 |
|---|---|---|---|
| (1) | (2) | (3) | (4) |
| Annual capital cost per ton-mile | 1 | 1.84* | 0.24† |
| Maintenance cost per ton-mile | 2 | 1.61‡ | 0.13§ |
| Freight-carrying cost per ton-mile | 3 | 4.00 | 4.00 |
| Sub-total | 4 | 7.45 | 4.37 |
| Allowance of 50% for circuity | 5 | 3.72 | 2.18 |
| Total cost per ton-mile | 6 | 11.17 | 6.55 |
| Weighted average freight receipts of eight railroads near the Mississippi River | 7 | 10.09 | 10.09 |
| Total, in ton-miles | 8 | 2 951 000 000 | 45 000 000 000 |

* 4% on $135 000 000. † 4% on $270 000 000. ‡ 4% on $4 753 000. § 4% on $6 000 000.

Referring only to the 1928 values in Table 10, the report (page 196), states:

"The rail costs average 10.09 mills per ton-mile; the estimated *minimum* transportation costs on the Mississippi River average 11.17 mills per equivalent ton-mile, after allowance is made for the greater circuity of the water route."

Attention is invited to the unwarranted use of the word, "minimum", in the foregoing statement.

Inasmuch as the Bureau of Railway Economics has included in its waterway costs for 1928 all items which it considers necessary to conform to sound accounting practice, the total thus derived should be reduced by the 20% freight-rate differential saved on water shipments before a comparison is made with rail rates. The freight-carrying cost of 4 mills per ton-mile increased 50% on account of circuity or greater length of water haul over rail haul between ports becomes 6 mills. However, since the shipper, in paying this amount, saves 20% of the rail rate, his saving becomes 25% of 6 mills, or 1.5 mills per ton-mile. Subtracting 1.5 from 11.17 and 6.55, respectively, leaves 9.67 mills per ton-mile in 1928 and 5.05 mills per ton-mile by 1950, at which time (as indicated on Fig. 9) traffic will equal 45 000 000 000 ton-miles per annum on the Mississippi River alone. This indicated public

cost of 5.05 mills for future traffic is the figure which should be compared with rail rates of 10.09 mills per ton-mile to determine the relative public economy of the two methods of transportation.

Thus, it is shown that, by the railroad method of accounting, waterway transportation costs to the public on the Mississippi River in 1928 were slightly less than average rail rates, and that if and when water traffic equals 45 000 000 000 ton-miles per annum, the cost will be 5 mills per ton-mile less than present average rail rates.

The Bureau report (page 198) shows, in the same way, that water costs on the Ohio River in 1928 were 12.36 mills per ton-mile and that comparable average rail rates were 8.83 mills. The water costs covering capital and maintenance are based on 2 702 416 316 ton-miles of traffic in 1928. Fig. 9 indicates that by 1945 Ohio River traffic will be five times the present traffic, in which event the capital and maintenance charges would be one-fifth of the amounts shown by the Bureau report for 1928. By making this adjustment the indicated water cost for 1945 becomes 6.91 mills per ton-mile, or 1.92 mills less than present average rail rates.

Numerous railroad officials and economists in public addresses (many of which have been reproduced in the public press) and railway periodicals, supplemented by editorial agreement therewith, have repeatedly asserted that, if inland waterway transportation on the Mississippi River had to bear the cost of the construction and maintenance of the channel as railroads do with respect to this right of way, the cost of water transportation would be shown to be greater than the cost by rail. Their methods of accounting for capital and maintenance of channel costs are not in accord with the National policy. However, if their method is accepted as economically sound, their assertions are reasonably correct with respect to present-day traffic, but very incorrect if water traffic develops in large volume. Economic justification, therefore, depends not upon present-day costs, but upon the development of a large volume of water traffic which will reduce these overhead, or so-called subsidy, items to almost negligible figures.

E. A. Hadley, M. Am. Soc. C. E. (by letter).—The several discussions of the writer's paper have been given careful consideration. The operating statistics and capital expenditures made by the railroads are readily available to any one interested in the subject, from the reports which are required to be made to the Interstate Commerce Commission; and all such statistics and reports are made on a uniform basis in a manner prescribed by the Commission.

On the other hand, information and statistics regarding waterway development and operation must be gathered with great effort from a large number of official reports of various departments of the Government. Many of these reports are issued by the Chief of Engineers of the United States Army and others appear in the reports of the Inland Waterways Corporation, a Government organization. The annual reports of the Chief of Engineers consist of bound volumes aggregating from 3 000 to 6 000 pages, from which it is no small task to assemble data pertinent to the subject under discussion.

The Bureau of Railway Economics, which has been established by the railways of the United States for the scientific study of transportation problems, issued a volume, designated as Special Series No. 56, and dated Washington, D. C., October 15, 1930, entitled: "An Economic Survey of Inland Waterway Transportation in the United States." The information and statistics given in the volume are as nearly correct as it is possible to have them, based upon the official and unofficial sources of information from which it has been compiled. This volume furnished a considerable portion of the foundation for the discussion in the writer's paper.

A joint report[32] of the U. S. Corps of Engineers and the U. S. Shipping Board issued in 1927 has laid down the principle that when the cost of water transportation is to be compared with the corresponding cost of rail transportation, the former should include interest charges on the capital investment in the waterway improvements plus the annual cost of operation and maintenance. Using these basic principles, and applying them to available statistics regarding the Mississippi River, the Ohio River, and the New York State Barge Canal, the following situation is developed:

(1) Transportation costs on the Mississippi River are not less than 11.17 mills per ton-mile, with allowance made for circuitous river channels; on eight railroads which, in general, parallel that river, the average inclusive freight charge per ton-mile is 10.09 mills.

(2) Transportation costs on the Ohio River, determined in a similar manner, are not less than 12.36 mills per ton-mile; on seven railways which, in general, parallel that river, the average inclusive freight charge per ton-mile is 8.83 mills.

(3) Transportation costs on the New York Barge Canal are computed at 19.41 mills per ton-mile; on the railways of the Eastern District the average inclusive freight charge per ton-mile is 10.90 mills.

It must be remembered that the financial statements issued by the Inland Waterways Corporation do not make any allowance for return on the capital stock issued by it to the Government. The expenses of the Corporation do not include any provision for taxes because the Government pays no taxes to itself. These items must be considered a charge against revenue before any private investor would judge the operations of the Barge Line to have carried out the purpose for which it was established, namely, to demonstrate whether or not the service can be carried on by private capital at a profit.

Because of lack of statistics it is not possible to compare the operations of private river carriers and those of the Government Barge Line with respect to their profitableness. Even if the private carriers use free-of-charge, improved waterways made possible by expenditures of Government funds, they do pay taxes and may be presumed to earn a return on their investment or they could not remain in business. The same condition is true of those companies which utilize the improved waterways for hauling their own raw materials and products in that they use the waterways free of tolls and find the water transportation a more or less profitable extension of their plant operations.

[32] "Transportation on the Ohio River System" (Interim Rept.), 1927, p. 17.

The statement is repeatedly made that the present means of transportation will not suffice to meet the future growth of traffic incident to the growth of the country in population and wealth. President Roosevelt in his letter creating the Inland Waterways Commission, in 1907, wrote:[33]

"It is common knowledge that the railroads of the United States are no longer able to move crops and manufactures rapidly enough to secure the prompt transaction of the business of the nation, and there is small prospect of immediate relief. * * * There is reason to doubt whether any development of the railroads possible in the near future will suffice to keep transportation abreast of production."

President Roosevelt had before him the relatively large rail-traffic totals for 1906 when he wrote this letter. Despite his predictions, however, the rail traffic of 1929 was more than double that of 1906, and this increased traffic was moved promptly without congestion and without delay to shippers or receivers.

In its 1908 Annual Report, the Inland Waterways Commission, stated:[34] "It is clear that at seasons recurring with increasing frequency they (the railways) are unable to keep pace with production or to meet the requirements of transportation."

The National Waterways Commission in 1912 stated[35] that the rapid expansion of traffic between 1904 and 1907 had exhausted the surplus capacity of the railroads and added: "With the next period of expansion there is strong probability of a worse congestion of traffic than occurred before."

While he was Secretary of Commerce, President Hoover made addresses throughout the country advocating the consolidation of the scattered sections of improved waterways. In this connection he made the statement that the growth of population within twenty-five years would produce such an increase of traffic that the railways would be unable to meet it. Using past history as a basis for forecast of the future, the railways will undoubtedly keep ahead of the growing demands of traffic upon them. For several years no traffic congestion has occurred and reports of the Department of Commerce have emphasized the remarkable improvement of the transportation service rendered by the railway industry.

The construction and operation of any system of transportation involves large expenditures of money and it may be briefly considered that the principal items of expenditure are, as follows:

(1) The cost of construction of the system itself, which usually runs into hundreds of millions of dollars for any large project. In the case of a railroad its cost covers the right of way, tracks, and other permanent structures. In the case of an inland waterway, it covers the cost of construction of the canal or improvement of the river, with locks, dams, and other appurtenant structures.

(2) The annual charge for capital; that is, the annual interest charge on the money invested in the construction or improvement.

(3) The cost of necessary equipment, whether in the form of railroad locomotives and rolling stock, or of ships and barges.

[33] Preliminary Rept., Inland Waterways Comm., 1908, p. 16.
[34] *Loc. cit.*, 1908, p. 19.
[35] Final Rept., National Waterways Comm., 1912, p. 575.

(4) The annual carrying charge for capital invested in equipment.
(5) The cost of maintenance, both of the transportation route (railroad right of way and tracks, or river and canal), and of the equipment operated thereon.
(6) Proper charges for depreciation on plant and equipment.
(7) Necessary payments of insurance premiums and taxes.
(8) The direct cost of the transportation service itself, including wages, cost of fuel, materials, and supplies, and the cost of supervision and general expense.

Unless all these items are considered and accounted for, no fair comparison of the relative costs of the two forms of transportation can be made.

The paper presented by Mr. Cornish as a part of the Symposium makes an attempt at forecasting the annual freight transportation demand of the United States by 1950, together with an estimate of additional railroad facilities required to provide for proper handling of that portion of the increase which would go to the railroads.

In discussion, Professor Sorrell sets forth in a most convincing manner the fallacy of attempting to forecast the probable freight traffic to be carried by the railroads in 1950. Furthermore, he states the results of similar forecasts brought down to the year 1943 showing such wide variances that he reaches the conclusion that "it is unsafe to assume that the trend for the next twenty-five years will be on the same basis as that for the last forty."

In his comparison of costs of transportation between the railroads and the waterways, Mr. Cornish overlooks the fact that the present average ton-mile earnings of the railroad include return on the investment and taxes, and he has also used the arbitrary differential of 20% in water rates under the rail rates as his measure of the saving in transportation costs by use of the waterways.

Mr. Cornish has further disregarded capital outlays already made for river improvements and terminals by use of public funds, except those terminals used by the Federal Barge Line. He also assumes that the present average freight receipts of the railroads of about 11 mills per ton-mile will prevail in 1950; however, should the increase in traffic on the railroads develop to the point estimated by him, it is probable that freight rates could be reduced materially, which would lessen the savings he estimates due to waterway improvements.

On the other hand, if all the figures going to make up the cost of waterways transportation are considered, the estimated savings on this account would largely disappear, particularly if the gain in waterways traffic did not reach the total of his estimate.

Many of the same fallacies in reasoning appear in the discussions by Colonel Kutz, and Mr. Hobbs. Mr. Brent comments somewhat on the paper by Mr. Cornish and toward the end of his discussion makes the following statement:

"The day of cheap railroad transportation is past. Sweeping increases in rates are being made in all important territories to bring railroad revenues to the mark fixed upon as necessary to support and expand the plant."

In 1922, the Interstate Commerce Commission ordered a 10% general reduction of freight rates in the belief that this would give "fuller assurance to the carriers of realizing the fair return contemplated by the law." Since that date the Commission has granted no "sweeping increases in rates", but on the contrary there has been a continual paring downward of rates so that the present per ton-mile earnings of the railroads are less than they were following the reduction made in 1922, and there appears to be no indication on the part of the Commission of allowing any general increase in rates.

In the last analysis it appears that most of the proponents of waterways transportation give consideration to only a part of the costs of such service in making their comparisons, the remainder being borne by the Federal Government, or other public authority, while the railroad figures include all the elements of such costs and are borne directly by the railroads themselves. The total cost of each form of transportation should constitute the only basis for comparison.

Paper No. 1780

# FREQUENCY AND INTENSITY OF EXCESSIVE RAINFALLS AT BOSTON, MASSACHUSETTS[1]

By Charles W. Sherman,[2] M. Am. Soc. C. E.

With Discussion By Messrs. W. W. Horner, C. S. Jarvis, Milton F. Wagnitz and Lewis C. Wilcoxen, and Charles W. Sherman.

Synopsis

This paper presents the results of a study of the records of the recording rain gauge at Chestnut Hill Reservoir in Boston, Mass., covering a term of 50 years, and durations of heavy rain up to 72 hours. Curves of intensity of precipitation, corresponding to any period of time up to 72 hours, for various frequencies of occurrence are derived and discussed.

The form of curve showing the relation between the duration and the (average) intensity of precipitation is discussed, and the possibility of the application to other localities of the general formula herein derived, with the coefficients and exponents suitably modified, is suggested.

## Intensity of Rainfall

The rate at which precipitation occurs during heavy storms has been recognized for many years as the most significant of the information required in the design of storm-water drains and combined sewers. At first, the hourly rate, often taken as the presumable maximum for the locality, was commonly used, irrespective of the magnitude of the area to be drained. Later, it was recognized that the "time of concentration" for the particular area represented the period for which the rate of precipitation was desired; and it was noted that there was a relation between the length of the period and the corresponding intensity of precipitation.

For some time it was held that only periods of uniform intensity of precipitation were of significance in estimating storm-water run-off from rates of

[1] Published in April, 1930, *Proceedings*.

[2] Cons. Engr. (Metcalf & Eddy), Boston, Mass.

rainfall. In particular, the late Emil Kuichling, M. Am. Soc. C. E.,[3] emphasized the fact that if the rain fell at varying rates during the period of concentration, it was practically impossible to make trustworthy estimates of run-off from the rainfall record. If this criterion were rigidly applied, there would be comparatively few records of heavy rain of more than 20 or 30 min. duration which could be used; yet it is obvious that the effect of storms of variable intensity in producing run-off must usually be as great as, and sometimes greater than, that of a storm of uniform intensity and the same total precipitation in the particular period of time. Therefore, average intensities have been accepted as significant, and are utilized in the same way as though the precipitation fell at a uniform rate throughout the period under consideration; although it is recognized that the rate of rainfall was substantially uniform throughout the period in comparatively few cases where the duration exceeded 30 min.

### Recording Rain Gauge at Chestnut Hill Reservoir

This gauge was established by the late Desmond FitzGerald, Past-President, Am. Soc. C. E.,[4] in 1878, and there are now records from it covering a period of fifty years. It is maintained by the Metropolitan District Commission. A description of the gauge and its exposure is contained in a paper by Harrison P. Eddy, M. Am. Soc. C. E., entitled "Maximum Rates of Precipitation at Boston for Various Frequencies of Occurrence".[5]

*Effect of Elevation of Gauge.*—The collector of this gauge is on the roof of a building, about 25 ft. above the ground. An ordinary rain gauge is maintained at ground level, about 800 ft. from the present location of the recording gauge and about 450 ft. from the position which it occupied previous to 1898. In general, the total precipitation in any storm as shown by the elevated gauge was somewhat less than that collected in the ground gauge, although there were a few cases in which the former showed the larger amount.

The ground gauge has been assumed to be correct in all cases, and the records of the recording gauge have been adjusted by applying for each storm, a factor obtained by dividing the total collection, as shown by the ground gauge, by that indicated by the recording gauge. This factor has been applied to all periods of a storm, as there is no basis for modifying it. In value, it varied from 0.95 to 1.56; for the highest intensities, its value ranged from 1.03 to 1.16

*Comparison with U. S. Weather Bureau Gauge.*—In Mr. Eddy's paper referred to previously, the records of the gauge at the Chestnut Hill Reservoir, for the 38-year period then available, were analyzed and also those of the U. S. Weather Bureau gauge at Boston for 26 years. The distance between the two is about 5 miles. Although there were differences in the results obtained it was concluded that, on the whole, they were as nearly the same as could be expected; and as the records obtained at Chestnut Hill

[5] *Journal*, Boston Soc. of Civ. Engrs., 1920, Vol. VII, p. 47.

were adjusted by comparison with those of a ground gauge, while no such adjustment of the Weather Bureau gauge was possible, the former were thought to be the better.

In this paper, no comparison with the records of the U. S. Weather Bureau gauge is attempted.

*Duration of Intense Rainfall.*—In earlier analyses of records of intense rainfalls, comparatively little attention was paid to storms lasting more than 2 hours. In the cases in which longer periods were considered, it appears probable that but few of the significant storms were considered.

In view of the greater extent to which storm flow is now being estimated from rainfall, for periods of concentration as long as 2 or 3 hours, or even more, and of the recent application of this method in estimating flood flows of streams for which the period of concentration may be 3 days, or more, particular attention was paid in this analysis to heavy rains covering the longer periods. It was found that, in Mr. Eddy's paper, a number of storms which in reality lasted 3 hours, or more, at high rates were actually included in the study only for periods of 80 min., or less.

All storms which showed a precipitation of more than 1 in. in 24 hours, 2 in. in 48 hours, or 3 in. in total precipitation, were also studied in detail, and rates of precipitation for longer periods up to 72 hours were computed and utilized in the present analysis.

*"Extended Duration" Principle.*—As a logical extension of the use of average rates of precipitation, all storms in which the total precipitation was sufficient to show significant average rates for periods longer than the actual duration of the rainfall were considered as though they had continued for the longer times. Thus, a storm which yielded a total precipitation of 1.50 in. in 50 min., had an average intensity of 1.80 in. per hour for that period, of 1.50 in. per hour for 60 min., and of 1.13 in. per hour for 80 min., all of which might be of significance in the analysis.

In tabulating the 50 highest intensities for each duration from 5 to 180 min., only 10 of the 650 figures were supplied in this way. In the case of long-time storms, however, a considerable number were tabulated for longer periods than the actual durations of the storms.

*Analysis of Records.*—The quantities of precipitation, adjusted to agree with the ground gauge, and the corresponding intensities for periods of 5, 10, 15, 20, 25, 30, 45, 60, 80, 100, 120, 150, and 180 min., were tabulated for the significant storms, so as to obtain the fifty greatest intensities for each of these periods, utilizing the "extended duration" principle wherever applicable. The records of long storms were analyzed by hours, to ascertain the greatest intensities for periods of 4, 5, 6, 8, 10, 12, 15, 18, 21, 24, 30, 36, 42, 48, 54, 60, 66, and 72 hours, so as to obtain at least the highest ten intensities for each of these periods.

## FREQUENCY

If the 50-year record were a fair representation of the average 50-year period at Boston, then the greatest intensity for each of the periods should be that which is likely to recur once in 50 years, or that which is likely to

have a frequency of 50 years. The points of second magnitude represent intensities which might be expected to be equalled or exceeded twice in 50 years, or to have a frequency of 25 years; and the points of the fifth magnitude would have a frequency of 10 years.

It is reasonable to suppose, however, that some of the maximum points may be high enough so that similar intensities will not recur for 100, or even 500 years; the 500-year maximum must occur within some 50-year period, and it may have been in that studied. It is probable also that some of the maximum points may be lower than they would be for an average frequency of 50 years, if the record had covered a longer term, such as 200 years. That is, the curve showing the relation of intensity to duration for a frequency of 50 years can not be very satisfactorily determined from the maximum points of a 50-year record. The 25-year curve is much more definitely fixed, because the record covers two full periods of 25 years; and curves of greater frequency are still more definitely determined.

## Form of Intensity-Duration Curve

Intensity-duration curves for the several frequencies which might be expected to be fairly reliable, namely, those occurring three times in 50 years, and oftener, showed that the curves for all frequencies were of the same general form, although there were several places where the smooth curves were at some distance from the plotted points. The similarity in form of curve suggested that a single form of equation, with suitable modification of the constants, might be applicable to intensity-duration curves for all frequencies. Plotting on logarithmic cross-section paper with intensities as ordinates and durations as abscissas resulted in nearly parallel lines of slight curvature, which were convex upward. Then, assume an equation of the form:

$$i = \frac{K}{(t + b)^d} \quad \ldots\ldots (1)$$

in which, $i$ represents intensity of precipitation, in inches per hour; $t$, the period of time, in minutes; and $K$, $b$, and $d$ are constants; it was found by trial that a value of $b = 7.0$ was reasonably applicable to the points of each set (that is, for a particular frequency). Values of $i$ were then plotted as ordinates against $t + 7$ as abscissas, and it was found that all the points of each magnitude, from the third to the fiftieth, would lie very nearly on a straight line, while those for the first and second magnitudes were reasonably distributed about such lines. They were very nearly parallel; and if $d$ were taken as 0.7 in each case, the resulting parallel lines were satisfactory as representing the whole series of observations. The general formula for relation between intensity of precipitation and length of period is, therefore,

$$i = \frac{K}{(t + 7)^{0.7}} \quad \ldots\ldots (2)$$

*Value of Coefficient, K.*—Values of $K$ corresponding to the third, fifth, tenth, twenty-fifth, and fiftieth magnitudes have been taken from a diagram

upon which the lines representing Equation (2) were drawn, with the following results:

| Frequency, in years. | Values of $K$ |
|---|---|
| 1 | 16.0 |
| 2 | 20.0 |
| 5 | 24.8 |
| 10 | 30.5 |
| $16\frac{2}{3}$ | 34.6 |

Values for frequencies of 25 and 50 years were not obtained by drawing intensity-duration curves, since the points departed so much from any straight lines (on logarithmic paper) that the positions of the most probable lines could not be fixed with satisfaction, at least on the basis of the study of precipitations of durations up to 180 min. It appears, however, that the relation between values of $K$ as listed herein can be expressed satisfactorily by the equation:

$$K = 16\, F^{0.27} \qquad (3)$$

in which, $F$ represents frequency, in years. The resulting values of $K$, compared with those taken from the diagram, are shown in Table 1.

TABLE 1.—VALUES OF COEFFICIENT AND RATIOS OF INTENSITY CORRESPONDING TO VARIOUS FREQUENCIES OF INTENSE RAINFALL.

| Frequency, in years. | Values of $K$. | | Ratio of Intensity to That for: | |
|---|---|---|---|---|
| | Computed. | From diagram. | 1-year frequency. | 10-year frequency. |
| 1 | 16.0 | 16.0 | 1.00 | 0.54 |

| 25 | 38.1 | .... | 2.38 | 1.28 |
| 50 | 45.9 | .... | 2.87 | 1.54 |
| 100 | 55.5 | .... | 3.47 | 1.86 |

There is doubt as to the propriety of applying the computation to a frequency of 100 years, but it is interesting to note the results secured and compare them with the greatest figures obtained from the records; and they are probably of significance as giving some indication of what may occur sometime in the way of phenomenal precipitation.

*Relative Intensities for Various Frequencies.*—The relationship shown by Equation (3) indicates that the intensity to be expected for any frequency of recurrence bears a direct relation to that for any other frequency; some of the ratios are arranged for comparison in Table 1.

## COMPARISON BETWEEN COMPUTED AND OBSERVED VALUES

Fig. 1 shows graphically the relation between the length of period (duration) and the intensity obtained from the records of the storms of first, second, third, fifth, and tenth magnitudes for all periods up to 72 hours, and of the twenty-fifth and fiftieth magnitudes for periods up to 3 hours. These

magnitudes are indicated by numerals beside the observed points. Fig. 1 also shows the curves derived for frequencies of 100, 50, 25, 16⅔, 10, 5, 2, and 1 years. The use of logarithmic cross-section paper makes it possible to bring all this information within the limits of a single chart.

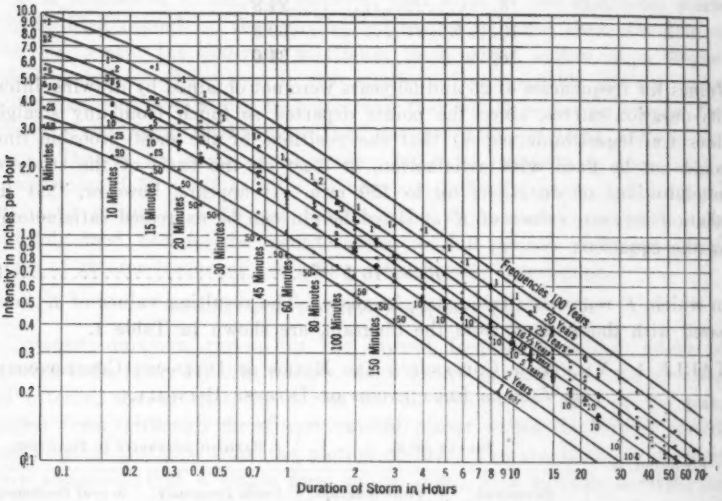

FIG. 1.—INTENSITY OF PRECIPITATION AT BOSTON, MASS., FOR VARIOUS DURATIONS AND FREQUENCIES.

The comparisons are believed to justify the conclusions that Equations (2) and (3) do represent satisfactorily the conditions existing at Boston for frequencies up to 50 years and durations up to 72 hours. There does not seem to be any record of a really excessive storm lasting more than 3 days, and it seems likely that such an occurrence, like total rainfalls in excess of 10 in. in a single storm, will be of great rarity.

*Comparison with Previous Studies.*—Some of the most significant of the earlier records observed at this station were the basis of another paper by the writer,[6] but the question of frequency was not discussed. Few if any engineers at that time had definite ideas on the relative frequency of rainfalls of high intensity, and records of rates of precipitation were insufficient to warrant any positive conclusion on that matter. A general form of equation was not developed, although two curves were suggested, as follows:

For maximum intensities,[7]

$$i = \frac{38.64}{t^{0.687}} \quad \ldots\ldots (4)$$

and for use as a basis for designs,[8]

$$i = \frac{25.12}{t^{0.687}} \quad \ldots\ldots (5)$$

[6] "Maximum Rates of Rainfall at Boston," by Charles W. Sherman, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. LIV (1905), p. 173.

[7] *Loc. cit.*, p. 178.

[8] *Loc. cit.*, p. 179.

It is interesting to note that the curves represented by Equations (4) and (5) compare reasonably well with those derived herein for 50-year and 10-year frequencies, respectively.

## Application of Formulas to Other Localities

It seems logical to assume that formulas of the same kind may be applicable in other localities. The writer has not found opportunity to make a similar analysis of other rainfall records; but a study made in 1920[9] resulted in the conclusion that the curve of rainfall intensities for the 15-year frequency at Boston, as given by Mr. Eddy[10] was a good one for a 5-year frequency at Springfield, Mass.; and that, in general, rainfall curves for Springfield were nearly like those which had been published for New York City. This indicates the possibility that suitable variations in the values of $K$ may be all that is necessary to make the formula herein derived applicable to a considerable area, such as New England and New York. In other localities, variations in one or both of the constants, $b$ and $d$, in Equation (1) probably will be required.

## Occurrence of Excessive Rates During Storms

In fixing run-off coefficients for use in computing storm flow from rainfall, some engineers use the so-called "zone principle" according to which the area is assumed to be divided into zones on which the rain has been falling for different lengths of time. The assumption is usually made that the rate of precipitation is greatest at the beginning of the storm, and, therefore, that smaller coefficients of run-off can be made with higher, than with lower, rates of precipitation. Comparatively little definite information as to the correctness of this assumption is available, and, therefore, this study was extended to determine the significant data as to the time, with reference to the beginning of the storm, when the excessive precipitation actually occurred.

The records of the ten highest intensities, having durations from 15 to 180 min., were examined to ascertain the quantity of rain falling in a period of equal duration and immediately preceding that in which the intense rainfall occurred. The results are shown in Table 2. They indicate that the assumption of a substantially dry ground surface at the beginning of the intense precipitation is reasonably correct; although there have been cases of heavy rains (not those of greatest average intensity), in which the quantity falling before the intense precipitation began was considerable. The latter condition might result in rates of run-off substantially as high as those from more intense rain falling on practically dry ground.

## Storms of Long Duration

It was noted previously that the study of long-duration storms was undertaken because it was believed that any formula representing the relation between intensity of precipitation and duration of precipitation should give

as reasonable results for periods of 1 day, or more, as for 1 hour or 2 hours, and also because of the increasing use of rainfall records in estimating probable flood flows of streams. In order to visualize the way in which the rain falls in such storms, the records of cumulative amounts in the twenty-two storms of greatest significance which occurred at Chestnut Hill Reservoir in the 50-year period, 1879-1928, have been plotted in Fig. 2. The curves show the computed maxima to be equalled or exceeded at average intervals of 50 years, according to Equation (2).

## ACKNOWLEDGMENTS

The writer is indebted to William E. Foss, Director and Chief Engineer, Water Division, Boston Metropolitan District, for permission to make use of the records contained in this paper, and to John W. Raymond, Assistant Engineer, Metcalf and Eddy, Boston, for assistance in the preparation of the paper.

## DISCUSSION

W. W. HORNER,[11] M. AM. SOC. C. E. (by letter).—Every designing engineer responsible for a combined or a storm sewer system would like to say:

"I am proportioning my sewers and drains to take the run-off corresponding to a 10-year frequency (or other frequency, as the case may be), because I have analyzed the conditions that will prevail when the less frequent and more intense precipitations occur.

"I find that rains corresponding to the 15-year curve will overcharge the sewers by a certain percentage; will cause a raising of the hydraulic grades which will back water into a certain percentage of the basements; and will create damage in the amount of so many dollars. I find that the still less frequent and more intense 20, 25, and 50-year types of rains will produce certain additional definite damages which I have evaluated.

"Summarizing all these damages, it appears that the average annual damage which will result from the occasional insufficiency of the sewers designed for the 10-year rain has a certain definite value, the capitalization of which is less than the cost of providing more capacious structures. Consequently, my choice of a 10-year frequency represents the exact economic solution of this particular problem."

It is highly improbable that any engineering designer has ever made any statement of this kind. Until now there has not been available a sufficiently good understanding of rainfall rates and frequencies to justify such study, nor has there been any indication that the character of land improvements within a drainage area can ever be so definitely known, and the use of the improvement so completely determined, that damages on the basis suggested could be arrived at with any reasonable approach to accuracy. Most engineers determine their choice on the knowledge of the temper of the citizenship and build sewers of a certain size, because they have come to believe that the use of smaller sizes would result in such frequent overcharge as to produce a mass of small damages and of great aggravations; and that the people are willing to pay for this particular type of sewer rather than to undergo the inconvenience and expense which the smaller and cheaper structures will involve.

It seems most unfortunate that a better economic analysis has not been possible. Although the extremes of detail set out in the hypothetical case noted are never expected to be available, it is desirable to approach that condition. Mr. Sherman's studies and results certainly offer at least a little advance toward the end desired.

There have been studies of rainfall frequencies of short storms in the past. Many engineers have delved into the matter crudely for office purposes. One very good preliminary study of this kind has been presented in the progress reports of the Committee on Rainfall and Run-Off, of the Municipal Engineers of the City of New York, but nothing heretofore has approached Mr. Sherman's work in the logic of handling, or in the careful detail of development.

If any difference of opinion were possible, it might lie in the placing of his curves with reference to points between 30 and 70 hours' duration.

[11] Chf. Engr., Sewers and Paving, St. Louis, Mo.

It looks as if his frequency curves are somewhat higher than the data justify for these longer storms, and this possibility is further borne out by the inspection of Fig. 2. If the storm of 1895 were considered as being possibly of the 100-year order, then his 50-year frequency envelope might well remain below the 7-in. line.

Considering the entire economic phase again, it is possible that the writer is over pessimistic as to the ultimate possibility of definite detailed analyses. While these are not likely to be used for newly developing areas, it is not impossible that matters involving relief sewers or flood channels for well developed districts of relatively unchanging use will occasionally be found to be susceptible to such treatment. When and if such occasions do arise, the author's data will be of inestimable value.

C. S. JARVIS,[12] M. AM. SOC. C. E. (by letter).—The author has set forth in summarized form some of the outstanding meteorological data with which a designer of waterways should be concerned. Only after a thorough analysis and concentration, comparable with the well-known process developed by the mining industry, will the greatest values of such records be made available. While discoveries or observations locate and define the immense volumes in which values may be found, the processes of reduction and separation bring forth the precious elements from the inert mass.

Some of the quantities displayed in Fig. 1 are re-arranged in Table 3.

TABLE 3.—MAXIMUM RAINFALL INTENSITIES AT BOSTON, MASSACHUSETTS.
(Expressed in inches per hour.)

| Rainfall periods. | FREQUENCIES, IN YEARS. | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| | 1. | 2. | 5. | 10. | 16⅔. | 25. | 50. | 100. |
| 5 min. | 2.8 | 3.3 | 4.3 | 5.3 | 5.8 | 6.7 | 8.1 | 10.0 |
| 15 min. | 1.85 | 2.3 | 2.8 | 3.4 | 3.8 | 4.3 | 5.4 | 6.5 |
| 60 min. | 0.83 | 1.0 | 1.3 | 1.6 | 1.75 | 2.0 | 2.4 | 2.9 |
| 3 hours | 0.40 | 0.48 | 0.63 | 0.75 | 0.84 | 0.98 | 1.20 | 1.50 |
| 24 hours | 0.10 | 0.13 | 0.16 | 0.18 | 0.20 | 0.24 | 0.27 | 0.34 |

This table shows that the maximum intensity to be expected during a century is about double that of a 10-year period, or four times that of yearly frequency. Conversely, a 10-year maximum intensity is to that of a 1-year frequency as a century maximum is to a 10-year maximum. Furthermore, a 50-year maximum is approximately double that of a 5-year maximum; and, similarly, for any other periods differing by a factor, 10. The logical assumption from the foregoing is that the 1 000-year maximum would be double the intensity listed in Table 3 recorded for a century, for each designated period, whether for minutes, hours, or for a day.

Examining the various columns of Table 2, it is apparent that the summations of maximum rates for the ten recorded storms during 15, 30, 45, 60, 120, and 180-min. intervals, respectively, are nearly 5.5, 8, 9, 9.5, 10, and 6.5 times

[12] Prin. Hydr. Engr., U. S. Engr. Office, War Dept., Washington, D. C.

greater than for the equal periods immediately preceding the intense rainfall. This is quite in accordance with the usual rainfall habits in temperate zones. The first few drops serve as a warning even though the sky may be bright or only slightly cloudy overhead. As the storm cloud advances the curtain of rain often inclines at a considerable angle, or whips about similarly to window draperies. Later, the brief intermittent squalls are displaced either by a steady downpour, or by a period of calm succeeding the storm, depending on the location of the atmospheric disturbance, its duration, and the path described.

It is re-assuring to find some semblance of consistency even among habits proverbially regarded as fitful and uncertain, such as those displayed by rainfall. The author has performed a lasting service by his presentation of the subject.

MILTON F. WAGNITZ,[13] M. AM. SOC. C. E., and LEWIS C. WILCOXEN,[14] ASSOC. M. AM. SOC. C. E. (by letter).—This paper is of particular importance. It establishes a basis by which the rainfall characteristics of different parts of the United States may be compared, and paves the way for determining the general laws of rainfall.

The writers' discussion is limited to the analysis of the rainfall data of Detroit, Mich. Before submitting the results for comparative purposes, an explanation of these data will be made. The statistical method used will also be outlined because it is believed that, for comparative purposes, the more exact results obtained are decidedly worth the labor. The rainfall data used are those of the U. S. Weather Bureau Station, situated on the Majestic Building, in Detroit. The records cover the 30-year period from 1896 to 1925, inclusive.

Records of excessive storms were tabulated by standard methods, that is, the period rates of each storm were tabulated, beginning with the period of maximum intensity. The periods taken were 5, 10, 15, 20, 30, 45, 60, 80, 100, 120, 150, 180, 210, 240, 270, 300, and 360 min. Intensities which were lower than those of succeeding periods were tabulated on the principle of extended duration, that is, the period of low intensity was credited with the rate of the higher succeeding period. The 1-year storm was taken as that hypothetical storm, the period intensities of which were equalled or exceeded thirty times. The 2-year storm is the one the period intensities of which were equalled or exceeded fifteen times, etc. The hypothetical frequency storms determined on this basis are shown on Fig. 3. It will be seen that the higher frequencies become progressively irregular. This, of course, should be expected since data by which they are determined, decrease in proportion to the frequency.

In fitting a system of curves to these data, it is believed that the importance of each frequency curve should be weighted, according to the number of storms by which it was determined. The determination of the weighted average frequency curve was, therefore, the first step in the analysis.

In the logarithmic form, Equation (1) (which is the general curve to be fitted) becomes $\log i = \log K + d \log (t + b)$. A value of 6 was first assumed

[13] Engr. of Public Structures, City Engr.'s Office, Detroit, Mich.

[14] Asst. Civ. Engr., City Engr.'s Office, Detroit, Mich.

for $b$, and $K$ and $d$ were determined by least squares. The normal equations for this solution are:

$$\log i = n \log K + d \Sigma [\log (t + 6)] \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

and,

$$\Sigma [\log i \times \log (t + 6)] = \Sigma [\log (t + 6)] \log K + d \Sigma [\log (t + 6)]^2 \ldots (7)$$

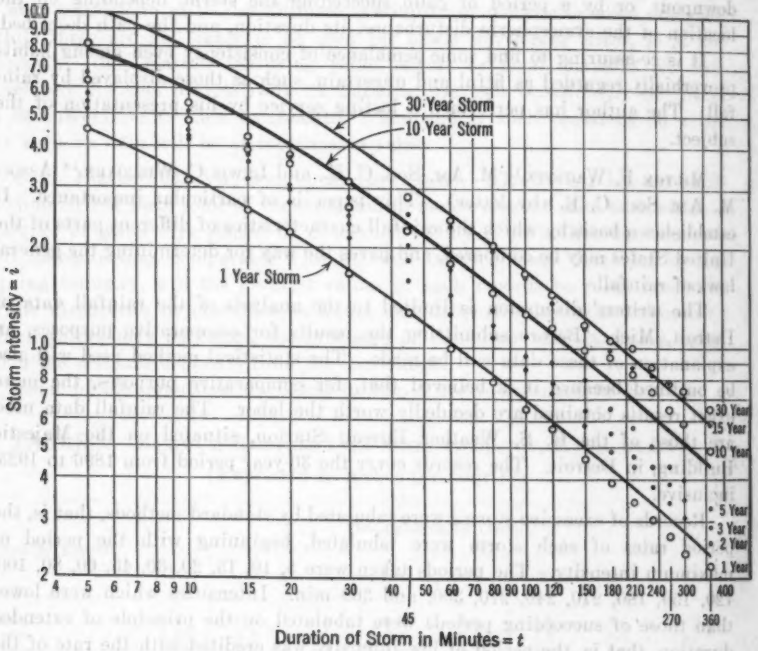

FIG. 3.—RAINFALL FREQUENCY CURVES.

Solving Equations (6) and (7) simultaneously, the resulting equation is:

$$i = \frac{40.73}{(t + 6)^{0.8368}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8)$$

By the same method, Equation (1) was solved assuming, successively, $b = 7$; $b = 8$; and $b = 9$. In the resulting equations the corresponding values of $K$ and $d$ are as listed, in Table 4.

The relative worth of these equations is determined by finding the squares of their respective standard errors $\left(\text{standard error} = \sqrt{\frac{\Sigma \text{ errors}^2}{n}}\right)$. These were next determined (see Table 4). The squares of these standard errors are plotted in Fig. 4. It will be noted that they are a minimum between $b = 8$ and $b = 9$, and very close to $b = 8$. Based on the 30-year rainfall record, the equation of the most probable rainfall curve for Detroit is: $i = \frac{K}{(t + 8)^{0.855}}$.

TABLE 4.—CONSTANTS FOR SUBSTITUTION IN EQUATION (1).

| $b$. | $K$. | $d$. | Standard error. |
|---|---|---|---|
| 6 | 40.73 | 0.8368 | 0.1185 |
| 7 | 43.62 | 0.8482 | 0.0720 |
| 8 | 45.80 | 0.8554 | 0.0292 |
| 9 | 52.75 | 0.8822 | 0.0415 |

The constants for the different frequency curves were next determined by the formula:

$$K = \frac{\Sigma [i\ (t + 8)^{0.855}]}{n} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

The results are noted in Column (2) of Table 5.

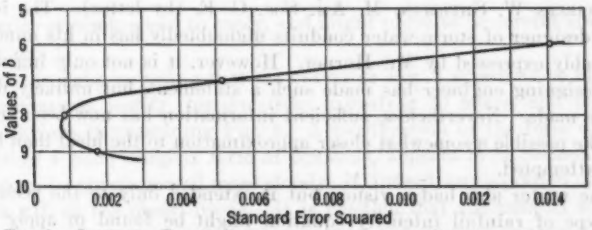

FIG. 4.—STANDARD ERROR, SQUARED, OF RAINFALL CURVE WITH VARIOUS VALUES OF $b$.

Fitting the curve, $K = a F^b$, to these data by least squares gives:

$$K = 37.6\, F^{0.263} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (10)$$

TABLE 5.—FREQUENCY CONSTANTS FOR DETROIT RAINFALL CURVES.

| Frequency, in years. | Values of $K$ ($= 37.6\, F^{0.263}$). | | Percentage error of actual $K$. |
|---|---|---|---|
| | Actual. | Computed. | |
| (1) | (2) | (3) | (4) |
| 1 | 35.9 | 37.6 | 4.5 |
| 2 | 45.5 | 45.1 | 0.9 |

The various $K$ values for the different frequency curves have been computed and are noted in Column (3) of Table 5, for comparison with the original data. To summarize the results of this analysis, it would appear:

1.—That the use of the least squares method for analysis of the data is desirable.

2.—That the Detroit rainfall curve has a different rate of change from that at Boston, Mass., and, hence, this may be expected to be different in different localities.

3.—That the relations of the intensities of the different frequency storms are almost exactly the same for Boston and Detroit, and, hence, that this may be a universal law.

4.—That because this frequency relation may be universal it seems likely that, if rainfall data were available covering a more extended period, the empirical rainfall curves of Detroit would more closely fit the curves herewith derived.

5.—That the data from other districts should be analyzed in order to verify Conclusions 1 to 4.

CHARLES W. SHERMAN, M. AM. SOC. C. E. (by letter).—The ideal which every designer of storm-water conduits undoubtedly has in his mind, has been admirably expressed by Mr. Horner. However, it is not only improbable that any designing engineer has made such a statement, but unlikely that it ever can be made. Nevertheless, sufficient information has now been accumulated to make possible a somewhat closer approximation to the ideal than has usually been attempted.

The writer also had a vision, but it extended only to the possibility that one type of rainfall intensity equation might be found to apply to a large section of the country—perhaps to the portion east of the Rocky Mountains—and that the frequency relation might be the same for all localities. If this were so it would be necessary only to determine the value of $K_1$ (in which, $K$ corresponds to a frequency of one year), and all the necessary figures relating to rainfall intensity would be available. Moreover, analyses of precipitation records at a considerable number of stations would then make it possible to prepare a map showing lines for equal values of $K_1$, and interpolations between these lines would be sufficient, in most cases, to find a proper rainfall-intensity coefficient for almost any locality.

This vision may have been a mirage, and although the writer is disappointed, he is not surprised to learn that Messrs. Wagnitz and Wilcoxen do not find the same form of equation applicable at Detroit as that derived for Boston. That the frequency relation should be approximately the same in both cases, appears worthy of special notice. To be sure, the analysis of Detroit figures did not include any durations beyond 360 min., and it is possible that somewhat different results would have been obtained if longer storms had been taken into account.

The use of the method of least squares in computing the constants for the formulas, by Messrs. Wagnitz and Wilcoxen, appears to be advantageous, particularly in determining the best possible form of curve to fit a particular set of records. However, it appears from an examination of Fig. 3 that the form of curve resulting from these computations does not conform very well with the observed values of the first, second, and third magnitudes, and even the divergence from the points of thirtieth magnitude (1-year storm) is considerable. This may mean that for Detroit conditions the form of equation

for each frequency is different from that for every other frequency. Perhaps, however, if the data were available for storms of longer duration, the apparent discrepancy between curves and plotted points would be less marked. It may be noted that if Fig. 1 had extended only to 3-hour storms, the divergence between the curves and the observations would have been more noticeable than is actually the case.

In view of the many items in storm-water design, which have to be fixed by the exercise of judgment, it is not impossible that a formula for intensity-duration relation of the form suggested in the paper may be close enough for general use; that the denominator should be $(t + 7)$, or $(t + 8)$, with an exponent of $\frac{3}{4}$, $\frac{4}{5}$, or $\frac{5}{6}$; and that the frequency relation may be taken as a function of $F^{\frac{1}{4}}$. Such figures, like the $\frac{3}{2}$-exponent in the usual weir formula, would be easy to remember and to apply, and might prove to be correct enough for ordinary use.

Mr. Horner is right in noting that the curves of Fig. 1 appear to be higher than the observations justify, for durations exceeding 30 hours, and this is particularly obvious in examining Fig. 2. A modification of the form of the curve, requiring a more complex form of equation, appears to be necessary if the points are to be approximated more closely; if, indeed, any equation can be found which will fit the observations. It is possible that the parallel curves obtained from the Boston observations represent a fortuitous circumstance, and that records at other places will not show similar results. Until the records of a considerable number of stations have been analyzed, it is possible only to speculate on this point.

Mr. Jarvis' comparison of the relations between intensities and frequencies is interesting, and is in such a form as to be easily remembered and applied. Since the Detroit data furnish some degree of confirmation of the figures obtained for Boston, these relations may be considered more likely to be of general application than any of the other figures presented. Whether the "semblance of consistency" in the intensity-duration relation is really reassuring, or just interesting and suggestive, can only be known when other records have been studied in a similar manner.

The writer agrees with Merrill M. Bernard, M. Am. Soc. C. E.,[15] that the intensity-duration formulas of the types, $i = \frac{K}{t + b}$ and $i = \frac{K}{t^d}$, are not equally applicable to both long and short periods of duration; but he believes that the type, $i = \frac{K}{(t + b)^d}$, is equally applicable to both long and short durations. Obviously, when $t$ is large and $b$ is less than 10, the difference between $t^d$ and $(t + b)^d$ is insignificant.

There is considerable probability of error in using the Morgan and Meyer data in the way Mr. Bernard has done in the paper cited, first, because few,

[15] "Formulas for Rainfall Intensities of Long Duration," *Proceedings*, Am. Soc. C. E., October, 1930, Papers and Discussions, p. 1835.

if any, "1-day", "2-day", or "3-day" storms lasted exactly 24, 48, or 72 hours; and, second, because the estimation of frequencies by computations based upon the sum of the length of records at several stations is open to severe criticism. Obviously, the sum of 100 one-year records, all for the same year, at 100 stations, cannot be equivalent to a record of a century at a single station. However, taking the figures given in Mr. Bernard's Table 3[16] for Quadrangle 15-*E*, and leaving out of consideration the slight differences in exponent of the denominator, it would appear that the frequency relation would be a function of $F^{0.22}$. Possibly this may be taken as further confirmation of the idea that the frequency relation may generally approximate a function of $F^{\frac{1}{4}}$.

# THE TRAINING WALL ACROSS THE LIAO BAR IN MANCHURIA[1]

By P. N. Fawcett,[2] M. Am. Soc. C. E.

With Discussion by Messrs. R. D. Goodrich, Herbert Chatley, H. C. Ripley, B. Okazaki, and P. N. Fawcett.

## Synopsis

This paper describes in detail the problems in harbor work encountered at the Port of Niuchuang in Southern Manchuria. The discharge of the Liao River has been such as to form a bar at its mouth, that continually hampers free navigation. The paper presents a description of the movement of this bar before the construction of the single training wall as well as during its construction. It also contains supplementary data concerning tides, winds, rainfall, velocities of river flow, and other information important to a study of this kind.

## Location

The Liao River is the most important waterway in Manchuria. Its length is 600 miles (of which 350 are navigable for junk traffic) and its drainage area is 80 000 sq. miles. It empties into the northern extremity of the shallow Gulf of Liaotung and the Gulf of Pechihli. The Port of Niuchuang (Newchwang), for which the improvements described in this paper were made, is shown in Fig. 1, at the northern end of the Gulf of Liaotung.

## Tidal Data

Fig. 2 shows the tidal curves for this river. Spring tides range between 10 and 13 ft. and neap tides between 7 and 8 ft.; the diurnal inequality during the spring tides is sometimes as much as 4 ft., the variation being confined

[1] Published in May, 1930, *Proceedings*.

[2] Engr. in Chf., Lower Liao River Conservancy, Niuchuang, Manchuria, North China; Care, F. Hewett, The Windmill, Hythe, near Southampton, England.

to the high waters, with practically none in the low waters. Owing to the peculiar formation of the entrance to the Gulf of Pechihli the tides are greatly influenced by winds. A northerly wind drives the water out of the Gulf, thus reducing the depths along the coasts, while a southerly wind forces the water into it, between Korea and the Shantung Peninsula, thereby augmenting the depth all over this shoal Gulf. Fig. 3 contains curves of simultaneous tidal lines and of high-water and low-water planes corresponding to Fig. 2. The readings are for stations along the river from about 6 miles below the Signal Station to a station at Uu-tai-tzu, about 65 miles up stream from Swan Island (see Fig. 4).

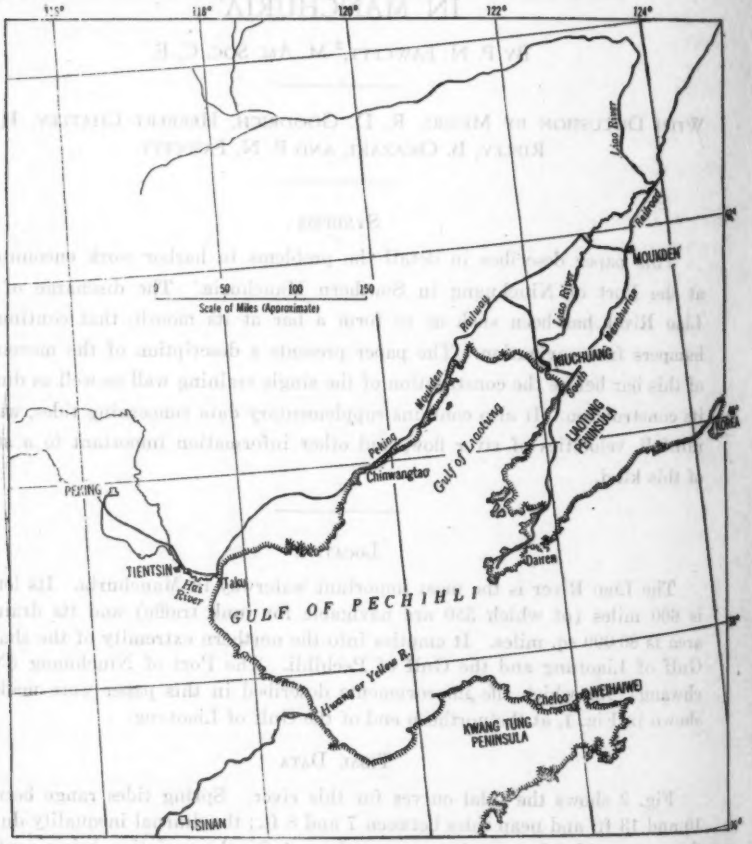

FIG. 1.—MAP OF DRAINAGE AREA OF THE LIAO RIVER.

The tidal charge of the flood of a spring tide, during the period of no freshets, is 140 000 000 cu. yd., or 210 000 cu. ft. per sec., and the ebb discharge is 152 000 000 cu. yd., or 154 000 cu. ft. per sec. The fresh-water discharge is

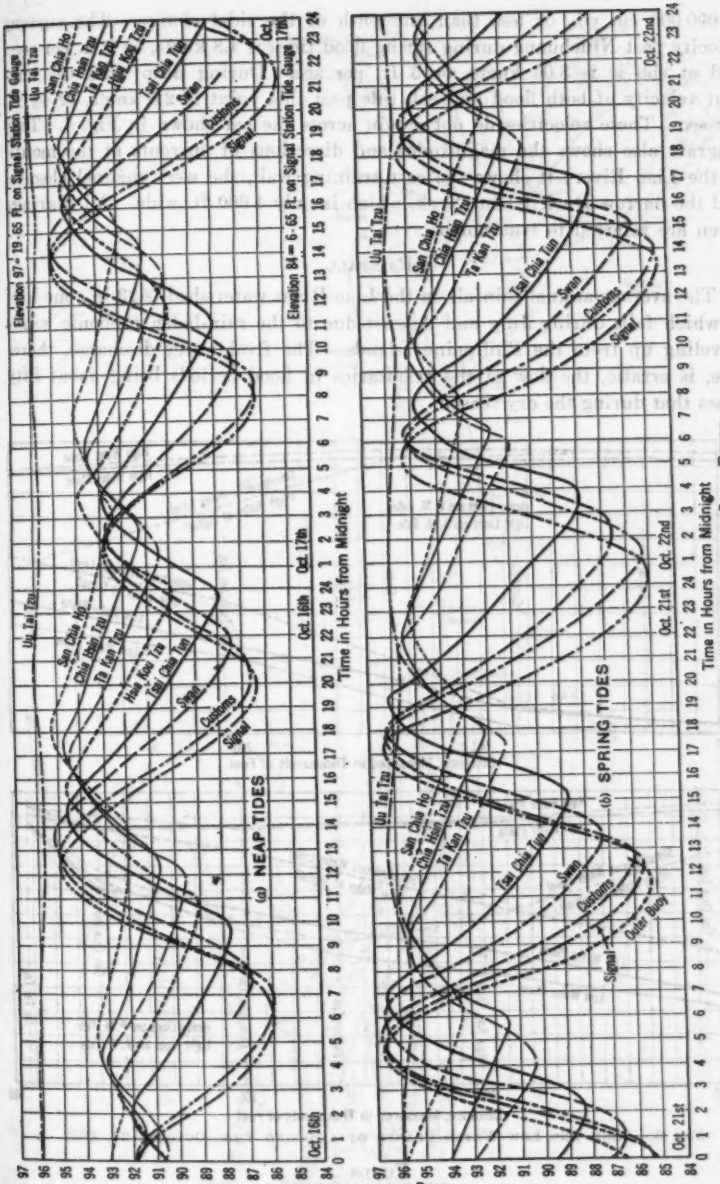

FIG. 2.—TIDE CURVES FOR THE LIAO RIVER.

12 000 000 cu. yd., or less than one-tenth of the tidal charge. The current velocity past Niuchuang during spring flood tides is 4.8 knots, or 8 ft. per sec., and at ebb it is 3.06 knots, or 5 ft. per sec. During neap tides the current velocity of both flood and ebb tide past this point is 2.6 knots, or 4½ ft. per sec. These velocities do not obtain across the bar shown in Fig. 4. This diagram also shows the magnitudes and directions of currents at the mouth of the Liao River; it shows the east training wall, the west channel closure, and the narrow Duck Island Neck, which is only 1 600 ft. wide. All bearings given are referred to true north.

## Rainfall

The average annual rainfall on the Liao River water-shed is 23 in., one-half of which falls during July and August due to the rain-laden typhonic winds traveling up from the Philippine Islands. The fresh-water discharge, therefore, is erratic, the flow of the tributaries in flood periods being about fifty times that during the dry season.

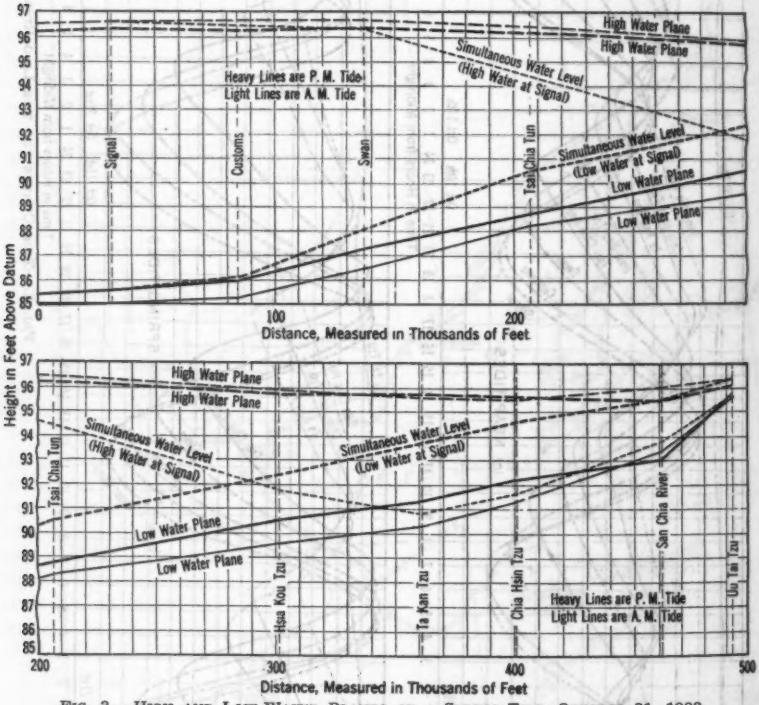

Fig. 3.—High and Low-Water Planes of a Spring Tide, October 21, 1922.

## Funds

The Lower Liao River Conservancy District was formed in 1914 by the Chambers of Commerce of Niuchuang, for the purpose of controlling the

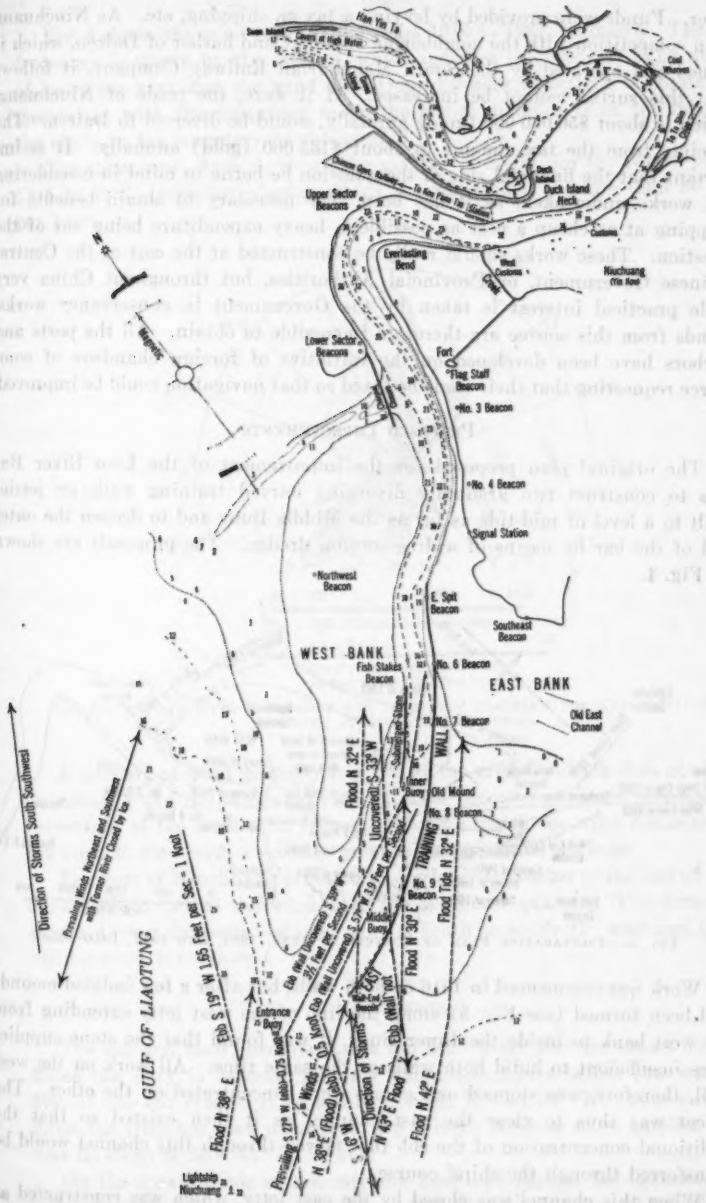

FIG. 4.—DIRECTIONS AND SPEEDS OF CURRENTS IN THE VICINITY OF LIAO BAR.

river. Funds were provided by levying a tax on shipping, etc. As Niuchuang is in competition with the neighboring free port and harbor of Dairen, which is owned and operated by the South Manchurian Railway Company, it follows that this surtax cannot be increased. If it were, the trade of Niuchuang, which is about $50 000 000 (gold) annually, would be diverted to Dairen. The receipts from the tax amount to about $135 000 (gold) annually. It is important that the financial side of the question be borne in mind in considering the works undertaken, as it has been very necessary to obtain benefits for shipping at as cheap a cost as possible, a heavy expenditure being out of the question. These works should really be constructed at the cost of the Central Chinese Government, or Provincial Authorities, but throughout China very little practical interest is taken by the Government in conservancy works. Funds from this source are therefore impossible to obtain. All the ports and harbors have been developed on the initiative of foreign chambers of commerce requesting that their trade be taxed so that navigation could be improved.

## Proposed Improvements

The original plan proposed for the improvement of the Liao River Bar was to construct two gradually diverging curved training walls or jetties built to a level of mid-tide as far as the Middle Buoy and to deepen the outer end of the bar by means of a drag-suction dredge. The proposals are shown on Fig. 4.

Fig. 5.—Comparative Plan of Surveys of 1889, 1907, and 1927, Liao Bar.

Work was commenced in 1916 on both walls, but after a few isolated mounds had been formed (see Fig. 5) along the line of the west jetty extending from the west bank to inside the Inner Buoy, it was found that the stone supplies were insufficient to build both walls at the same time. All work on the west wall, therefore, was stopped and efforts were concentrated on the other. The object was thus to close the east channel as it then existed so that the additional concentration of the ebb that flowed through this channel would be transferred through the ships' course.

When this channel was closed by the east jetty, which was constructed as far as the Middle Buoy, the west jetty was then to be completed.

## Wind

Fig. 6 shows the wind rose for the years 1916 to 1927, inclusive. The wind frequency is shown by the area, *B*, which includes the area, *A*. The number of hours per year that the wind blew from different directions is obtained by measuring, with the frequency scale, the radial distance from the center of the circle to the boundary of the area, *B*.

The inner rose, Area *A*, shows the number of hours, for the twelve years—1916 to 1927, inclusive—during which the wind blew at more than 56 miles per hour.

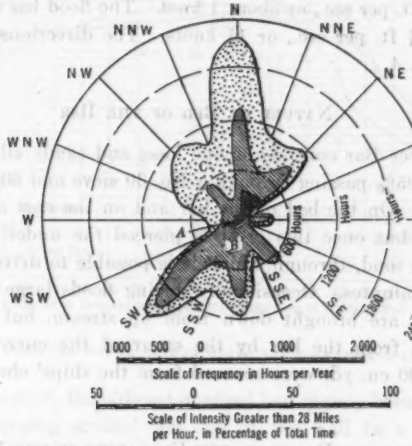

Fig. 6.—Annual Wind Frequency and Intensity Diagrams for Years 1916–1927, Observed at Niuchuang Customs.

A measure of wind intensity is given by the area, *C*, which does not include the areas, *A* and *B*. Measured radially, with the intensity scale, it indicates the percentage of the total wind frequency during which the wind measured from the area, *B*, blew with a velocity greater than 28 miles per hour.

The Port of Niuchuang is closed by ice from December to the end of March, during which period the wind is in the northeast quarter. The direction of storms during the period of open port is south to south 22° west and the prevailing wind is southwest.

## Currents

The ebb and flood currents across the Liao River Bar are shown on Fig. 4. Since the jetty is exposed for only about two hours before low water, the first of the ebb crosses it in a direction, S. 30° to 35° W. (true meridian). After the jetty has been uncovered, the current becomes more parallel with it, that is, about S. 55° W.

On the seaward side of the entrance buoy and beyond the influence of the jetty, the ebb currents flow S. 16° to 33° W.; the more southerly direction

being the ebb current flowing down and practically parallel with the west side of the west sand-bank. The flood tides flow in a direction from N. 25° to 35° E.

### Velocities of Flow

During spring tides the velocity of the ebb current within the influence of the training wall is from 2½ to 3½ ft. per sec., or a mean of 3 ft. per sec. The velocity of flow at the bottom is 2 ft. per sec. On the seaward side of the Entrance Buoy and along the west side of the west sand-bank, the velocity is from 1 ft. to 1½ ft. per sec., or about 1 knot. The flood has a speed throughout of from 2¼ to 2¾ ft. per sec., or 1½ knots. The directions and velocities are as shown on Fig. 4.

### Nature of Bed of the Bar

The Liao River Bar consists of fine loess and sandy silt brought down by the river, about 95% passing through a No. 30 sieve and 50% passing through a No. 175 sieve. On the bed of the bar and on the east and west banks the surface is hard, but once this crest is pierced the underlying material is a gummy clay like mud, through which it is possible to drive a water jet down 20 ft. in a few minutes. Occasionally during floods large quantities of pure fresh-water sand are brought down from up stream, but such deposits are quickly removed from the bar by the scour of the currents. In 1920, for example, 1 250 000 cu. yd. were scoured from the ships' channel in the course of 15 days.

### Littoral Drift and the Formation of the Bar

There appears to be no littoral drift at the Liao Bar and comparative surveys (see Fig. 5) do not show a definite relation between storms and changes in the low-water contours or depths. Again, contrary to the generally expressed opinion that bars at the mouths of tidal rivers are formed of the materials thrown up from the ocean bed during storms, those at the entrances of the Liao, Hai, and Yellow Rivers, flowing into the Gulf of Pechihli, are all formed by alluvia brought down by the rivers themselves and deposited in the sea in a similar manner to deltaic formations at the mouths of non-tidal rivers. The bars of the Liao and Hai Rivers both shoal from 1 ft. to 2 ft. during the freshet season which occurs in August and September, the period of calm weather. As far as can be ascertained storms appear to have very little effect upon the Liao Bar.

### Improvement of the Bar by the Construction of the East Jetty Only

Fig. 7 shows three longitudinal profiles across the bar and along ships' courses as they were in the years 1917, 1927, and 1928 (see Fig. 5). In 1917, one year after construction had begun on the east wall, the bar was 2 miles

long. At that time the crossing channel was only 6 ft. deep and during the greater part of the year it was only 5 ft. deep at low water of ordinary spring tides.

When a second survey was made in 1922 the wall had been constructed to a point opposite the Middle Buoy. Originally, this was to have been the end of two training walls, which were to have been assisted by a dredge.

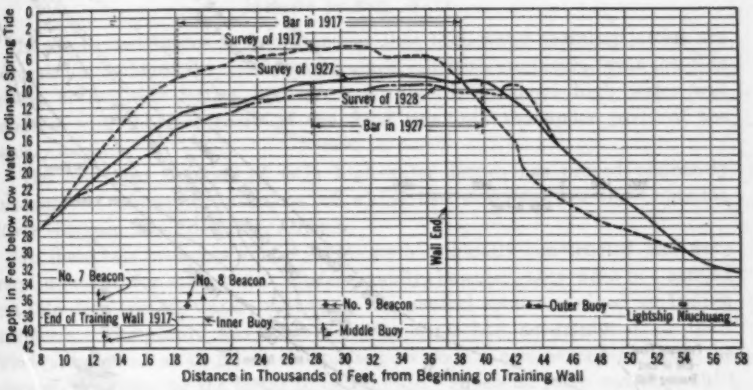

FIG. 7.—LONGITUDINAL SECTIONS ALONG LINE OF SHIPS' COURSES DURING 1917, 1927, AND 1928.

At that time, however, the old east channel had merely been pushed seaward and was still continuing around the end of the wall in a direction about S. 16° W. This is the same direction as the ebb currents in this vicinity and is in a mean direction of the prevailing winds and the storms.

The third survey made in 1924, after the wall had been extended still farther in a direction toward the Entrance Buoy, showed this easterly channel still persisting. During 1923, following a heavy freshet, the main body of the bar and ships' channel silted 2 ft. more than this easterly channel. Consequently, the easterly channel was made into the ships' course for a period of about one month until the silt and sand had been scoured off the bar. Then the old course was resumed and the construction of the wall was continued.

In 1926 the training wall was 6 miles long and a survey showed that the east channel was practically closed. An examination of these four surveys (1917, 1922, 1924, and 1926) showed that a depth of 9 ft. has always been obtained up to the existing end of the jetty and that by 1926 there was a navigable depth of 8 ft. across the bar. The positions of the bar in 1927 and 1928 are shown in Fig. 7. In 1928 the bar had a minimum navigable depth of 9 ft. and the wall was 37 750 ft. long.

The present (1928) plan is to terminate this wall in 14 ft. at low water opposite the Entrance Buoy (see Fig. 6). From Fig. 7 it will be noted that the bar has been advanced seaward into deeper water.

### Advance of the 9-Foot Contour

Fig. 8 shows the 9-ft. contour for a number of years from 1917 to 1928. The total advance is 22 500 ft. and has always followed the advance of the training wall. In fact, about 1 000 ft. up stream from the position of the contour for any year can be assumed to be the end of the wall for that year.

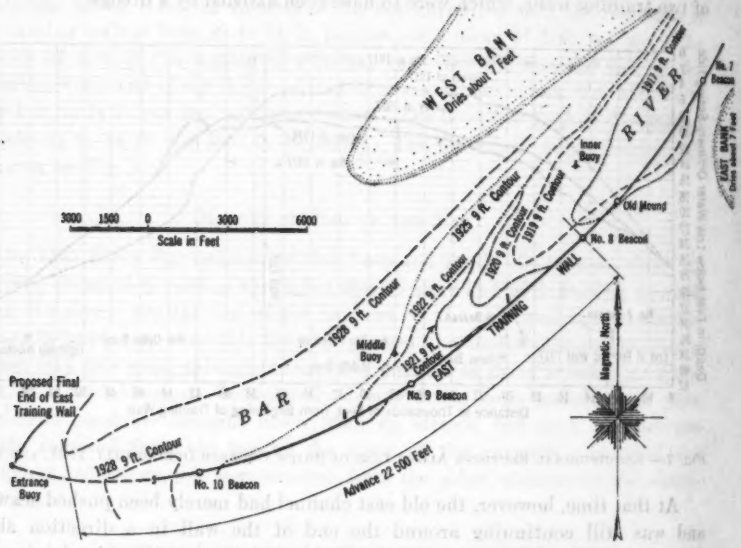

Fig. 8.—Liao Bar: 9-Foot Contour from 1917 to 1928.

The width from the wall to the west side of the contour (about 3 000 ft.) shows that the deepening has not been caused by over-fall during flood tide. The flood tide tops the wall after its first half hour of flow and passes over it very quietly and without any great disturbance. In another part of the river there is constructed a wall across what was known as the west channel. In this locality the early flood tide passes over with a head of about 1 ft. and causes a deepening on the river side due to over-fall. This deepening, however, is very narrow (about 100 ft.) and an excessive shoaling is formed in front of it.

Were the deepening across the bar caused by over-fall one would expect to find a corresponding shoaling in the main channel. The contrary is the case; the deepening that is taking place in the vicinity of the west bank extension is a disquietening feature because it is considered that should the channel deepen over too great a width, a shoaling will take place and necessitate the construction of a west wall. The deepening across the bar has undoubtedly been caused by the scour of the ebb tide excavating the bar and depositing it seaward into deep water.

### Quantity Scoured Off the Bar

The quantity scoured from the bar—irrespective of the annual freshet deposits—is equal to 22 000 000 cu. yd.

The annual freshet deposit is at times very great. In the freshet of 1923, surveys showed that a quantity of 1 250 000 cu. yd. of clean sand were removed in 15 days, or at the rate of 80 000 cu. yd. per day. Had such a deposit taken place prior to the construction of the wall, the bar would have shoaled for a year, or probably more, since there would have been no confined and trained ebb current to scour it away.

## Height of the Wall

In the United States it would appear that high-water training jetties are advocated and almost invariably constructed. British engineers favor low-tide jetties, or half-tide jetties, because a jetty built to above high water will interfere with the free entry of the flood tide into the upper parts of the estuary or river.

The American practice of twin high-water jetties has proved eminently successful in numerous instances, of which two examples are the Columbia River entrance and Coos Bay, Oregon.

In these two instances single jetties were originally constructed and were very successful for some time. Unfortunately, however, they were not carried out into deep enough water; that is, to the neutral zone as defined by Italian engineers. The result was that after the sand had accumulated on their windward side so as to fill in the space provided, it commenced to enter the channel, thus causing the latter to deteriorate. A second jetty was then built extending out into deep water and the original jetty was also lengthened.

This work met with great success, but it seems unfortunate that the original single jetties were not extended first, so as to pass the sand drift around their outer ends, and so that the effects could be observed. By this means equally successful results might have been achieved without having recourse to the second jetty.

In the case of the Liao entrance the east and west banks form what are really two low-tide jetties which maintain a channel between their 20-ft. contours over a width of almost 2 000 ft. It would appear reasonable to expect two low-tide walls to act in a similar manner if extended seaward.

Irrespective of this point of view and because of ice drifting across the jetty during the winter months, it has been found that the wall across the Liao Bar must be either practically a low-tide one, or that it must be built completely above high water.

The present method is achieving immediate results while at the same time it permits the jetty to be carried above high water, should that be deemed advisable at any future date when the trade of the port becomes sufficient to justify the expense. Model tests would be invaluable in solving several problems of this nature.

The solution of the problem became a question of attempting to get the best results for a minimum expenditure. Since the whole body of the ebb tide travels in a south-southwesterly direction, or away from the west jetty (if that is ever built), and since it was seen that the low tide east jetty always deepened the bar to 9 ft., as its construction advanced, it was decided to continue extending the east jetty and to hold the construction of a west jetty in abeyance.

Before arriving at this decision, the question of costs was analyzed. To date (1928), the cost has been approximately $1 250 000 (gold). Maintenance charges are likely to equal about $60 000 (gold) per year, whereas the cost of a suitable drag suction dredge would be $650 000 (gold) and operating expenses $60 000 (gold) per year.

It would appear, therefore, to be more economical to abandon the intention of building the second jetty or heightening the present one and to rely on any further deepening to be obtained by dredging. This would save half the original first cost of the west jetty—or all the cost of heightening the east jetty—plus the additional interest and amortization charges. The latter would be sufficient to provide a new dredging unit every ten years.

## Comparative Surveys

Comparative surveys previously mentioned, show that the 1-fathom depths have had an eastward advance of about 5 400 ft. between 1860 and 1927, or at the rate of about 80 ft. annually. The direction of the channel in 1860 and in 1889 was S. 53° W.; in 1907, it was southwest; and, in 1927, the channel trained by the east jetty was S. 67° W. Since 1907 the old east channel has been on the east side of the jetty. It is now filling rapidly with silt.

The writer has also studied the relative movement of the 2, 3, 4 and 5-fathom contours. They are of interest inasmuch as they show that the advance of the silt takes place southeast of the Entrance Buoy. The 3-fathom contour has moved seaward a distance of 8 000 ft. in 67 years, or at the rate of 120 ft. annually.

Furthermore, during the whole of this period, the contours north of the Entrance Buoy on the west side of the west sand-bank have maintained their position with very little change. This is believed to be due to the action of the flood and ebb tides passing straight up and down along these contours in a north and south direction, respectively, and thus carrying away any deposits that may be made from time to time in this locality.

## Location of the Wall

Hydraulic engineers are not in agreement as to the necessary direction and alignment of training walls across bars subject to tidal action. Some engineers recommend that the end of the wall be in line with and along the axis of the flood and ebb currents and directly facing into the direction of the prevailing winds and storms.[3]

Others favor inclining the wall away from the prevailing winds and heaviest seas and locating it so that these and the flood tide meet the wall slightly on its convex side.[4] This is the location that has been adopted in the case of the Liao Bar.

The survey made in 1927 shows clearly the steep slopes of the sea bed north of the entrance buoy (see Fig. 9, Curve *B D F*). The other surveys since 1860 show these slopes to have been maintained at the same location without

[3] See Bibliography (Appendix), Items (3), p. 121; (6), pp. 303–304; (14), p. 354; (20), p. 194; (21), p. 99; (22); and (23), p. 207.

[4] See Bibliography (Appendix), Items (4), p. 485; (5), p. 536; (7), p. 6; (10), p. 10; (1); and (2).

practical alteration since that date. On the other hand, the sea bed slopes east of the jetty, along the axis of the east channel, and along the direction of the flood and ebb currents and the direction of prevailing winds and storms, are extremely flat, as shown by the longitudinal section, *C E F*, in Fig. 9.

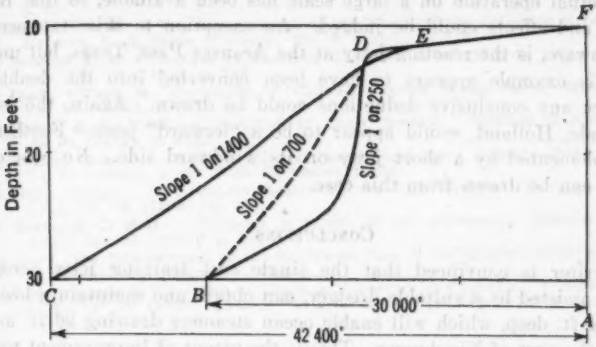

FIG. 9.—LONGITUDINAL SECTIONS NORTH OF THE ENTRANCE BUOY, LIAO BAR.

The question to be considered, therefore, was the correct direction to adopt. The old east channel course appears to be the natural direction of both the flood and ebb currents. This route would have provided a channel facing directly into the prevailing winds and greatest storms as advocated by some authorities; but it would also have led along a line of flat sea-bed slopes in a direction such that the greatest accretion and contour advance due to the deposits from the river would have been taking place.

The other alternative was to oppose the ebb currents by the training wall and attempt to guide the channel so as to terminate at or north of the Entrance Buoy in a locality of steep sea-bed slopes. As previously stated (see Fig. 9), the contours here have remained practically stationary for as far back as there are any records, that is, 1860. This procedure, on the other hand, would necessitate the flood tide, prevailing winds, and greatest storms being received on the convex side of the wall. Furthermore, the ebb currents on passing the end of the wall would have to make a more or less oblique bend to the southwest.

The pressure of the ice drift during the winter months and the abrasion against a wall that opposes the ebb currents in any way is very great and this no doubt increases the maintenance charges. Nevertheless, it was considered best to end the wall where the sea bed was steep because any other location would probably make it necessary to extend the wall continually to keep ahead of shoals formed by deposits brought down by the river. It was after consideration of these various factors that the present direction was adopted.

### SINGLE OR DOUBLE TRAINING JETTIES

The question as to the advisability of constructing single or double training jetties at the entrances of tidal rivers for the purpose of providing a

navigable channel across bars has been frequently discussed before the Society. Many eminent engineers have advocated a single jetty[5] and others, equally eminent, have advocated double jetties.[6]

The great difficulty has been that apparently no example of a single jetty in actual operation on a large scale has been available, so that relative behaviors and effects could be judged. An exception to this statement, the writer is aware, is the reaction jetty at the Aransas Pass, Texas, but unfortunately, this example appears to have been converted into the double-jetty type before any conclusive deductions could be drawn. Again, the jetty at Swinemünde, Holland, would appear to be a "leeward" jetty. Furthermore, it is supplemented by a short jetty on its windward side. No conclusions, therefore, can be drawn from this case.

## Conclusions

The writer is convinced that the single east training jetty across the Liao Bar, assisted by a suitable dredger, can obtain and maintain a low-water channel 14 ft. deep, which will enable ocean steamers drawing 26 ft. to enter and leave the port of Niuchuang. This is the extent of improvement required in this particular case. As it is, vessels with a draft of as much as 22 ft. enter and leave the port, whereas previous to the construction of the jetty, 17½ ft. was the limiting draft.

## DISCUSSION

R. D. GOODRICH,[7] M. AM. SOC. C. E. (by letter).—A record of construction experience such as that presented in this paper, is always of value to the profession.

As shown in Fig. 1, there are four principal ports in the Gulfs of Liaotung and Pechihli. Dairen and Chinwangtao are located in natural indentations of the coast and are free from ice during the winter months. On the other hand, Niuchuang (Newchwang) and Tientsin have harbors in rivers that drain large areas and they are usually closed for several months in the winter. In many respects these two drainage systems are similar.

As the author states, the average fresh-water discharge of these rivers is not sufficient in itself to maintain proper channels for navigation by ocean steamers. The situation is made worse by the character of the floods, which carry enormous quantities of silt. Samples containing 10% by weight of silt are not uncommon. Commerce at Tientsin has been greatly handicapped in recent years by the silting of the channel from Tientsin to Taku, practically closing the Hai River to ocean steamers for months.

These conditions would naturally tend to the development of Dairen and Chinwangtao as the logical ports of North China. However, there are many other considerations having great weight in port development. Distribution to the interior from these two ports must of necessity be almost entirely by rail. On the other hand, Tientsin and Niuchuang have the decided advantage of inland waterways as well as railways for the collection and distribution of ocean freight. From Tientsin there are three waterways and three rail routes, north, south, and west, not all of which are shown on the outline map (Fig. 1). The greater cost of transportation by rail compared with that by Chinese river boats for many commodities, and the greater length of haul and consequent cost of freight from the winter ports to the points of distribution to the interior markets, largely offset the difficulty of maintaining river ports and harbors. There is, therefore, keen competition between these ocean terminals, influenced also by the large investments already made at each point. Not only must the present works be maintained, but improvements must be made in order to protect the business and investments in all these ports.

The most serious and difficult problem involved in the maintenance of these rivers and harbors is that caused by the formation of a bar outside the mouth of any of the larger streams of China. At the mouth of the Yellow River conditions are such as practically to prohibit the construction of a harbor for the interchange of freight between ocean steamers and river boats. The rate at which the coast line is being extended at this point is much greater than at the mouth of either the Hai River or the Liao River.

In 1925, the construction of training walls was also undertaken at the mouth of the Hai River. It is understood that this project contemplated the use of walls carried above high tide on both sides of the channel. The writer has always felt that a single curved jetty might have provided the desired

[7] Prof., Civ. Eng., Coll. of Eng., Univ. of Wyoming; Senior Hydr. Engr., U. S. Engr. Office, War Dept., Sacramento, Calif.

benefits at much less cost to the interests involved. As noted by the author, all such local improvements must be financed largely by the collection of harbor dues, over and above the regular customs rates. It is evident, therefore, that development depends almost entirely upon the initiative and enterprise of the commercial interests, both Chinese and foreign, at each individual port. In earlier days dredging and other modern harbor works were instigated by the foreign shipping interests, but due to western influence Chinese capital is now also largely involved, the amount varying of course with the locality.

In view of all the difficult conditions connected with the maintenance and development of facilities for commerce in the Orient, the paper presents a very valuable record of experience and progress.

HERBERT CHATLEY,[8] Esq. (by letter).—The problem of the Liao Bar typifies conditions in North China and provides an interesting commentary on the question of single or double training walls. The regulation of the bar of the Whangpoo River presents some analogies. Before regulation this bar had a lowest low-water depth on the crest of 15 ft. Between 1907 and 1909 a training wall 5 500 ft. long was built on the left bank above half-tide level with a radius of about 7 000 ft., extending to the 36-ft. lowest low-water contour of the Yangtze River, of which the Whangpoo is a tributary. This wall reduced the natural "flare" of the mouth by about 40% and its concavity concentrated both flood and ebb, with the result that by 1912 the lowest low-water depth on the crest was increased to 21 ft., at which it remained stationary for three years. The lowest low-water sectional area of the stream above the training wall is about 42 500 sq. ft. The tidal influx varies from 400 000 000 to 5 000 000 000 cu. ft. and the efflux from 1 500 000 000 to 4 400 000 000 cu. ft. The non-tidal discharge averaged 12 600 cu. ft. per sec.

The material of the bar consists of Yangtze mud, about 90% passing a 200-mesh screen. There is about 10% colloid which makes the material fairly cohesive. In shallow areas coarser particles may be segregated, forming patches of fine, fairly clean sand, but this is not found in the channel. The water is charged with silt which is brought in by the flood tide from the Yangtze in quantities sometimes greater than 500 parts by weight per million.

In 1914 a second training wall, 7 000 ft. long, to half-tide level was built on the right shore parallel to, and 2 500 ft. from, the other and, from that date to 1928, the lowest low-water depth on the crest of the bar increased to 30½ ft. Since then no appreciable change has occurred. This second wall reduced the low-water flare at the mouth by a further large amount, leaving only a taper of 1 in 100 between the walls. Parts of the areas between the walls and the old shore have since been reclaimed without appreciable effect on the bar.

While the conditions are very different from those of the Liao, the Whangpoo results show that the scour induced by a single concave wall can be usefully supplemented by the concentration of stream flow caused by a second wall.

H. C. RIPLEY,[9] M. AM. SOC. C. E. (by letter).—This paper is a record, not of the method of improving the entrance to a harbor in the best and most economical way, but rather of securing the greatest channel depth at the entrance with the limited funds available. With this in view, the author seems to have met with considerable success.

The location and shape of the training wall are eminently suited for the purpose. The movement of material composing the bar at different stages of the tide is as follows: During flood the current crosses the wall at an angle, from the convex to the concave side, and by its overfall produces a deepening of the channel along the concave side and causes accretion on the convex side. During ebb exactly the opposite effects are produced until the tide has fallen sufficiently to uncover the top of the training wall. Then the wall becomes a real curved jetty and produces an effect as such. For the remaining two hours of the ebb, erosion takes place in the channel and the material thus excavated is carried across the channel and deposited on the convex side. Subsequently, a part of this material is washed back into the channel by the next returning ebb current, and the process is repeated by every recurring flood and ebb tide. However, the results have shown that the erosion in the channel is greater than the accretion; hence the beneficial effect of the training wall. The unfortunate feature of these effects is shown in the advance of the bar seaward, which will necessitate the continual extension of the training wall to keep up with the advance of the bar.

The author claims that no deepening of the channel is due to overfall during flood tide. It is believed, however, that the builders of dams who have to provide against the undermining action at the base of weirs and others familiar with the results of overfall will be loath to accept the conclusions of the author in this regard.

If, on the other hand, the plan had been designed to make the best improvement regardless of any limit as to expenditure—except that necessary to carry out the plan—it would have been for a curved jetty instead of the curved training wall and the work would proceed as follows: A foundation would be built 3 ft. in thickness and of sufficient width to prevent settlement of that portion upon which the superstructure would be located for the full length of the proposed jetty from the shore to a point a short distance beyond the crest of the bar. Commencing at the outer end, the superstructure would be built toward the shore to a height of high water of the greatest spring tide. In this way the advance of the bar would be prevented and no dredging would be required to develop the maximum channel that the curvature would permit.[10]

The cross-profile of the channel which a curved jetty will develop can be computed from the following formula:

$$Y = P\left(1 - \frac{X^2}{W^2}\right) + P\,\frac{26.28}{R}\left(1 - \frac{X^2}{W^2}\right)X \quad \ldots\ldots\ldots\ldots (1)$$

in which, $P$ is the mean depth of the channel multiplied by 1.65; $W$ is the

[9] Cons. Civ. Engr. (*Retired*), Brooklyn, N. Y. Mr. Ripley died January 9, 1931.

[10] See *Transactions*, Am. Soc. C. E., Vol. LXXV (1912), p. 1040, also Vol. 90 (1927), p. 207.

half width of the channel; $R$ is the radius of curvature of the jetty; and $X$ and $Y$ are the co-ordinates of the cross-profile, the origin being at the center of the channel at the surface of the water.

The value of $P$ must be determined from the cross-section of the channel at the mouth when the river is at a high flood stage and the spring tide is at its maximum.

The navigability of the channel for the deeper-draft vessels entering the port may be increased to a limited extent by diminishing the width of the channel at the river, thus increasing the value of $P$ and reducing the value of $W$.

A further enlargement of the channel if desired can be effected by dredging. This enlargement will be maintained by the jetty without additional cost for maintenance.

B. Okazaki,[11] M. Am. Soc. C. E. (by letter).—After ten years of experimenting the Lower Liao River Conservancy Board has finally succeeded in obtaining about 3 ft. of additional depth in the channel by means of a single jetty across the Liao Bar. The results are praiseworthy. The writer agrees with the author as to the importance of utilizing the flow of the tides for their scouring effect especially since that flow is great enough when guided by a jetty. In the case of the Liao River, the scouring is due mostly to tidal currents rather than to the natural flow of the river. Across this bar, for example, the flow is about 210 000 cu. ft. per sec., which is more than ten times that of the fresh-water discharge from the stream itself.

Furthermore, unless the Upper Liao River is improved generally by the construction of dikes, levees, and other forms of bank protection there is not much hope of controlling the river flow as a scouring medium across the bar. The improvements that would be necessary should be constructed along the well-established principles of good engineering, contrasting in this respect with the present system of permitting the farmers who own the lands along the river banks to construct levees that are almost useless in times of great floods. At present (1930), much of the river flow is naturally impounded on the low flat farm lands in the valley, due to ubiquitous breaks of the poorly located levees mentioned in case of flood. It is then released so gradually that any "flushing" effect that would be brought about by periods of maximum flow is considerably reduced. Under conditions as they exist at present it will require centuries for China to undertake these necessary improvements in the Upper Liao River.

The present Conservancy Board does not have the necessary resources and, therefore, it must continue to depend upon tidal action for the proper maintenance of depth in the navigable channel. Before the relative importance of tidal flow as compared to river flow was generally recognized, members of the Liao River Conservancy Boards were generally of the opinion that all the flood water from the Upper Liao River should be reverted so as to pass the Port of Newchwang. Much of the river flow had previously been by-passed away from Newchwang through the Shuang-tai-tzu Channel. This branch

[11] Executive Chf. Engr., Upper Liao River Conservancy, Newchwang, China.

broke through in 1890, eighty miles up stream from Newchwang, and empties into the Gulf of Liao-tung in the vicinity of Pan-shen-hsien (Fig. 10) many miles to the westward. Practically three-fourths of the entire discharge of the river is thus diverted away from Newchwang.

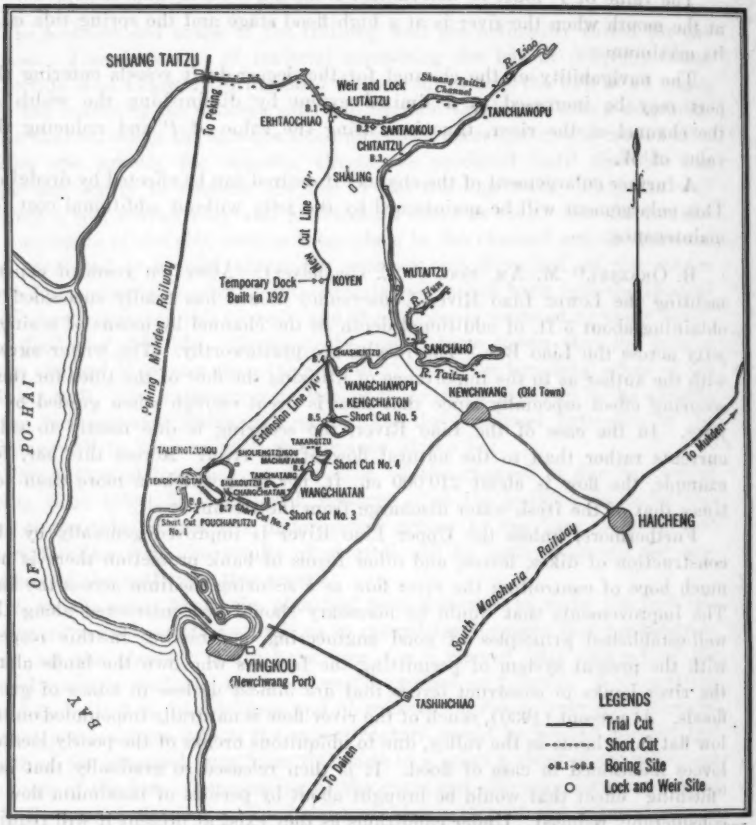

FIG. 10.—KEY PLAN OF LOWER LIAO BAR.

Handicapped by lack of funds, the Upper Liao River Conservancy Board was obliged to limit the extent of improvement works to the construction of a movable weir across the Shuang-tai-tzu Channel at Erh-tao-chiao, fifteen miles below Tan-chia-wo-pu, although one lock was constructed in connection with this weir and a new canal about fourteen miles long was excavated from Erh-tao-chiao to Chia-shen-tsu. The cross-section of this canal was sufficient only to carry the ordinary low-water discharge of the Upper Liao River. However, with the excavated material built up as levees 400 ft. from the center line on each side, provision was made to meet the demands of part of the flood discharge to be expected.

The object of these improvements by the Upper Liao River Conservancy Board—working in co-operation with the Lower Liao River Conservancy Board as outlined by Mr. Fawcett and the writer—was (1) to recover the inland trade carried by junks; (2) to facilitate navigation in the vicinity of Newchwang in general; and (3) to supplement the scouring force of the tides across Liao Bar with the natural discharge of the river.

At the time these proposed improvements were begun, the writer began making several hydraulic investigations. He soon discovered that, despite the great extent of the drainage area contributing to the river flow, the maximum flood discharge at Tan-chia-wo-pu is only about 60 000 cu. ft. per sec. Comparing this with the 210 000 cu. ft. per sec. of tidal flow at the bar, the relative importance of these two sources of natural power may readily be seen. Subsequently, the Conservancy Board decided to focus its attention on the improvement of the most effective of these two forces rather than to expend the time and money necessary for improving a supply that would be relatively unimportant at best. It was decided that in order to be economical as well as successful from an engineering point of view the improvement of the fresh-water flow would have to await that of the entire river course on a large scale.

TABLE 1.—MONTHLY AVERAGE PERCENTAGE OF SILT, APRIL, 1925, TO MARCH, 1926, INCLUSIVE.

(Figures denote grammes of silt per 100 grammes of water.)

| Station and river. | April. | May. | June. | July. | August. | September. | October. | November. | December. | January. | February. | March. | Monthly average. |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| Liao above Tang-chia-wo-pu | 0.476 | 0.359 | 0.599 | 0.674 | 0.636 | 0.234 | 0.164 | 0.093 | 0.027 | 0.016 | 0.004 | 0.011 | 0.274 |
| Liao below Tang-chia-wo-pu | 0.497 | 0.371 | 0.614 | 0.646 | 0.623 | 0.262 | 0.166 | 0.108 | 0.017 | 0.014 | 0.004 | 0.013 | 0.278 |
| Shuang-tai-tzu below Tang-chia-wo-pu | 0.503 | 0.351 | 0.621 | 0.622 | 0.673 | 0.237 | 0.154 | 0.099 | 0.013 | 0.017 | 0.007 | 0.011 | 0.276 |
| Liao above San-chia-ho | 0.381 | 0.328 | 0.712 | 0.633 | 0.645 | 0.220 | 0.150 | 0.094 | 0.016 | 0.025 | 0.044 | 0.020 | 0.272 |
| Liao below San-chia-ho | 0.191 | 0.133 | 0.418 | 0.357 | 0.335 | 0.059 | 0.069 | 0.047 | 0.021 | 0.032 | 0.060 | 0.039 | 0.147 |
| Tai-tzu-ho at San-chia-ho | 0.085 | 0.042 | 0.251 | 0.238 | 0.226 | 0.026 | 0.032 | 0.034 | 0.008 | 0.015 | 0.028 | 0.016 | 0.083 |
| Shuang-tai-tzu at Erh-tao-chiao | 0.553 | 0.365 | 0.749 | 0.821 | 0.690 | 0.266 | 0.158 | 0.068 | 0.024 | 0.031 | 0.015 | 0.039 | 0.315 |
| Liao at Chia-shin-tzu | 0.211 | 0.151 | 0.217 | 0.256 | 0.323 | 0.068 | 0.059 | 0.160 | 0.094 | 0.045 | 0.013 | 0.021 | 0.135 |

Aside from the foregoing considerations, there is another factor to be considered in any plan for utilizing the fresh-water flow. The Liao River may be classed as one of the muddiest rivers in the world. During 1925-26 the writer made extensive silt determinations at various places along the Liao River proper. Average determinations for each of the twelve months were made for surface, mid-depth, and bottom elevations. A summary of these results is presented in Table 1, in which the average silt content for the entire section is given at each station. By comparing the silt content of the main or Shuang-tai-tzu River with that of the tributaries (Tai-tzu-ho and Hun-ho) combined, it is seen that the latter carries far less in suspension than the former. Therefore, it is clear that if more water is turned back into the Liao River

proper the silt content of this stream would be considerably increased, thus transporting to the bar much more sediment than is being brought by the fresh-water flow and removed by the force of both tidal and fresh-water flow combined, as at present.

In other words, if the fresh-water flow is to be increased for its scouring effect on the bar, this should be done so as to exclude as much of the silt as possible. If an adequate supply of funds could be made available for this purpose it would be advisable to spend it in removing many of the sharp bends and irregularities in the lower reach of the river so as to increase the effect of the tide and to shorten the navigable distance from the Gulf of Liao-Tung to old Newchwang (not new Newchwang where the present port is situated).

The original plan for the improvement of the Upper Liao River is practically completed and that for the lower river, as described by Mr. Fawcett, will be completed in a few years, after obtaining the proper type of dredge for maintenance work. Then the trade of China should be promoted by taking advantage of the benefits derived from works of such magnitude and importance as those of the Upper and Lower Liao River Conservancy Districts. The immediate need is not so much to utilize the river flow as it is to appreciate fully the scouring effect of the tidal currents. This is the most important phase of the problem and should be accomplished with a view to maintaining a channel across the bar by means of dredges and the single training wall (as suggested by the author). Furthermore, the tidal currents should be utilized, with river flow as it is at present; that is, without diverting any more muddy fresh water from up stream (although that may not be in conformity with the author's original idea).

It is desirable that the author submit a method of computing the quantity of silt deposits before selecting equipment for dredging and maintaining a 14-ft. channel alongside and beyond the end of the training wall and also to give an estimate of what fraction of the entire job in view is capable of being done by the small dredge which was recently purchased by the Conservancy. Furthermore, the writer would like to suggest that Mr. Fawcett give the heights of the waves that occur in the vicinity of the bar. If there are no such data available perhaps the author could give some estimates based on his long experience. Is there any information available concerning the probable extent that storms and other sea disturbances would damage the bed of the channel after it has been dredged, especially near the end of the jetty?

P. N. Fawcett, M. Am. Soc. C. E. (by letter).—Mr. Goodrich has supplemented the paper considerably with particulars of the ports of North China and their respective advantages and disadvantages. His previous association with the Chihli River Commission makes his remarks of particular value. As he states, all the rivers of North China are obstructed by ocean bars. These bars and the very extensive mud-flats, which reach many miles out to sea beyond the coast line, are formed from the deposits of silt brought down from up river during the "freshet" season. Mr. Goodrich states that the percentage of silt in the waters of the Hai River on occasions has been as high as 10, furthermore, the silt is composed of the so-called "loess" soil

and is of so fine a nature that it offers considerable difficulty to being removed by drag-suction, hopper dredges because its fineness prevents its settlement in the hoppers.

This class of dredge has been used on the Hai River Bar since about 1914, but the plant is insufficient to obtain a depth of more than 9 ft. at low water, and the maintenance of this depth offers considerable difficulties, so that it is frequently reduced to 6 or 7 ft. during the "freshet" season.

As Mr. Goodrich states, in 1925, the construction of two training walls was undertaken, at the mouth of the Hai River. These walls were completed in 1927, and the work of dredging a channel between them was commenced at the opening of the 1928 season, by means of large bucket dredges. The walls were built to a height of high-water neap tides and extended seaward across the south flat, but only to a point where a low-water depth of 4 ft. naturally obtained. The sites of the two walls at the bend in the Hai River, known as Deep Hole, are shown on Fig. 11. They were to extend about 3.5 miles into the sea beyond Point *C*.

Unfortunately, when dredging was begun, no sill was placed at *Q C* across the Deep Hole where there is a low-water depth of 40 ft., and to make matters worse, the engineers placed a dam across the entrance between the two dikes. This dam was carried to the same height as the dikes, and, therefore, it placed the dredges in a kind of dock. It is evident that if any success was to be obtained, no dam should have been placed across the entrance, but on the other hand, every inducement should have been offered to the ebb currents to enter the cut and assist the dredging. A submerged dam, built to 10 ft. below low water (so as to allow navigation with the same depth as was available across the bar) should have been placed across the Deep Hole at *Q C* (Fig 11), thus throwing as much of the current as possible between the dikes. The dikes should have been extended into deep water and the use of timber should have been avoided.

It was found that after two years intensive dredging, the mud level still remained the same between the dikes as it was outside them, because these methods had not been adopted.

The Conservancy Board, in 1929, called in a Commission of Consulting Engineers, of which the writer was a member, to report upon the project. This Commission—partly because the financial plan resources of the Conservancy were insufficient to pursue the plan further, and partly from a technical viewpoint—recommended the abandonment of the plan and the pulling up of the dikes.

In the writer's opinion, the dikes were incorrectly located, the present natural Deep Hole Channel should have been utilized and trained and carried out in its continuation across the bar. As it is, more than $1 000 000 (gold) was spent on this plan, all of which was a total loss.

Mr. Goodrich has always felt that a single curved jetty across the Hai Bar might have provided the desired benefits. The writer concurs with this opinion, and such a wall was designed and proposed by Mr. A. de Linde, as

long ago as 1902, while he was Engineer-in-Chief of the Hai River Commission.

Dr. Chatley gives some interesting data of the Whangpoo River and describes results obtained by the single training wall originally constructed at its mouth, which was afterward supplemented by an additional wall. In this particular locality, the single wall increased the depth across the bar from 15 to 21 ft., and the double wall further increased this depth to 30½ ft. He is of the opinion that the results obtained on the Whangpoo River show that the scour induced by a single training wall can be usefully supplemented by a double wall.

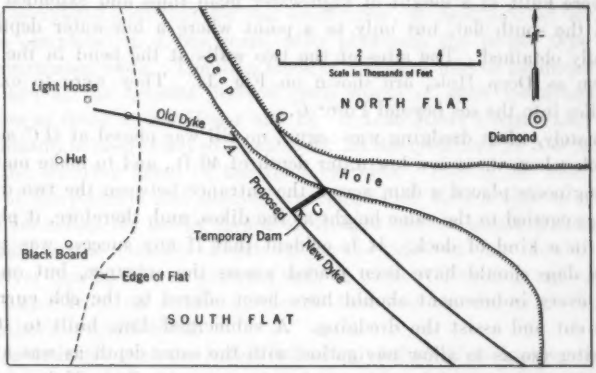

FIG. 11.—SYSTEMATIZATION OF THE HAI RIVER ENTRANCE AND BAR CHANNEL

As Dr. Chatley states, the conditions in the two localities are very different. In the case of the Whangpoo the bar was situated where the river debouched into the Yangtze River, a fairly sheltered locality as compared to the sea coast. Every situation must be judged on its merits and each of them presents its own particular problems. In the case of the Liao Bar, where the ebb and flow of the tidal currents take place in the directions described in the paper, and where the bar is situated eight miles from the river entrance, the writer is of the opinion that the construction of a second training wall would necessitate too great a risk that the expenditure involved would not be justified by the increase in the depth that might or might not result. Added to this, and partly owing to the intensive ice action, a very high annual maintenance charge would need to be added to the capital cost. It was with these points in view that the writer limited the construction to a single wall.

Mr. Ripley considers that the increase in depth across the Liao Bar is caused by overfall of the flood tide. This, however, is not the case, there being practically no overfall, the flow of the flood tide taking place very quietly and the surface of the water being at the same level on both sides of the wall. The writer is, of course, familiar with Mr. Ripley's proposed

method of deepening a bar by beginning the construction from the seaward end, and working inshore, but considers that it would be difficult to persuade commercial bodies to sanction such a method of work.

Dr. Okazaki is quite correct in pointing out the difficulties of improving the flow of the Upper Liao River owing to the refusal of the Chinese authorities to take any constructive interest in matters of conservancy. Had funds been forthcoming, the training wall across the Liao Bar could have been completed in two instead of ten years. Furthermore, it is probable that a greater improved depth would have been obtained, since the alteration of the surface slopes would have taken place more suddenly.

The writer agrees with Dr. Okazaki that the tidal flow is of the greatest importance in obtaining and maintaining a channel across the bar. He does not concur, however, with the view expressed, that the improvement of the fresh-water flow should not be undertaken pending the completion of works on the bar. Far from this, the records of this locality show that the deterioration of the bar dated from about the time when the Liao River was diverted down the Shuang-tai-tzu River. Furthermore, since that date the entire estuary of the Liao has become encumbered with sand-banks and islands which are accreting with great rapidity and thus excluding the tidal influx, so that it is only a matter of time—unless adequate steps are taken—when the estuary will be filled up.

It is a well-known axiom that "tidal rivers cannot be maintained without their fresh-water flow." It was with the intention of securing its original fresh-water discharge back to the Liao Estuary that works were built by the Conservancy Board in the upper river, and the weir and cutting described by Dr. Okazaki were constructed at a cost of approximately $700 000 (gold).

In spite of the writer's continued warnings, these works are not being utilized to their full extent, and practically no reversion of fresh water has occurred since they were completed. Unfortunately, the Board has no control over the area, as it is under Chinese jurisdiction. In the case in point, instead of causing the cutting to be scoured to its full width of 800 ft. and the fresh water reverted past Newchwang, the cut is maintained at a width of about 100 ft., and the remainder of the land between the embankments is leased by the officials for farming in spite of the fact that this land was bought by the Conservancy Board.

Works built up country in China are also subject to much damage and interruption by the local population and banditti, and a weir constructed across the Shuang-tai-tzu River in 1912 to re-divert the flow back into the Liao was destroyed by the villagers as soon as it was completed, because it interfered with the lucrative practice of salt smuggling.

Dr. Okazaki believes that it is better for the estuary and bar if this fresh-water discharge is allowed to continue to escape down the Shuang-tai-tzu River as it carries an extremely high silt content, whereas the tributaries, the Tai-tzu and the Hun, are comparatively siltless. The writer's views are entirely the opposite, and he would point out that the silt of the Shuang-tai-tzu is of so extremely fine a character that it is all carried completely across the

bar into deep water at sea before settlement occurs. The Hun River and Tai-tzu River, on the other hand, show clean and clear fresh-water discharges; yet, in times of heavy rains, these two rivers roll large quantities of extremely heavy sand along the bottom, which, on one occasion, completely silted the Newchwang Estuary, to a depth of 12 ft.

During this "freshet" samples taken for silt content, 1 ft. above the river bed, gave no indication of this sand. In view of this, the silt table (Table 1) presented by Dr. Okazaki would give no indication of the true nature of the problem.

The fineness of the Upper Liao silt is somewhat remarkable as shown in Table 2. In this study, 51% of the Liao soil was found to have a grain diameter of less than 0.050 mm.

In writing this paper to describe the effect on the Liao Bar of constructing the single training wall, the writer felt that particular interest would attach to the effects, considering the fact that no dredge had been used in collaboration with the construction of the training wall. The reason for this was entirely due to the fact that funds available were not sufficient for its purchase.

In 1929, the author was enabled to purchase the drag-suction hopper dredge, *Java*, from the Dutch East Indies Government. This vessel, built in 1911, is fitted with twin pumps and propellers driven by engines of 560 and 900 i.h.p., respectively. The suction pipe is 37½ in. in diameter and the hopper of 750 cu. yd. capacity.

TABLE 2.—COMPARISON OF FINENESS OF SILT

| Item | Ymuiden | Seine | Rotterdam Waterway | Hai-Ho | Liao-Ho |
|---|---|---|---|---|---|
| Percentage passed through sieve of 4 900 meshes per square centimeter | 2 | 23 | 45 | 48 | 94 |
| Mean size of grain, in millimeters* | 0.167 | .... | 0.102 | .... | 0.053 |

* After method described by Messrs. T. Heyblom and A. G. Maris, Paper 76, XIV Inter. Cong. of Navigation.

Dredging was begun in April, 1930, and in spite of many interruptions, due to the enormous quantities of iron bars, wire rope, Chinese anchors, etc., that kept interrupting the work, a channel 12 ft. deep and 200 ft. wide had almost been completed by the end of September. Freshets then brought down large quantities of sand from the Tai-tzu and Hun Rivers, with the result that the dredged cut almost became obliterated.

With the Shuang-tai-tzu fresh-water discharge returned to the Liao Estuary the writer is of the opinion that the damaging sand deposits of the Tai-tzu and Hun Rivers would be flushed across the bar and deposited out at sea. The situation is very similar to that at Tientsin to which Mr. Goodrich calls attention, where disaster is caused to the improvement works in the lower river and harbor, by the neglect that has been allowed, of the upper portions of the rivers and tributaries. The writer is, therefore, not in

agreement with Dr. Okazaki and considers that the permanent improvement of the bar is impossible, unless the tributaries and upper river are first put in order.

As regards the dredging plant required, a 14-ft. channel across the bar should be obtainable with the dredge, *Java*, as long as no further excessive sand deposits occur.

The writer does not consider that the height of the waves ever exceed 10 ft., and no flattening of the channel has ever been experienced after storms. On the other hand, at the Hai River Bar, the channel is beaten down and reduced in depth after each severe storm. The failure of such storms to flatten the Liao Bar, the writer believes, is entirely due to the protection offered to the channel by the training wall, which receives the force of the waves on its convex side.

# EVAPORATION AS A FUNCTION OF INSOLATION[1]

BY BURT RICHARDSON,[2] ESQ.

WITH DISCUSSION BY MESSRS. H. H. KIMBALL, C. G. ABBOT, D. P. KRYNINE, R. C. WELLS, N. W. CUMMINGS, AND BURT RICHARDSON.

## SYNOPSIS

In the Western States water is scarce and valuable, and rates of evaporation are high. Heretofore, evaporation losses have been ascertained by direct measurements. The writer considers it possible to approach the problem by a study of the physical cause of evaporation. The principal cause is insolation which may be defined, briefly as "exposure to the rays of the sun."

This paper is concerned with the effect of insolation and with the measurement of the quantity of radiant heat imparted by the sun and sky to the water and the bottom of a reservoir. In a sense, this effect may be considered a measure of insolation. For example, it may be said that, in Pasadena, Calif., on a sunny day, the "insolation" is roughly 600 calories per sq. cm. per day.

## INTRODUCTION

The quantitative effect of insolation is variable and depends on the sun's elevation, the length of the day, cloudiness, smoke, etc. It may be determined by three independent methods:

(1) By means of a Weather Bureau, recording, thermo-electric pyrheliometer.
(2) By computing the quantity as a geometric problem from a knowledge of the sun's radiation, altitude, etc., together with the latitude of the reservoir or lake.
(3) By tracing the radiant heat energy which strikes the water surface of a heat-insulated tank.

NOTE.—The Special Committee on Irrigation Hydraulics selected the subject of "Evaporation Losses from Reservoirs" as one of ten for study and research. This paper was submitted to the Committee by its author, and the Committee recommended its publication (see Progress Report of the Committee, *Proceedings*, Am. Soc. C. E., March, 1928, Society Affairs, p. 176).

[1] Published in May, 1930, *Proceedings*.

[2] Prof., Dept. of Physics, Occidental Coll., Los Angeles, Calif.

Having determined the value of insolation for a particular site it is possible to show what part of it goes into evaporation and to place definite limits on the quantity of evaporation. By using either Method (1) or Method (2) in combination with Method (3) the evaporation from a lake or proposed reservoir may be determined. Attention is called to the fact that there is a regrettable scarcity of reliable data for evaporation studies. The data desirable for such studies include:

(*a*) Daily, monthly, and yearly records of evaporation from lakes and pans all observed in a uniform manner.
(*b*) Insolation records, especially in country districts and in the Western States (the present (1929), six U. S. Weather Bureau Stations at which insolation records are secured, are located in cities).
(*c*) Records of the temperature gradient of lakes.
(*d*) Cloudiness records kept in a uniform manner (at present, there is no unit for cloudiness, and it is impossible to convey to another the meaning of a cloudy or very cloudy day).
(*e*) Records of transmission coefficients of the atmosphere for various sections of the United States to ascertain if there exists a "mean weighted transmission coefficient" for a certain district.
(*f*) Data concerning water surface and air temperatures of lakes to provide a means of computing radiation, which is a factor in the evaporation equation.

## Notation

The notation adopted for use in this paper is as follows:

$A$ = correction coefficient = $\frac{\text{solar radiation}}{\text{total radiation}}$.
$a$ = the radiation constant introduced by Stefan-Boltzmann.
$B_r$ = the radiation from water.
$b$ = a constant which permits the use of the air temperature above a body of water instead of the sky temperature to which the radiation actually goes.
$C$ = a factor representing the conduction of heat through the walls of the tank.
$C'$ = the percentage of cloudiness that occurred during a certain month, as given in *Monthly Weather Review* reports.
$d$ = the sun's declination for a certain day of the year.
$E$ = quantity of water evaporated.
$F$ = factor denoting the relative clearness of the sky above the particular body of water in question.
$H$ = original vapor pressure of the air passing over the surface of the water.
$i$ = angle of incidence.
$I$ = the quantity of radiant heat, in calories per minute, that reaches a certain area on the surface of the earth.
$I_{ex}$ = insolation incident upon the exterior of the earth's atmosphere.
$K$ = the solar constant.
$k$ = ratio of the incident to the reflected intensity of radiation.
$L$ = latent heat of evaporation.
$n$ = index of refraction.
$P$ = atmospheric pressure.
$P_w$ = original vapor pressure of the air contact with the water surface.
$Q$ = the observed radiant energy that passes through local clouds.
$Q_s$ = the observed radiant energy that passes through a clear sky.

$R$ = the ratio convection evaporation.
$r$ = angle of refraction.
$S$ = the sensible heat measured by the warming or cooling of the water.
$T_a$ = original temperature, centigrade, of the air passing over the surface of the water.
$T_w$ = original temperature, centigrade, of the air in contact with the water surface.
$t$ = time, in minutes.
$w = \frac{2\pi}{24 \times 60}$ radians per min. = angular velocity of the earth on its axis.
$\lambda$ = the latitude of the station.
$\rho$ = the transmission coefficient of the earth's atmosphere.
$\rho'$ = the mean transmission coefficient of the atmosphere at a particular place.
$\psi$ = the zenith angle of the sun.

### (1) Insolation Recorded by Thermo-Electric Pyrheliometers

The Weather Bureau of the U. S. Department of Agriculture maintains six stations at which recording thermo-electric pyrheliometers[3] are used and their records of insolation are published in the *Monthly Weather Review*. Due to the difference in latitude, cloudiness, etc., the value of insolation is, of course, not the same for all stations. For example, the average number of calories reaching each square centimeter of the earth's surface per day during the month of July, 1928, at certain places is indicated in Table 1.

TABLE 1.—Values of Insolation at Seven Stations in the United States.

| Location. | Insolation, in calories per square centimeter per day. | Location. | Insolation, in calories per square centimeter per day. |
|---|---|---|---|
| New York, N. Y. | 378.5 | Lincoln Nebr. | 531.2 |
| Washington, D. C. | 540.8 | Twin Falls, Idaho | 737.2 |
| Chicago, Ill. | 412.8 | Scripps Institute of Oceanography, La Jolla, Calif. | 544.7 |
| Madison, Wis. | 509.2 | | |

The insolation varies also from day to day at any one station, as illustrated by data observed at the Scripps Institute of Oceanography at La Jolla, Calif. While this is not a U. S. Weather Bureau Station, it uses the U. S. Weather Bureau Pyrheliometer No. 17.

Observations for each day of July, 1928, are given in Table 2. The total insolation for the 31 days was 16 886.3 calories, which is the equivalent of 10.35 in. of evaporation, or an average of 544.7 calories per day.

Considering that it requires 585.4 calories to evaporate 1 cu. cm. of water at 20° cent., it is easily seen how much a given water surface would drop each day due to evaporation, should all the insolation go into evaporation. Actually, the ratio of observed evaporation to observed insolation is between 40 and 60 per cent.

Table 3 gives all the records of insolation that have been observed for stations in the United States. It has been compiled from various sources. Items

[3] H. H. Kimball and H. E. Hobbs, *Journal*, Optical Soc. of America, Vol. 7, September, 1923.

Nos. 1 to 18, inclusive, are records at six stations of the U. S. Weather Bureau where insolation is observed;[4] Items Nos. 19 to 42, inclusive, are records reported from sundry other stations;[5] and the observations listed for the last five stations are those observed by the writer, using the pan method.[6]

### (2) INSOLATION COMPUTED AS A GEOMETRIC PROBLEM

It is possible to determine the value of insolation from a knowledge of the sun's radiation, its altitude, etc., and the latitude of the reservoir or lake. A formula may be set up for insolation, as follows:

$$I = K \int_{t_1}^{t_2} \cos \psi \, \rho^{\sec \psi} \, dt \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)$$

Differentiating with respect to time to obtain the rate of insolation,

$$\frac{dI}{dt} = K \cos \psi \, \rho^{\sec \psi} \quad \ldots\ldots\ldots\ldots\ldots\ldots (2)$$

The solar constant, $K$, as determined by Abbot,[7] is 1.93 calories per sq. cm. per min. To illustrate the use of Equation (2) consider the parallel of 40° N. latitude. Use Abbot's value for the solar constant ($K = 1.93$); for simplicity assume a transmission coefficient of $\rho = 0.7$, and insert proper values of $\psi$ for each minute of each day of each month, successively. The values of $I$ thus obtained are given in Table 4.

At this point something must be said about $\rho$, the transmission coefficient[7] of the earth's atmosphere used in Equation (2). The only available values of this coefficient are as shown in Table 5. These were weighted values com-

puted from the mean solar intensity and coefficient for a particular wave length.

Values of the transmission coefficient for other places in the United States have not been computed so that research on this coefficient is highly desirable. The writer suggests that this coefficient may be computed directly by means of Equation (2). The left side of this equation which represents the rate of insolation is known from the pyrheliometer record by direct reading for a particular minute of the day, and the zenith angle[8] corresponding to this minute is also known, which leaves the one unknown, $\rho$.

TABLE 4.—COMPUTED VALUES OF $I$ AT 40° NORTH LATITUDE.

| Month. | Values of $I$, in calories per square centimeter per day. | Month. | Values of $I$, in calories per square centimeter per day. |
|---|---|---|---|
| January | 140.0 | July | 553.3 |

| March | 356.5 | September | 347.7 |
| April | 465.7 | October | 240.0 |
| May | 573.7 | November | 136.0 |
| June | 586.7 | December | 100.1 |

Total energy, including scattered sky radiation, is recorded by a pyrheliometer. Therefore, it is necessary to correct the pyrheliometer records by a coefficient, $A$, which represents the ratio of solar radiation to total radiation. Typical values of $A$ for four stations[9] are given in Table 5.

TABLE 5.—OBSERVED VALUES OF $\rho$ AND $A$.

| Station. | North latitude. | Values of $\rho$. | VALUES OF $A$ FOR DIFFERENT ZENITH ANGLES, $\psi$. | | | | | | |

| Lincoln, Nebr. | 43°-05′ | ..... | 87 | 86 | 84 | 84 | 84 | 79 | 76 |

The rate of insolation from the sun (not including sky radiation) equals:

$$\frac{d\,I'}{d\,t} = A\,\frac{d\,I}{d\,t} = K\cos\psi\,\rho^{\sec\psi} \qquad (3)$$

and, making the necessary transpositions:

$$\rho = \log^{-1}\left[\frac{\log\left(\dfrac{A\,\dfrac{d\,I}{d\,t}}{K\cos\psi}\right)}{\sec\psi}\right] \qquad (4)$$

[8] "American Practical Navigator," Bowditch.

[9] *Monthly Weather Review*, April, 1927, p. 156.

To illustrate this method for computing the transmission coefficient, the pyrheliometer records of fourteen different days of 1926 for Pasadena, Calif., were used, and when monthly values were plotted, a mean value for $\rho$ of 0.751 was obtained.

The value of insolation is not constant along any parallel of latitude, but changes at points of different longitude, due to variation in the transmission coefficient, humidity, local clouds, smoke, dust, etc. Therefore, in order to use Equation (2) for points of different longitude, values of the transmission coefficient must be observed by Abbot's method or computed by Equation (4).

### (3) Insolation by Tracing Radiant Heat Energy

The third method[10] for measuring insolation is to trace the heat energy which comes to water contained in an open tank. In this case insolation (when corrected for reflection) will be equal to the summation of: (*a*) Evaporation; (*b*) convection losses, due to the circulation of air above water; (*c*) sensible heat, measured by the warming of the water; (*d*) conduction, due to loss of heat through the walls of the tank; and (*e*) radiation, from the water to colder air. This is simply a statement of the Law of Conservation of Energy.

The ratio, $k$, of the incident to the reflected intensity of radiation is given by Fresnel's equation:

$$k = \frac{1}{2}\frac{\sin^2(i-r)}{\sin^2(i-r)} - \frac{1}{2}\frac{\tan^2(i-r)}{\tan^2(i-r)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (5)$$

in which, $i$ and $r$ are the angles of incidence and of refraction, respectively, and are connected by the relation, $n = \dfrac{\sin i}{\sin r}$ = index of refraction.

Let $n$, for water, be equal to 1.33; then $r$ may be found for corresponding values of $i$ and these, substituted in Equation (5), will give values of $k$ for any angle of incidence. This is the correction factor for reflection.

Insolation is a positive quantity during the day, but at night it is equal to zero. Evaporation is always positive, while the other terms—convection, sensible heat, conduction, and radiation—may be either positive or negative. In symbols, then:

$$I = LE + LER + S + C + B_r \quad \ldots\ldots\ldots\ldots\ldots\ldots (6)$$

in which, $L$ is the latent heat of evaporation (585.4 at 20° cent.); $E$ is cubic centimeters of water evaporated; and $R$ is the ratio, $\dfrac{\text{convection}}{\text{evaporation}}$.

Bowen[11] has found that:

$$R = \frac{0.46\,(T_w - T_a)\,P}{(P_w - H)\,760} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7)$$

in which, $T_a$ and $H$ are the original temperature and vapor pressure of the air passing over the surface of the water; $T_w$ and $P_w$ are the corresponding quantities for the layer of air in contact with the water surface; $P$ is the

[10] N. W. Cummings and Burt Richardson, *Physical Review*, October, 1927.
[11] *Physical Review*, June, 1926.

atmospheric pressure; $S$ is the sensible heat measured by the warming or cooling of the water; and $C$ represents the conduction of heat through the walls of the tank.

$B_r$ is the radiation from water[12] and may be computed by the formula:

$$B_r = (0.906\ a\ T_w^4 - b\ a\ T_a^4) \quad (8)$$

in which, the decimal, 0.906, represents an important constant which takes care of the fact that water does not radiate as a perfectly black body; $a$ is the Stefan-Boltzmann radiation constant, amounting to $5.7 \times 10^{-5}$ ergs per sq. cm. per sec. per degree to the fourth power; while $b$ permits the use of air temperature in the formula in place of temperature of the sky which receives the radiant heat energy. The average value of the constant, $b$, in the radiation Equation (8) has been observed at four stations, to be as follows:

| Station. | Mean value of $b$. |
|---|---|
| Tank at Pasadena, Calif. | 0.815 |
| Tank at Fort Collins, Colo. | 0.760 |
| Murray Lake, San Diego, Calif. | 0.794 |
| Crystal Springs Lake, San Francisco, Calif. | 0.757 |
| Average (weighted) | 0.790 |

When the temperature of the water and air is known, by using the mean value of 0.790 for $b$, radiation may be computed by Equation (8). However, when these temperatures were not known, it was possible, in the case of California water surfaces, to estimate the value of radiation from the data collected at other places. The radiation from the water to the sky, in calories per square centimeter per day, has thus been found for five places as shown in Table 6.

TABLE 6.—RADIATION FROM THE WATER TO THE SKY, IN CALORIES PER SQUARE CENTIMETER PER DAY.

| Location. | Radiation. |
|---|---|
| Pasadena, Calif. | 117.0 |
| Fort Collins, Colo. | 132.0 |
| Murray Lake, San Diego, Calif. | 128.0 |
| Crystal Lake, San Francisco, Calif. | 148.0 |
| La Jolla, Calif. | 130.3 |
| Average value (weighted) | 131.4 |

From Equation (6) the exact amount of radiation may be determined for the night, since insolation during the night is zero and all other quantities of the equation are measurable. Thus, the insolation may be determined by adding all the heat energy coming to the body of water. Table 7 demonstrates the order of magnitude of each item that enters into insolation. A similar tabu-

[12] National Research Council, *Bulletin No. 68*, April, 1929.

lation for observations at Murray Lake, San Diego, Calif. (July 7 to July 27, 1927), gave corresponding average daily values, as follows:

| Factors. | Calories per square centimeter per day. |
|---|---|
| Evaporation | 485.9 |
| Sensible heat | 0.8 |
| Convection | 34.4 |
| Back radiation | 128.2 |
| Conduction | 13.0 |
| Observed insolation | 662.3 |

As a test of this method, tanks of different areas and depths have been measured hourly over long periods of time with a resulting difference of less than 3 per cent. As one illustration, Table 8 will show a comparison of the results obtained from three tanks of different areas and depths and a Weather Bureau pyrheliometer (No. 17) over a period of five days, at the Scripps Institute of Oceanography, La Jolla, Calif.

### Description of Method for Measuring Evaporation

By transposing Equation (6) which is in metric units, and converting to inches, it may be written:

$$E = \frac{I - S - C - B_r}{2.54\ L\ (1 + R)} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

This expression, which gives evaporation as a function of insolation, water temperature, wet and dry bulb temperatures, and vapor and atmospheric pressures, is a true equation; but the tedious process of evaluating each term hourly (as was done in the case of data mentioned in this paper) would defeat the purpose of this method for practical use. As a result of research, it is possible to assign limiting values to each term of Equation (9) and by considering certain variables constant, an equation may be obtained which is simple to handle. Thus, by considering sensible heat and conduction negligible, using 585 for the latent heat of evaporation, and 0.22 for Bowen's ratio, $R$, Equation (9) becomes, in inch units:

$$E = \frac{I - B_r}{2.54 \times 585 \times 1.22} = \frac{I - B_r}{1\,814} \quad \ldots\ldots\ldots\ldots\ldots\ldots (10)$$

Thus far, no mention has been made of the effect of wind upon evaporation, because in the expression for insolation given by Equation (6) this effect would be measured, calorie for calorie, in changes in sensible heat and in convection. Sensible heat as well as the value of conduction for a short period or over a yearly cycle, as determined from a study of data collected in California, is negligible. Furthermore, no serious error will result from considering $R$ as a constant equal to 0.22. This may be seen by referring to Table 9 which gives the values of $R$ computed under dissimilar circumstances and over a long period of time with hourly readings.

TABLE 9.—Comparison of Values of $R$ Computed Under Dissimilar Circumstances.

| Location. | Date. | Interval, in days. | Ratio, $R$. |
|---|---|---|---|
| Pasadena, Calif. | June, 1926 | 10 | 0.193 |
| Fort Collins, Colo. | September, 1926 | 10 | 0.221 |
| Murray Lake, San Diego, Calif. | July, 1927 | 20 | 0.165 |
| Crystal Springs Lake, San Francisco, Calif. | August, 1927 | 20 | 0.280 |
| Scripps Institution Pier, La Jolla, Calif. | July, 1928 | 5 | 0.180 |
| Pacific Ocean, Santa Babara Channel, Calif. | July, 1928 | 12 | 0.280 |
| U. S. Naval Air Station: San Diego Bay, Calif. | August, 1928 | 31 | 0.190 |
| San Diego Bay, Calif. | September, 1928 | 30 | 0.206 |
| San Diego Bay, Calif. | November, 1928 | 30 | 0.171 |
| San Diego Bay, Calif. | March, 1929 | 31 | 0.170 |
| San Diego Bay, Calif. | April, 1929 | 30 | 0.152 |

The maximum deviation in these values of $R$ from the mean is 0.06, and since evaporation equals 50% of insolation on the average, the resulting error in insolation caused by taking $R$ equal to a constant, 0.22, instead of the largest or smallest value of $R$ computed, would be 3 per cent.

* "Regulation of the Great Lakes," by John R. Freeman, Past-President, Am. Soc. C. E., 1926.

† *Engineering-News*, 1910.

‡ *Monthly Weather Review*, July, 1927, p. 320.

It is interesting to note that by using the insolation quantity as computed by Method (2) and by using the value of radiation, ($B_r$), given for any one of four places mentioned in Table 6, the evaporation computed for the fifth place was within 5% of the observed evaporation in each case.

Before taking up the practical applications of Equation (10) it is well to consider Table 10, which contains good evaporation records for stations in the United States. Unfortunately, these records were from tanks which were not of the same size. It is well also to bear in mind that the amount of evaporation from a small tank next to a lake is not the same as that from the larger body of water, but represents simply an index. The data in Table 10 were compiled from records presented in various places, as noted. Equation (10) may be solved by substituting observed values of $I$ from sources such as Table 3 and by determining values of $B_r$ from Equation (8). Table 11 gives a comparison of the observed and computed evaporation near pyrheliometer stations.

TABLE 11.—Comparison Between Observed and Computed Evaporation.

| Station. | Insolation observed at pyrheliometer stations, in inches per year, divided by 1.22. | Back radiation, in inches per year, divided by 1.22. | Computed evaporation, in inches per year. | Observed evaporation, in inches per year. |
|---|---|---|---|---|
| Boston, Mass. | 60.0 | 17.3 | 42.7 | 39.11 |
| New York, N. Y. | 50.4 | 17.3 | 33.1 | 31.76 |
| Cincinnati, Ohio | 66.0 | 17.3 | 48.7 | 49.99 |
| Great Lakes | 49.5 | 17.3 | 32.2 | 27.96 |
| Birmingham, Ala. | 66.1 | 15.0 | 51.1 | 51.3 |
| Mitchell, Nebr. | 73.7 | 17.0 | 56.7 | 65.67 |
| Boise, Idaho | 78 | 17.3 | 60.7 | 77.43 |
| Klamath, Ore. | 62.7 | 17.3 | 45.4 | 54.40 |
| Lake Tahoe, Calif. | 62.7 | 17.3 | 45.4 | 42.2 |

Evaporation rates have been computed for the stations given in Table 10 with good correspondence. The results of three other computations were as follows: Roger C. Wells, of the U. S. Geological Survey, determined the evaporation of Chesapeake Bay to be 120.9 cm. per year,[13] while the computed amount, using his excellent data, was 124.3. McEwen by one method and Grunsky by another[14] determined the evaporation of Lake Mendota (near Madison, Wis., a pyrheliometer station) for a 5-month period, to be 41.45 and 45.5 cm., respectively, while the computed amount was 39.66. The evaporation of Swiss Alps lakes,[15] from a 90-day period amounted to 198.3 cm., while the computed amount was 193.7.

When the value of insolation is not known from pyrheliometer records it is possible to compute the insolation, $I_{ex}$, incident upon the exterior of the earth's atmosphere for any latitude, and, later, to convert this into actual Insolation ($I$) by means of the two coefficients, $\rho'$ and $F$, the mean transmission coefficient

[13] *Journal*, Washington Academy of Science, October 19, 1928; U. S. Geological Survey, Dept. of the Interior, *Professional Paper 154C*, March 14, 1929.

[14] Technical Series, Scripps Institution of Oceanography, Univ. of California, Vol. 2, No. 6, September, 1929, pp. 177–206.

[15] *Monthly Weather Review*, August, 1925, p. 355.

of the atmosphere at a particular place and the clearness factor, respectively. The relation may be expressed by the integral:

$$I_{ex} = 2\,K \int_0^t = \cos\psi\, d\, t \ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

Integrating, after writing for $\cos\psi$ its equivalent, $\sin\lambda \sin d + \cos\lambda \cos d \cos w\, t$, Equation (11) becomes:

$$I_{ex} = (2\,K\,t \sin\lambda \sin d) + \left(\frac{2\,K}{w} \cos\lambda \cos d \sin w\, t\right) \ldots\ldots\ldots (12)$$

in which, $\lambda$ = the latitude of the station; $d$ = the sun's declination for a certain day of the year; and $w = \dfrac{2\,\pi}{24 \times 60}$ = the angular velocity of the earth about its axis.

declination, $d$, vary from + 23° on June 21 to — 23° on December 21 of each year. The results of applying these values in Equation (12) to obtain quantitatively the insolation striking the exterior of the earth's atmosphere are given in Table 3 in "Computed Insolation." Table 12 gives additional values of exterior insolation for eleven different latitudes extending from Canada to Mexico, together with the equivalent, in inches of evaporation. These values of evaporation would represent the physical maximum because they assume a constant back radiation, no clouds, and a transmission coefficient of 1.00.

## Clearness Factors

At the beginning of this paper the writer stated that there is need for a unit of cloudiness and for records of cloudiness, kept in a uniform manner. At present, this factor may be expressed as a clearness factor to be computed by Kimball's formula:[16]

$$F = \frac{Q}{Q_s} = 0.22 + 0.78\,(1.0 - C') \qquad (13)$$

in which, $F$ is a clearness factor; $Q$ is the observed radiant energy that passes through local clouds; $Q_s$, the observed radiant energy that passes through a clear sky; and $C'$ the percentage of cloudiness that occurred during a certain month as given in *Monthly Weather Review* reports.

This value is useful in converting the insolation, $I_{ex}$, on the exterior of the earth's atmosphere to surface insolation, $I$, and to evaporation. In algebraic terms:

$$I = I_{ex}\,\rho'\,F \qquad (14)$$

Equation (14) demonstrates that the combined effect of relative cloudiness and the atmospheric transmission coefficient may be expressed as the ratio, $\frac{I}{I_{ex}}$. This is an important reason for accumulating insolation data. Table 13 includes values of this ratio.

## Conclusions

It is possible to determine the value of insolation by three distinct methods, and the results obtained by these different methods check experimentally within 5 per cent. The six Government stations that record insolation are mostly in the eastern part of the United States and more stations in the Western States are highly desirable. Where it is not possible to get a ratio of evaporation to insolation from pyrheliometer records, it is necessary to compute the insolation on the exterior of the earth's atmosphere and correct this quantity by a transmission coefficient for the earth's atmosphere and by a clearness factor (see Equation (14)). The evaporation formula (Equation (9)) given in terms of insolation and radiation checks experimentally with observed evaporation in California, and when applied to bodies of water outside California it gives satisfactory results.

The author is indebted to Franklin Thomas, M. Am. Soc. C. E., for encouragement that led to the preparation of this paper.

[16] *Monthly Weather Review*, April, 1927, p. 156.

## DISCUSSION

H. H. KIMBALL,[17] ESQ. (by letter).—That a close relation exists between insolation and evaporation is well known. Thus, in a paper entitled "Applications of Heat Radiation Measurements to the Problems of the Evaporation from Lakes and the Heat Convection at Their Surfaces",[18] A. Angström assumes a balance between (1) the insolation absorbed at a water surface; (2) the heat loss from the surface through radiation, convection, and conduction; (3) the heat energy expended in raising the temperature of the water; and (4) in the process of evaporation at its surface. It is evident that if Components (1), (2), and (3), of this balanced system, can be measured or computed, Component (4) will be known.

However, when, at a later date, in a paper entitled "On Radiation and Climate",[19] Angström undertook to account for the expenditure of the radiant energy received from the sun, he computed, from evaporation measurements and the latent heat of evaporation, the energy expended in evaporating moisture from various surfaces, including water surfaces.

In his paper, the author goes back to Angström's earlier method, shows how the values of various terms may be computed, and states that, if the quantity of insolation received at the water surface is known, the rate of evaporation may be computed; or, *vice versa*, if the rate of evaporation is known, the insolation may be computed.

In Table 11, comparisons are given between observed and computed amounts of evaporation, the computed amounts being based on "insolation observed at pyrheliometer stations."

Pyrheliometric readings are available for only a few of the stations named in the table. Therefore, the values given for insolation cannot be considered of a high order of accuracy.

The author states that,

"When the value of insolation is not known from pyrheliometer records it is possible to compute the insolation, $I_{ex}$, incident upon the exterior of the earth's atmosphere at any latitude, and, later, to convert this into actual Insolation $I$ by means of two coefficients $\rho'$ and $F$, the mean transmission coefficient of the atmosphere at a particular place and the clearness factor, respectively."

This is true if the atmospheric conditions are known, as has been shown by the writer in a recent paper entitled "Measurements of Solar Radiation Intensity and Determinations of Its Depletion by the Atmosphere"[20]; but it will by no means do to assume an annual mean value for $\rho'$, which is dependent especially upon the water vapor and dust content of the atmosphere. Both these factors are subject to marked seasonal or annual variations, especially near sea level. (See, for example, values of $\rho'$, or $a_{0-1}$, for Washington, D. C., determined for zenithal sun, $\psi = 0°$.)

C. G. Abbot,[21] Esq. (by letter).—While no doubt valuable in engineering estimates the use of the coefficient of atmospheric transmission as a single valued quantity is not, of course, exact, for it varies with the wave length, with the station, with the month, and from day to day in a very wide range. Therefore, the results reached by treating it as a single valued constant can be no more than rough average approximations.

D. P. Krynine,[22] M. Am. Soc. C. E. (by letter).—At first glance this paper seems to be very theoretical. Nevertheless, it must be considered as having a particular interest both for research men and practising engineers working in those fields of engineering connected with soils, water, and evaporation. The basic idea of the proposed methods seems to be correct, but for practical application, corrections corresponding to points of different longitude, due to local circumstances, must be studied further. Climatology and meteorology as applied to Civil Engineering is a broad field which has scarcely been touched. The writer has in mind one other work dealing with this subject from an engineering point of view.[23]

*Determination of the Zenith Angle.*—The author suggests determining the value of the zenith angle, $\psi$, by methods described by Bowditch. The writer, however, recommends the equation:

$$\cos \psi = \sin \lambda \sin d + \cos \lambda \cos d \cos \omega t \ldots\ldots\ldots\ldots (15)$$

From this formula,[24] at a given time, $t$, the angle, $\psi$, may easily be found. The formula becomes very simple, if the observation is performed at noon. In this case the hour angle may be assumed equal to zero, and $\cos \psi = \sin \lambda \sin d + \cos \lambda \cos d$, or,

$$\psi = \lambda - d \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (16)$$

The methods proposed by Mr. Bowditch are based on Equation (15) and require the use of "American Ephemeris and Nautical Almanac."

*Determination of the Insolation Incident Upon the Exterior of the Earth's Atmosphere.*—In Equation (15) the declination, $d$, is not constant during a given day, but changes gradually, being thus a function of time. Therefore, strictly speaking, the integration, Equation (12), must be considered as approximate. However, the first derivative of the declination with respect to time is small (less than 1′ of arc per hour), and introducing a mean value of $d$, as suggested by Mr. Richardson, does not involve a serious error, especially since the coefficients, $\rho'$ and $F$, probably, are sufficiently far from being accurate.

The writer regrets that only a few data are given in the paper with respect to the mean transmission coefficient, $\rho'$, of the atmosphere at a particular place.

*Research to Determine Values of the Coefficient, $\rho$; Determination of the Values of $A$.*—The method of determining the coefficient, $\rho$, from Equation

[23] "The Influence of Climate on the Building, Maintenance, and Use of Roads in the United States," by F. H. Eno, M. Am. Soc. C. E., *Proceedings*, Ninth Annual Meeting, Highway Research Board, December, 1929, p. 211.

[24] The letter, $d$, corresponds to the declination of the sun; $\lambda$ is the latitude; and $\omega$, the angular velocity of the earth about its axis.

(2) as proposed by the author, is both simple and efficient. Actually, after using the pyrheliometer for determining $\rho$, the investigator does not need that instrument any more and may complete the remainder of the computations referring to evaporation without leaving his desk.

However, the difficulty with the method proposed by the author is due to the necessity of applying the coefficient, $A$, which represents the ratio of solar radiation to total radiation. The writer understands from Table 5 that the values of $A$ are known only for a few localities.

For practical engineering purposes probably a rough estimation of the coefficient, $A$, is all that is necessary. Suppose the experiment is begun by taking the reading of a pyrheliometer corresponding to a zenith angle as close to zero as possible in given circumstances. The notation proposed is given in Table 14.

TABLE 14.—NOTATION FOR DETERMINING APPROXIMATE VALUES OF $A_n$.

| Item. | | Initial reading on the pyrheliometer. | Any subsequent reading. | Imaginary reading (zenith angle being equal to 0). |
|---|---|---|---|---|
| (1) | Zenith angle | $\psi$ | $\psi_n$ | $\psi_0$ (= 0) |
| (2) | Secant of the zenith angle | $u$ | $U$ | $u_0$ (= 1) |
| (3) | Value of the pyrheliometer reading, $\frac{dI}{dt}$ | $p$ | $p_n$ | $p_0$ |
| (4) | Correction coefficient | $A$ | $A_n$ | $A_0$ |

By substituting these symbols, Equation (3) becomes:

$$p = \frac{K}{A} \times \frac{\rho^u}{u} \qquad (17)$$

Suppose, now, that another pyrheliometer reading is taken at such a time that the secant of the new zenith angle is $mu$, in which, $m$ is an arbitrary value. In this case, Equation (17) would be:

$$p_n = \frac{K}{A_n} \times \frac{\rho^{mu}}{mu} \qquad (18)$$

Raise both sides of Equation (17) to the $m$ power:

$$p^m = \left(\frac{K}{A}\right)^m \frac{\rho^{mu}}{u^m} \qquad (19)$$

and solve simultaneously with Equation (18), thus:

$$\left(\frac{Ap}{K}\right)^m u^m = \frac{A_n p_n}{K} \times mu \qquad (20)$$

Next, assume that the first reading on the pyrheliometer was made when the zenith angle was equal to zero. It may be possible that in the given locality such an angle may never be observed; but, nevertheless, Equation

(20) may be applied to such an imaginary case, by substituting the values: $A = A_0$; $p = p_0$; $u = u_0$; and $m = U$. Then, Equation (20) becomes:

$$A_n = \left(\frac{A_0\, p_0}{K}\right)^U \frac{p_n\, U}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (21)$$

Equation (21) includes three unknowns, $A_n$, $A_0$, and $p_0$. In Table 5, $A_0 = 0.87$ for $\psi = 0$ at all latitudes observed. Suppose the same condition occurs in the present case and that an approximate value of $p_0$ is:

$$p_0 = u\, p \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (22)$$

Then a formula may be obtained by which to make a quick determination of the coefficient, $A_n$:

$$A_n = \left(\frac{0.87\, u\, p}{K}\right)^U : \frac{p_n\, U}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (23)$$

in which, $K$ is the solar constant.

An examination of the function, $A_n$, and of its derivative with respect to $U$, will give an idea of the shape of the curve representing $A_n$.

*Isolines of* $f(u)$.—Let Equation (17) be written in the form:

$$p = \frac{f(u)}{A}$$

If the pyrheliometer's readings for a series of zenith angles are taken, the values of $A$ may be easily computed. (See Equation (23).) Thus, in a given locality, all the values of $f(u)$ are also known. It is possible to represent $f(u)$ by drawing isolines for different zenith angles, within a certain territory. Then it would be possible to determine insolation and, consequently, the evaporation, at any day and at any locality within the area so plotted. The investigator must use the "Nautical Almanac", in order to determine the minimum zenith angle corresponding to the given day in a given locality and the times at which the zenith angles shown on the isoline maps take place. Interpolation may also be needed. This idea, naturally, is rough and is subject to improvement. The assumption is also made that $f(u)$ is not subject to considerable seasonal variations.

The accurate determination of the coefficient, $\rho$, as such, is not essential for a civil engineer. It is possible, however, to estimate the value of $\rho$, even with a certain degree of accuracy, from the approximate pyrheliometer reading for the zero zenith angle:

$$\rho = \frac{p_0}{K} = \frac{p\, u}{K} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (24)$$

*Method of Measuring Evaporation.*—The author suggests computing evaporation, $E$, by means of Equation (10).

The value of $B_r$, in this equation is, in turn, given by a rather complicated formula, (Equation (8)) and varies between 117 calories per sq. cm. per day to 148 calories per sq. cm. per day (Table 6), the average value (weighted) being 131.4. Considering this average value as a 100%, the lower limit of $B_r$ would be equal to 89% and the upper limit, to 113%, the deviation from the average being thus 11 to 13 per cent. Considering the fact that the back radiation—as a factor that prevents evaporation—may be evaluated as 23 to 35%

(see Table 11), its final influence on the result is between 2½ and 4½%, the average being about 3½ per cent. Since the result of the computation may be only approximate, it seems to be advisable to change Equation (10) somewhat as follows:

$$E = \frac{I - 131.4}{c} \quad \ldots\ldots (25)$$

or, in general:

$$E = \frac{I}{c} - c_1 \quad \ldots\ldots (26)$$

in which, $c$ and $c_1$ are constants.

*Clearness Factors.*—Personally, the writer is very much interested in the problem of determining clearness factors, since it may have some application not only in irrigation, but also to highway engineering. Certain road treatments involving the use of liquids ought to be different on sunny and shaded sections of a road. For instance, forest sections seem to need surface treatment different from field sections. The writer was led to these conclusions during an examination of the experimental road at Branford, for the Connecticut State Highway Department.

Obviously, the "heavy machinery" of zenith-angle determinations and integral calculus is not necessary in improving modest country roads, but there is a need for a rough field method of determining clearness factors to be used in such work.

R. C. WELLS,[25] ESQ. (by letter).[26]—This paper is of special interest because it approaches the subject of evaporation from a new point of view. It covers rather a wide range of geo-physical and meteorological measurements, and too much space would be required to discuss these in detail. Some of the measurements can be made with considerable accuracy, but others depend on natural conditions, such as clearness of the sky, the transmission coefficient of the atmosphere, etc., and, in view of the fact that some observations are incorporated in the author's calculations in the form of averages over limited periods, the agreement shown between calculated and observed evaporation is surprisingly good.

A reference[27] is made to the work of the writer concerning evaporation from Chesapeake Bay, from which it would appear that this was actually measured. This was not the case; the figures quoted by the author as the determined evaporation refer to the rainfall. In a case like that of Chesapeake Bay no check on the calculated evaporation is possible. On the other hand, when comparisons are made between observed and calculated evaporation for pans, the observed conditions are not generally what they would be over large bodies of water, so that it is not clear just what figures should be used in calculating the evaporation for the larger bodies of water.

[25] Chf. Chemist, U. S. Geological Survey, Washington, D. C.

[26] Published with permission of the Director of the U. S. Geological Survey.

[27] *Journal*, Washington Academy of Science, October 19, 1928; U. S. Geological Survey, Dept. of the Interior, *Professional Paper 154C*, March 4, 1929.

The writer would be interested to have the notation explained somewhat more fully for $H$, $P_w$, $T_a$, and $T_w$, especially the exact distances, or approximate distances, meant by the words "above the water" and "over the water". He agrees fully with the author concerning the great scarcity of reliable observations on evaporation, and is glad to see a definite number of ascertainable features listed for further measurement.

It is noted that in Table 11 the observed evaporation is lower than the lowest calculated, as well as higher than the highest calculated. Is this due to the use of a constant value for $R$, which is the ratio of convection to evaporation? Convection must express climatic conditions to a considerable extent and records for convection for different localities would be of interest. In fact, they are probably similar to those for evaporation; yet the figures in Table 7 show that convection is variable from hour to hour and from day to day, and $R$ is there much more variable than $E$, the evaporation.

Another matter that perhaps should be discussed further before this problem is settled, is the bearing of the fact that insolation is practically zero at night whereas evaporation continues, and, in view of this fact, whether a variable that governs only when the sun shines furnishes as direct and as sound a basis for computing evaporation as some other that controls under all conditions.

The author has made a distinct contribution in tracing the heat gains and losses that may affect evaporation.

N. W. CUMMINGS,[28] ESQ. (by letter).—It may be some time before the true value of Mr. Richardson's paper is fully appreciated, because economic pressure has not yet compelled the abandonment of unnecessary complications in estimating evaporation from lakes and reservoirs. For example, there are now various "standard" types of pan differing with respect to dimensions and method of installation. Those investigators who are accustomed to any one type are desirous of seeing that type perpetuated and its use extended so as to make readings at different times and places "comparable" with the ones with which they are already acquainted.

The manner in which any type of pan is to be made comparable to any lake is a mystery which many writers avoid mentioning, although it is difficult to see what benefit can be derived from making various pans comparable to each other unless they are comparable to lakes.

The late R. B. Sleight, Assoc. M. Am. Soc. C. E., found[29] that the ratio of the depth of evaporation from a pan 1 ft. in diameter is 155, while that from a pan 2 ft. in diameter is 129, and that from one 3.39 ft. in diameter is 121, on the assumption that the value for a pan 12 ft. in diameter is 100. The complete explanation of this variation will not be attempted here, but heat leakage through the walls undoubtedly contributes largely to it, as is shown by the fact that the divergence vanishes almost entirely when thermally insulated vessels are used. This is proved by the results of observations made at the Scripps Institution of Oceanography, University of California, from

[28] Associate in Physics, The Scripps Inst. of Oceanography, Univ. of California, La Jolla, Calif.

[29] *Journal of Agricultural Research*, Vol. 10, No. 5, July 30, 1917, pp. 209–261.

September 11 to December 23, 1929. During this interval of time many varieties of weather were experienced.

A thermally insulated pan, 2 ft. square and 8 in. deep, and a 1-gal. vacuum-insulated jar were run side by side. The diameter of the mouth of the jar was 6 in.; yet the depth of loss from the two vessels differed by only 1.5 per cent. Furthermore, the correlation coefficient between accumulated departures of evaporation and accumulated departures of insolation was $0.91 \pm 0.01$; while the corresponding coefficient for evaporation and wind was $0.01 \pm 0.07$.

These experiments show that important simplifications result from insulating the pan thermally and basing evaporation calculations on energy considerations, because difficulties concerning dimensions and manner of exposure are either eliminated or reduced materially.

BURT RICHARDSON, ESQ. (by letter).—Much interest has been shown in this study of the evaporation from lakes, and the writer was gratified to receive inquiries regarding the possibility of computing the evaporation quantitatively from a knowledge of insolation. As might be expected the Western States showed the most interest in the subject. For instance, the Forestry Department of the University of California made inquiries; graduate students of the University of Southern California repeated the experiment described in the paper; the United States Naval Air Station, at San Diego, Calif., worked on a fog-prediction method and, therefore, showed its interest in evaporation and insolation data; the Scripps Institution of Oceanography of the University of California, at La Jolla, developed a plan for rainfall prediction for Southern California, in which evaporation and insolation are two important quantities; while the motion picture industry and the Stanford University Marine Biological Station welcomed the insolation and atmospheric absorption data.

The evaporation from a heat-insulated tank can always be computed with excellent results when the experiment is made with a pyrheliometer, sensitive instruments, and good atmospheric data such as those furnished by the Mount Wilson Observatory; but when the quantity of evaporation is from a lake, say, in Beesville, Tex., where no pyrheliometer station is located, where the absorption coefficient has never been computed, and where the observed value of evaporation has been measured by some caretaker of the lake—then the results must of necessity be rough average approximations, as suggested by Dr. Abbot. However, limiting values of each term used in the evaporation formula are known, and their use sets definite limits to the quantity of evaporation. In any event, these evaporation estimates should be more accurate than applying to a lake a method which is based on a knowledge of the rainfall and an estimate of the quantity of inflowing and outflowing water with a correction for seepage.

The mathematical "short-cuts" suggested by Professor Krynine are quite welcome. According to information received from the Mount Wilson Observatory, the values of the two terms, $A$ and $\rho$, used in this paper are not known for places in the United States other than those mentioned. The method of making observations of temperatures of water surface, wet-bulb, and dry-bulb,

which are required in computing the terms, $H$, $P_w$, $T_a$, and $T_w$, is rather fully described in the two references to the *Physical Review*.

No difficulty presents itself in applying the evaporation formula to a lake during the night when, of course, the insolation is equal to zero. At that time, if the water is warmer than the air, the heat that goes into evaporation, as well as the radiation, conduction, and convection, is taken, calorie for calorie, from the quantity of sensible heat stored in the body of the water.

Professor Cummings[30] has recently done some experimental work which shows clearly the rate of evaporation from tanks of various sizes. He has also shown the relation of evaporation to humidity and convection.

Since presenting this paper the writer has computed the evaporation from most of the lakes of the United States where evaporation had been previously observed, and the results obtained by comparing the computed and observed quantities have been satisfactory. The best results obtained were in cases where the lakes were near pyrheliometer stations.

The writer is convinced of the importance of evaporation studies and will continue to urge those who are interested in the storage of water to gather and publish data regarding observed evaporation and temperatures, which have been made in a uniform manner. He also will continue to urge those institutions that are financially able to do so to install Weather Bureau pyrheliometers; and he will attempt to interest astronomers and meteorologists in studying the absorption coefficient of the earth's atmosphere, in order that, in the future, a better knowledge of evaporation may be had.

# HIGHWAYS AS ELEMENTS OF TRANSPORTATION[1]

BY FRED LAVIS,[2] M. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. W. W. CROSBY, WALTER LORING WEBB, JAY DOWNER, S. JOHANNESSON, D. P. KRYNINE, HAROLD M. LEWIS, DONALD M. BAKER, EDWIN F. WENDT, H. W. HUDSON, AND FRED LAVIS.

SYNOPSIS

The paper shows that, for handling large volumes of traffic through congested areas, highways should be designed for the main purpose of transportation rather than as adjuncts of the abutting properties. It is pointed out that where congestion of existing city streets interferes with the reasonably free passage of vehicles and pedestrians, highways of the type described are necessary, not only to expedite through traffic, but also to restore such streets to their normal uses.

The author includes a brief description of the through trunk highway recently built by the State of New Jersey through Jersey City and Newark; discusses the factors which influenced its location; and develops a general economic theory which governs the relation between cost of construction and the operating costs of vehicles using highways of this character. This theory is based on the principles of Wellington's "Economic Theory of Railway Location."

## HISTORICAL DEVELOPMENT

Up to within very recent times, highways in large part have been developments of the old trails made by man before the eras of wheeled vehicles, or they have been laid out as means of reaching real property. Their design and construction as elements of transportation are very new and this is required of course, by the intensive development and use of motor vehicles.

[1] Published in August, 1930, *Proceedings*.

[2] Pres., International Rys. of Central America, New York, N. Y.

*Older Highways.*—Economic factors developed by the use of hard surfaces for highways were probably first recognized by Macadam and others at the end of the Eighteenth and the beginning of the Nineteenth Century. Experiments to determine the tractive effort required for haulage over various types of road surfaces were made by several investigators between 1840 and 1850.

In spite of the fact, however, that the economic relation between road surfaces, and the tractive effort required to haul loads, was recognized nearly a century ago, by a few competent engineers—men who recognized the principle that true engineering and economics are indissolubly linked together—there has not been, at least until recently, any attempt to actually evaluate the effect of the different elements of the location and types of construction on the cost of operation of the vehicles using the highways.

*Motor Vehicles and Modern Highways.*—The introduction of the motor vehicle has had a very notable effect on the construction of highway pavements, and has resulted also in certain improvements in alignment, rates of gradient, rise and fall, etc. Expenditures for these purposes have been enormous and are continuing at a rate which is almost staggering. Changes in the locations of existing highways, however, are quite definitely limited by long established conditions; such roads are an integral part of individual, as well as municipal and State, property rights; and any contemplated change must take these rights into consideration.

There has developed, however, in recent years a demand for a new type of road—a road more nearly analogous to the railroad; laid out on an entirely new right of way and designed and built primarily to meet a demand for transportation. Such roads must necessarily be designed from the point of view of their users rather than that of owners of abutting property.

The design and construction of this more modern road are based primarily on the needs of a large volume of intensely mobile traffic which desires to move from one place to another with the least resistance compatible with the physical conditions of the territory through which it must pass. It is a development of modern transportation which must be recognized and provided for.

*Transportation a Factor.*—The last century has shown the ever-increasing necessity and value of transportation as a factor in the development of commerce and as perhaps the most important and dominant factor in modern civilization.

The railway was and probably still is the most important element in this modern transportation development, other factors being steamships, motor vehicles, air craft, the telegraph, the telephone, and the radio. Modern business requires that railway traffic should not be delayed by stops at grade crossings, and the modern efficient railway is designed with alignment, rates of gradient, rise and fall, multiple tracks, and every adjunct necessary to permit the free rapid movement of its traffic.

These same conditions apply in degree to the type of highway herein described. The volume of railroad business handled has permitted large expenditures for improvements in the road-bed and for the removal of resis-

tances and delays to the passage of trains, so that freight and passengers are not only moved in quantity at high rates of speed, but also at low cost. Highways must be developed to permit the same safe uninterrupted flow of heavy traffic as now obtains on a modern trunk-line railway, and the cost of operating these motor vehicles becomes an economic factor of importance.

These results on the railways have been achieved by a careful consideration of the economic values involved, the relation between location, costs of construction, and costs of operation. A similar era is impending in connection with the construction of highways. The following discussion follows the principle of the "Economic Theory of Railway Location," developed by the late Arthur M. Wellington, M. Am. Soc. C. E.

*Need of Special Highways.*—It is not only necessary to provide smooth pavements as a matter of comfort and convenience, but it is more than ever necessary where the traffic demand is large, to provide for the free uninterrupted flow of the through traffic without interference with local uses.

In open country the ordinary types of modern highways can and do carry this traffic with reasonable efficiency and dispatch, but in the vicinity of large cities, and in these cities themselves, special provision for through traffic which there reaches large proportions, must be made so that the ordinary city streets may serve local needs and abutting property.

It is with the design of these special highways that this paper is principally concerned and its object is to emphasize the need of making such design and considering such highways on the basis of their efficiency as elements of transportation. These are trunk highways, located on their own rights of way and designed primarily for the economic movement of a large volume of traffic through a given area or between given points.

## A Modern Highway

*Route 25, New Jersey.*—The nature of the problem and suggested methods of solution can best be indicated perhaps by a description of the design and construction of the arterial highway between the Hudson River and Elizabeth, known as Route 25 of the New Jersey State Highways. This is also the eastern end of the transcontinental Lincoln Highway. It has a roadway 50 ft. wide, sufficient for five lanes of traffic, maximum gradients of 3.5%, and curves with a minimum radius of 1 000 ft.

At its eastern end (Fig. 1) it connects with the Holland Vehicular Tunnel under the Hudson River. Thence, it passes through Jersey City and thus over the trap dike which divides the Hudson River from the valley of the Lower Hackensack and Passaic Rivers (both being navigable streams), crosses this valley in the lower part of the Town of Kearny, then by-passes the City of Newark, skirting the edge of the uplands and meadows, and, finally, crosses the meadows to the City of Elizabeth, beyond which it connects with the main State highway routes leading toward the South.

The first 8 miles of this route are without crossings of other highways at grade, thus providing for the free, uninterrupted flow of traffic through the highly congested areas of Jersey City and Newark. Provision is made, of course, for connections with important highways by ramps, thus avoiding all

cross-traffic currents. This 8-mile section was estimated to cost $25 000 000, and, in connection with its location and design, a careful study was made of the governing economic factors.

*General Considerations Affecting Design.*—The so-called Metropolitan Area of Northern New Jersey comprises the Cities of Bayonne, Jersey City, Elizabeth, Newark, the Oranges, Montclair, Paterson, and Passaic, and other smaller communities. From a traffic point of view it constitutes a continuous, densely populated, barrier between the City of New York and the South and West of the United States. It is also in itself both a source and a destination of a large volume of traffic.

The Western States may be reached from New York City by traveling northward along the Hudson River Valley to Albany, N. Y., and then striking west, but the natural route is to cross the Hudson from New York City to New Jersey and continue westerly. Such traffic must then necessarily pass through this congested zone, as must, of course, all traffic destined to the Jersey Coast resorts, to Trenton, Philadelphia, Baltimore, Washington, and the South.

The construction of the Holland Vehicular Tunnel concentrated a large part of this trans-fluvial and transcontinental traffic at the lower end of New York and at the most congested area of Jersey City. West of the Hackensack and Passaic River Valleys the traffic again had to find its way by many twists and turns through the overburdened streets of the Cities of Newark and Elizabeth.

The primary cause for consideration of this highway was the need of relief for these overburdened streets in Jersey City, Newark, and Elizabeth, traffic on which had become so congested that neither citizens who desired to shop, shopkeepers who desired to sell, or manufacturers who desired to move materials, could do business except at great expense and delay.

Traffic counts at fourteen points in the City of Newark showed increases for the decade, 1912 to 1922, ranging from 64% to 1 183%, the average being 340 per cent. The increase in traffic on the main State highway at Rahway just south of Elizabeth between 1921 and 1926 was from about 12 000 to 44 000 vehicles for a 24-hour period, that is, nearly fourfold in five years. Other counts indicated similar increases throughout the region.

Most of Northern New Jersey is not only a manufacturing district of great importance, but one so conveniently accessible to the Port and City of New York and to railroad and highway transportation, to a great labor market, and to financial centers, that it is destined to continue to grow, and probably grow very rapidly, in importance, both as a manufacturing, retail business, and residential district.

This highway, therefore, has two important purposes: It will permit the through traffic to cross this congested area, leaving existing city streets and highways free for their normal local uses; and it will permit easy, rapid access between various points in this area, and between all these points and New York City. Further, the great airport built by the City of Newark, although separated from Broadway and the down-town business district of New York City by 10 miles of congested and densely built-up territory, can be reached over Route 25 within 20 to 30 min.

## Transportation to Be Provided

*Amount of Traffic.*—In developing the economic factors to determine values of the physical characteristics of this highway, curves were platted showing the actual existing traffic, its increase during the previous few years, and its probable future increase. These estimates not only were based on counts of traffic, motor vehicle registrations, etc., but they were checked by traffic statistics of other carriers, such as the ferries, railways, and the Holland Tunnel, by charts of the growth of population and use of motor vehicles, by similar statistics of other areas, etc., and by the peculiarities of this particular district.

The application of these data to the future is necessarily largely a matter of judgment, but, reviewing all the information assembled, it seemed entirely probable that the highway would be used to capacity very shortly after its completion. It then remained to determine its capacity, or the number of vehicles which would use it, in order to obtain a basis for the determination of the economic values.

*Highway Capacity.*—The highway is built with a 50-ft. roadway and is expected to carry four lanes of continuously moving traffic with one 10-ft. lane to spare.

Observations taken (which it is believed check with studies by others) indicated that with freely moving traffic the largest number of vehicles pass a given point when moving at the rate of about 15 to 20 miles per hour. On this assumption four lanes would give a maximum capacity of 5 455 vehicles per hour. It is well known, of course, that traffic not only varies throughout the hours of the day, but also on different days of the week and at different seasons.

The number of vehicles which can use any given highway at times of maximum demand also depends on the proportion of trucks and buses or other types of heavy vehicles to lighter or non-commercial types. (It is not expected that horse-drawn vehicles will use this highway.)

On Route 25, it was necessary to consider heavy peak loads at certain times, as for traffic to and from the New Jersey shore resorts over week-ends, to football games at Princeton, etc. The computation of the daily traffic, therefore, was based on the assumptions in Table 1; and it will be noted that, at times of peak traffic in one direction, it was assumed that the traffic on the other two lanes would be at half capacity.

Based on these assumptions, therefore, and on the desire to be quite conservative in all estimates, it was assumed that the maximum traffic would be 3 600 vehicles per hour, and the average, 54 000 per day, with a total of 18 360 000 per annum.

## Economic Factors

*Cost of Delays.*—One factor of great importance economically is that of the cost of delays, due to interruptions at grade crossings with other highways, etc. This factor, of course, has not been considered in railway practice

because of the obvious impracticability of stopping trains for these causes, although consideration has been given to the costs of delays of trains held at sidings for the passage of opposing trains on single-track lines, and the effect of this on the economics of operation.

Necessarily, the cost of delays must be measured, in the first instance, by a computation of the time lost by each vehicle and the total time lost by all vehicles delayed. It is obvious, also, that the delays at grade crossings will reach a maximum at times of peak loads, and be almost nil at hours of minimum traffic. At a drawbridge the amount of delays will be the time lost by the actual number of vehicles held up during openings.

TABLE 1.—ESTIMATED DAILY TRAFFIC, ROUTE 25.

| Hour. | Percentage of maximum traffic. | Cars per Hour per Line. | | Total cars per hour. |
|---|---|---|---|---|

| 11:00-12:00 P. M. | 100 | 1 200 | 600 | 3 600 |
| Total daily capacity (cars) | | | | 54 000 |

Due consideration also must be given to the loss involved by reason of the decreased use of the highway as a whole, or at least on the section affected by the delays. If, for instance, the normal capacity of 20 cars per lane per min. is reduced by reason of delays to 15 cars, the traffic capacity of the highway at times of peak demand is reduced by 25 per cent. Obviously, also, the cost of the delays must be calculated for the number of cars which can actually use the highway and not for the number which could use it if the traffic flow were free and uninterrupted.

In the case of a highway where the traffic demand is equal to the capacity of the highway any reduction in this capacity must be evaluated on the basis of the cost of the facilities so provided and not utilized, or on the basis of the cost of other facilities necessary to take care of the traffic not accommodated. On Route 25, it was estimated that if the traffic were delayed at a crossing

at grade with another highway under such conditions that the traffic on the main highway could flow continuously for 3 min. and be interrupted for 1 min., the daily loss to the traffic on the two highways would be:

| | |
|---|---|
| On the main highway | 14 532 car-min. per day |
| On the cross street | 9 000 car-min. per day |
| Total | 23 532 car-min. per day |

To be conservative and in view of all the conditions it was further assumed that the loss per annum would be at the rate of 7 000 000 car-min.

Assuming (on a basis to be developed) that a car-minute may be valued at 2 cents the yearly loss at such a crossing will be $140 000. This, capitalized at 6%, represents a value of $2 333 000. In addition, it was estimated that by reason of these delays, the traffic-carrying capacity was reduced by 12.1 per cent. If the cost of the highway be assumed to be $22 000 000, then this loss in efficiency can be calculated to be $2 662 000. The total amount, therefore, which might profitably be spent to eliminate a single isolated crossing under the conditions assumed would then be approximately $5 000 000.

Of course, if there were a group of crossings more or less close together, and if the traffic were properly regulated by a system of adequately controlled and synchronized signals, the economic loss due to the group would be only slightly greater than that due to one crossing only. It was assumed that the amount which could profitably be spent to eliminate a group of from two to five crossings would be as follows:

| | |
|---|---|
| One crossing | $5 000 000 |
| Two crossings | 5 300 000 |
| Three crossings | 5 600 000 |
| Four crossings | 5 840 000 |
| Five crossings | 6 080 000 |

It will be obvious, of course, that this aspect, as in fact all other aspects, of this problem, must be studied carefully from its own individual point of view, taking into consideration the effect of all local conditions. The mathematical computations must necessarily be made and interpreted with a great deal of judgment.

*Drawbridge Delays.*—Route 25 had to cross the Hackensack and Passaic Rivers. The crossings of these rivers were studied by the writer for tunnels, and for bridges with movable spans having 35 ft. clear head-room above mean high water as required by the War Department. (Later, studies were made for fixed spans with 135 ft. clear head-room.)

The data on which calculations of the costs of delays at the drawbridges were based, were taken from the draw-tenders' records at adjacent bridges on the two rivers. These showed the number of openings, duration of each, and time of day. In using these data account was taken of the fact that the proposed bridges on the new line would have 35 ft. clear head-room above high water, when closed, instead of the 10 or 12 ft. of the existing bridges, and this requires fewer openings, as much of the river traffic could then pass

without affecting the drawbridges. Future increases in the river traffic were estimated and allowance made therefor.

As in the case of grade crossings with other highways, two factors were taken into consideration: Actual losses due to delays of traffic, and losses due to decrease in capacity of the highway. In estimating the actual losses to vehicles, the average number of openings of the bridge for each hour of the day was applied to the number of cars estimated to use the highway during that hour, and the loss in car-minutes thus calculated.

These two items for the two bridges were evaluated as follows:

| | |
|---|---|
| For traffic delays, 32 470 000 car-min. at 2.0 cents per min., $649 400 capitalized at 6% | $10 823 000 |
| Loss of efficiency, 6.33% of $22 000 000 | 1 392 600 |
| Total capitalized value of delays due to openings of the drawbridges | $12 215 600 |

*Value of a Car-Minute.*—Reference has been made to the value of a "car-minute", that is, the costs of delays per car per minute. Of course, this differs for each type of vehicle, but the general methods of estimating it are the same, except that for commercial vehicles there are more definite charges for delays which prevent the operation of this part of the owner's plant. It will be realized that a motor vehicle used for commercial purposes is just as much part of a manufacturing plant or selling organization as a machine in a factory, or an employee in a store. If idle when it might be working, it represents an item of loss.

For commercial motor vehicles, therefore, the stoppage is an element of expense. For non-commercial vehicles, however, the loss is not so clear, as, at first thought, it would seem to be a matter of comparative indifference whether a passenger arrived at his destination 2 or 3 min. earlier or later.

An experience with a taxicab in a traffic jam is, however, an illuminating example of what these delays actually cost; and if, for instance, one happened to be in a line waiting to cross the Hudson River by ferry, one would usually be willing to pay something extra for the privilege of moving up to the head of the line and avoiding the delay. The extra payments made to agents for theater tickets to avoid waiting at the box office, the rush for the first car of a train, etc., are all evidences of an innate realization of the costs of delays. The value of this economic factor of loss due to small delays has been doubted by many, not only laymen but engineers; nevertheless, it is a factor which must be given consideration.

These delays, of course, affect only some of the costs of operation. For purposes of analysis the average costs for a 3-ton truck for one year in the vicinity of New York were used for these estimates approximately as given in Table 2.

If a vehicle be delayed or stopped, certain expenses continue, such as Items Nos. 1, 2, 3, 4, 5, and 11. If during the delay the engine continues to run, there is also, of course, a certain consumption of gasoline and lubricants, but this will be small and has been omitted in the calculations.

Using the data in Table 2, and making similar allowances for light commercial vehicles and passenger cars used for commercial purposes, the following values for the cost of delaying a car for 1 min. were established:

For trucks ..... 2.3 cents per car-min.
For light commercial vehicles..... 2.1 cents per car-min.
For non-commercial vehicles..... 1.0 cent per car-min.

It was further assumed that, for this particular highway, the economic values should be based on the assumption that the traffic would be divided in the following proportions:

| | Percentage. |
|---|---|
| Trucks ..... | 50 |
| Light commercial vehicles..... | 25 |
| Non-commercial vehicles..... | 25 |

The average value of a car-minute (delays per car per minute), therefore, was assumed to be 2.00 cents.

TABLE 2.—YEARLY EXPENSE OF RUNNING 3-TON TRUCK, NEW YORK CITY.

| Item No. | Classification. | Amount. |
|---|---|---|
| 1 | Interest on $3 000 at 6%..... | $ 180 |
| 2 | Depreciation, average life of 5 years ..... | 600 |
| 3 | Insurance..... | 300 |
| 4 | Driver's wages, 300 days at $5.60..... | 1 680 |
| 5 | License fee ..... | 20 |
| 6 | Gasoline, 6 miles per gal. at 25 cents..... | 500 |
| 7 | Lubricants..... | 75 |
| 8 | Tires ..... | 270 |
| 9 | Repairs and maintenance..... | 360 |
| 10 | Miscellaneous ..... | 200 |
| 11 | Overhead, 20%..... | 837 |
| Total..... | ..... | $5 022 |

*Savings in Distance.*—The economic effect of distance may be considered under two headings: Time, and operating cost. The value of time has already been studied in connection with delays at grade crossings and at drawbridges. It remains, therefore, to consider differences in operating costs due to increases or decreases of distance. These will be considered without reference to other elements, such as curvature, rise and fall, rates of gradient, or pavement surfaces. The cost of additional distance is affected, of course, quite appreciably by differences in types of pavement, but it can be assumed that the pavement will be of the same character on any two locations of the same route which may be under comparison, and that for highways of this type the pavement will generally be a smooth hard surface.

In computing operating costs not only are there several different classes of highways to be considered, but an almost bewildering variety of types and weights of cars, and almost as many degrees of ability in their operation and in conditions of efficiency. The determination of a cost unit, therefore, is not a matter of scientific accuracy. It has seemed possible, however, to develop average figures which are sufficiently accurate for the purpose in view,

that is, the comparative operating costs of two locations on the same route on which the traffic is to be the same.

In the estimates for Route 25 a comparison of operating costs obtained from various sources indicated that, for the items affected, namely, depreciation; fuel; lubricants; tires; repairs; and miscellaneous (see Table 2), the following is probably a fair average cost of operation for the traffic expected to use this highway:

| | Cents. | |
|---|---|---|
| 50% heavy trucks at 15 cents per mile..... | 7.5 | |
| 25% light trucks and buses at 10 cents per mile ..... | 2.5 | |
| 25% non-commercial at 6 cents per mile..... | 1.5 | |
| Average per mile..... | 11.5 | |
| Equivalent to ..... | | 2.18 per 1 000 ft. |

Assuming that 18 360 000 vehicles will use the highway annually, the decreased operating costs, due to a shortened distance of 1 000 ft., will be $400 248 per annum, which, capitalized at 6%, indicates that the sum of $6 670 000 might profitably be spent to save this distance.

*Rise and Fall.*—Results of experiments indicate that, because of certain deficiencies in the design of engines of motor vehicles, the cost of operation on moderate ascending gradients is no greater than on the level. While this may be true, it is perhaps reasonable to assume that such deficiencies may be corrected, and that the additional cost of operation on ascending gradients is that required to raise the load to a given height.

Experiments made at Iowa State College[3] indicated that the work done by a motor vehicle to raise a weight to a height of 1 ft. is approximately equal to the force required to propel the same weight over a level distance of 50 ft. on good pavements.

Taking the data previously used, it will be found that, for the average car on good pavements, the cost of producing power only, that is, fuel and oil, is approximately 3.22 cts. per mile, or about 0.03 cts. for 50 ft. Therefore, this may be assumed to be the cost of raising the average car (on this highway) 1 ft.

It is realized, of course, that, on highways as on railways, momentum will overcome certain smaller elevations without expenditure of power. It is considered further that the expenditure of power on light rates of gradient within certain limits of height may be negligible, but no information seems available to determine the limits within which this may apply. Arbitrary assumptions, therefore, were made in estimating operating costs due to rise and fall, but all these were believed to be conservative and to represent smaller, rather than greater, actual operating costs for this factor.

For a traffic of 18 360 000 cars per annum, the cost of 1 ft. of rise and fall at the rate of 0.03 cent per car is approximately $5 508, which, capitalized at 6%, represents a value of $91 800 as the amount which might profitably be expended to eliminate 1 ft. of rise and fall.

[3] "The Economics of Highway Grades," by T. R. Agg, M. Am. Soc. C. E., *Bulletin 65*, Eng. Experiment Station, Iowa State Coll., Ames, Iowa, February 28, 1923.

However, after due consideration of all the factors involved—and it may be noted again that this is a purely arbitrary assumption—it was decided on this Route 25 that values for rise and fall should only be applied to gradients of 2%, or more (the maximum is 3.5%), and be varied for total lengths of continuous rise, as follows:

| For total elevations of: | Profitable expenditure to reduce by 1 ft. |
|---|---|
| 15 ft., or less | None. |
| 18 to 20 ft | $30 600 |
| 20 to 25 ft | $61 200 |
| 25 ft., or more | $91 800 |

*Curvature.*—On Route 25, the minimum radius of curvature was fixed at 1 000 ft. It was considered that, for the proposed conditions, that is, a well-paved, non-skid (granite block) pavement, 50 ft. wide, curvature would have little or no effect on operating costs or capacity of the highway to carry traffic.

However, for highways with sharp curvature, where visibility is reduced, or conditions exist which slow up traffic, there will be costs due to delays and, in cases of maximum traffic demand, costs due to a decreased capacity of the highway to carry traffic.

Evidently, a certain amount of power is required to change the direction of a moving vehicle, but, so far as the writer knows, no experiments have been made to determine how much this may be for highway motor vehicles. Probably a reasonable estimate of the costs of delays, accident risk, and loss of capacity of any given highway would be a fair estimate of the cost of curvature or of the value of its removal. For the highway under consideration no account was taken of additional operating costs due to curvature.

## Design of Route 25

*Application of Economic Theory to Actual Location.*—In a general way two sets of factors determine the location of a new highway of the character herein described:

*First.*—The physical characteristics of the terrain and the need of reaching certain points for the benefit of the traffic and of the territory to be served; and

*Second.*—The economic factors affecting the operation of vehicles over the route.

The original legislative act authorizing the construction of this highway proposed it as an extension of old Route 1 which ran from Trenton to the westerly boundary of Elizabeth. This extension was, therefore, to run from Rahway Avenue, at the westerly boundary of Elizabeth, to the Jersey entrance to the Holland Tunnels in Jersey City.

On Fig. 1 is shown the original "Advisory Board" route and the location finally adopted for Route 25. It is worth while noting how physical and other conditions affected the location as well as how economic factors were applied to certain details.

*Governing Points.*—Doubtless if only through traffic traversing the whole length of the route were to be considered, in the quantity of 15 000 000 to 20 000 000 vehicles per annum, and if only the economic factors governing the

cost of moving it were taken into account, economic justification could be shown for a practically straight, almost level, line from the Holland Tunnels to at least the easterly edge of Elizabeth, passing through Jersey City in a deep-level tunnel.

This latter, however, was considered entirely impractical, inasmuch as this highway was required to serve the requirements of Jersey City, making connections with its street system. Along the westerly side of the top of the hill (Fig. 1) there already runs a main north-and-south artery, the Hudson County Boulevard, with which connection also was desired. It was further necessary to provide for joining the new north-and-south State Highway (Route 1, 1927) which it was expected (in 1924) would come in from the north connecting the 178th Street Bridge across the Hudson with the proposed Bayonne-Staten Island Bridge.

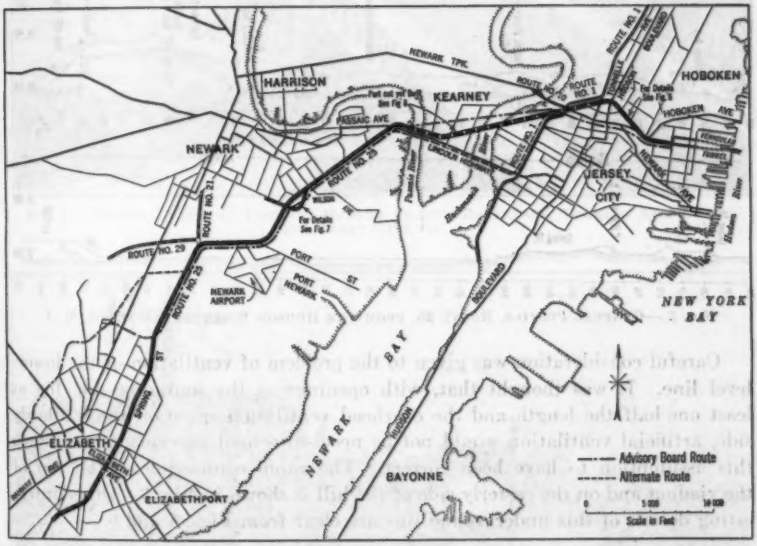

FIG. 1.—MAP OF JERSEY CITY, NEWARK, AND ELIZABETH, N. J., AND CONTIGUOUS TERRITORY, SHOWING LOCATION OF VARIOUS ROUTES.

These considerations determined the fact that the line would have to go over, instead of through, the hill, and an inspection of the profile, Fig. 2, will show that, in order to avoid crossings at grade with the Jersey City streets, crossings under the streets would probably be preferable to crossings over them. The maximum gradient of 3.5% on both sides of the hill just permitted the line to reach the elevation necessary to go under the streets. It also permitted a reasonable solution of the ramp connections to the main cross-streets (Fig. 3).

If, however, further justification were required from the point of view of economics of operation, it may be noted that, for an overhead line, the differ-

ence in elevation would have been approximately 40 ft., and this alone would have justified an additional expenditure of $91 800 \times 40 = \$3\,672\,000$, for the lower-level line. No calculations were made in this instance to show the difference in construction cost between an overhead and an underground line, because it was obvious that the lower line permitted easier solutions of the problems of connection by ramps to the important north-and-south highways. Also, it was fairly evident that an overhead line could not have been built for $3 672 000 less than the underground line which actually was built. Furthermore, an overhead line would have been objectionable from an æsthetic point of view.

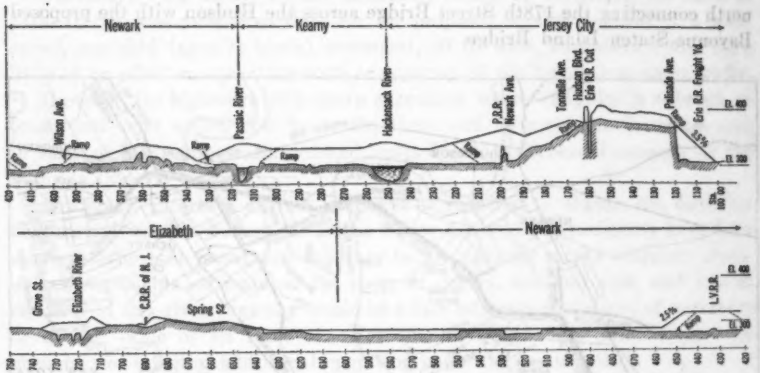

FIG. 2.—GENERAL PROFILE, ROUTE 25, FROM THE HUDSON RIVER TO ELIZABETH, N. J.

Careful consideration was given to the problem of ventilation of the lower-level line. It was thought that, with openings at the southerly side for at least one-half the length and the overhead ventilation space on the southerly side, artificial ventilation would not be necessary—and experience has shown this assumption to have been correct. The ramp connection at the top of the viaduct and on the easterly side of the hill is shown in Fig. 3. Other interesting details of this underground line are clear from Figs. 4 and 5.

## ALIGNMENT AT EASTERN END

*Location Through Jersey City.*—Of the various lines for the route through Jersey City (Fig. 6), the "Advisory Board" line was objected to by the authorities of Jersey City, because it was proposed as an open cut and it was felt that the two already existing open cuts, of the Erie and Pennsylvania Railroads, had created undesirable barriers across the city. Further study of the character of the line also indicated that the selection of Broadway (on the west side of the city) for the route was not entirely desirable.

The Erie Railroad Company objected to the use of its property on the south side of 12th Street because of certain plans it had for warehouse development there. This brought up questions of right of eminent domain as between

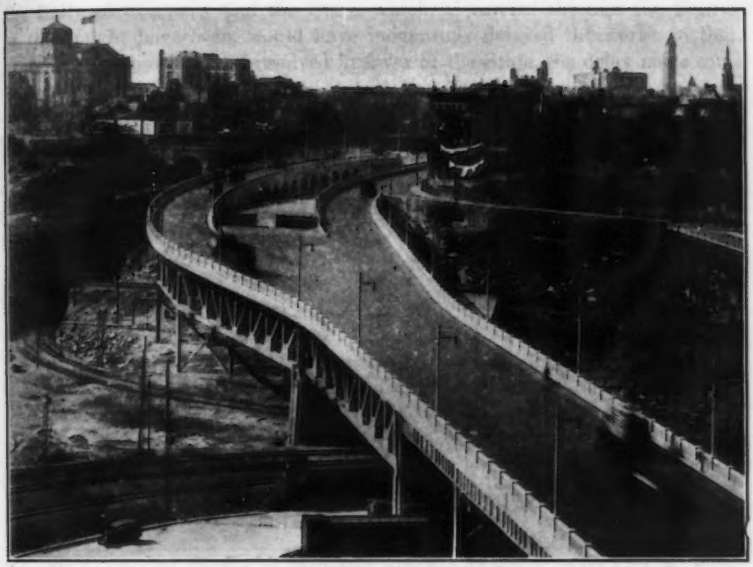

FIG. 3.—GENERAL VIEW OF VIADUCT, HUDSON COUNTY BOULEVARD, LOOKING NORTHWEST IN JERSEY CITY, N. J.

FIG. 4.—GENERAL VIEW OF COVERED CUT, HUDSON COUNTY BOULEVARD, JERSEY CITY, N. J., LOOKING EAST.

the Railroad Company and the State, which, if carried through the Courts, as they might have been, would have indefinitely delayed the work; so that, even had the question been resolved in favor of the State, the delay made some reasonable compromise desirable.

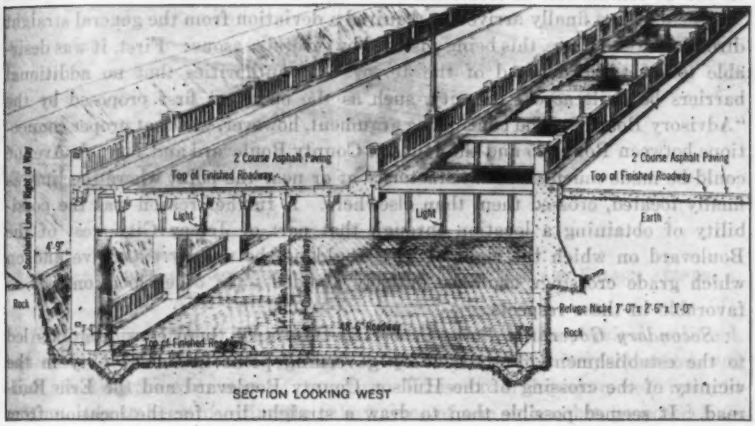

FIG. 5.—TYPICAL SECTION OF DEPRESSED HIGHWAY THROUGH JERSEY CITY, N. J.

Studies were made, as shown by Fig. 6. The Railroad Company desired to maintain sufficient right of way, so that its cut might be enlarged to provide for eight tracks; but, finally, after prolonged negotiations with the City and the Railroad Company, the filing of injunctions, etc., an agreement was reached resulting in the location shown on Fig. 1. This provided that the highway be located alongside of and to the north of the Erie cut, that it be covered, and that it have a roadway on top (Figs. 4 and 5).

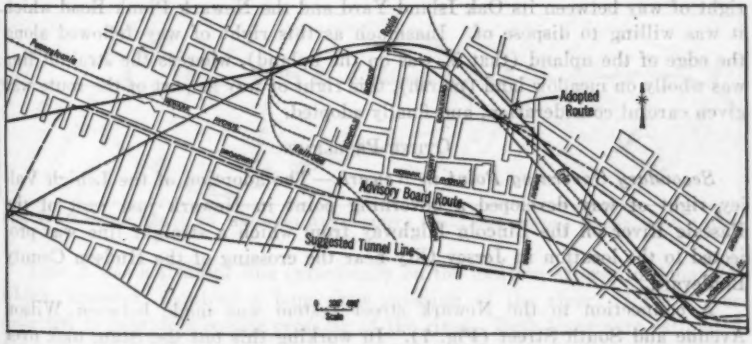

FIG. 6.—STUDIES OF VARIOUS LOCATIONS THROUGH JERSEY CITY, N. J.

In determining the location careful consideration was also given to the elements involved in the destruction of rateable values by reason of buildings

destroyed and land taken for highway purposes; also to the increment in valuations due to the creation of a broad boulevard crossing Jersey City (Fig. 4). All the governmental entities involved, City, County, and State, are vitally affected by these elements, and they exercise a considerable influence in the determination of locations.

The decision finally arrived at required a deviation from the general straight direction of the route, this being justified by several reasons: First, it was desirable to meet the demand of the Jersey City authorities that no additional barriers be built across the city, such as the open cut first proposed by the "Advisory Board". The controlling argument, however, was that proper connections between Route 25 and the Hudson County Boulevard and Tonnele Avenue could be made much more satisfactorily at or near the point where the line, as finally located, crossed them than elsewhere. A further reason was the possibility of obtaining a location through that part of Jersey City west of the Boulevard on which the right of way would not be unduly expensive and on which grade crossings could be entirely avoided. No other location was as favorable in these respects.

*Secondary Governing Point in Jersey City.*—All these considerations led to the establishment of a secondary governing point in Jersey City in the vicinity of the crossing of the Hudson County Boulevard and the Erie Railroad. It seemed possible then to draw a straight line for the location from this point to a point on the easterly boundary of Elizabeth.

Reconnaissances through Elizabeth had indicated this second point at approximately the location of the line as now built through Spring Street. This westerly objective, or governing point, however, was modified almost at once by the need of reaching the locality where Routes 21 and 29 now join this highway (Fig. 1). In some degree this was influenced also by the fact that the City of Newark had acquired and partly graded a right of way from near the airport to the Elizabeth line, which could be utilized for the highway.

It developed further that the Lehigh Valley Railroad Company owned a right of way between its Oak Island Yard and the Newark Plank Road which it was willing to dispose of. Inasmuch as this right of way followed along the edge of the upland (that is, was on the upland), whereas the straight line was wholly on meadow land (marsh), this right of way as part of the route was given careful consideration, and finally adopted.

### Other Problems

*Secondary Governing Point in Newark.*—The adoption of the Lehigh Valley right of way developed a governing point in Newark just west of the Passaic River on the Lincoln Highway from which a straight line was projected to the location in Jersey City near the crossing of the Hudson County Boulevard.

A connection to the Newark street system was made between Wilson Avenue and South Street (Fig. 7). In working this out the State took over an existing contract between the City of Newark and the Lehigh Valley and Pennsylvania Railroad Companies which involved the abandonment of Port Street, thus permitting the development of the Oak Island Yards of these

railways, which it crossed at grade, the State Highway at this point providing the principal means of access between the City of Newark, the Newark Airport, and Port Newark. This is an important example of effective co-operation between the local political and commercial interests, the railways, and the State, and between local and through traffic.

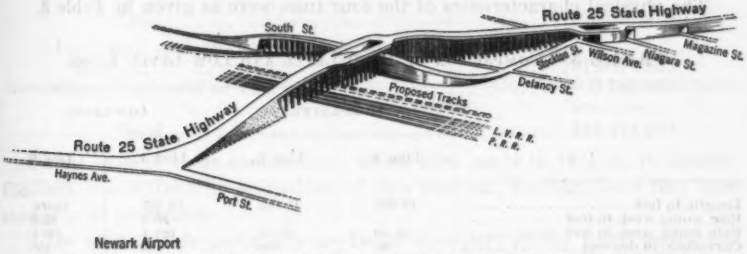

FIG. 7.—STREETS, CONNECTIONS, AND RAMPS AT SOUTH STREET AND WILSON AVENUE, NEWARK, N. J.

*Factors Other Than Economic.*—In considering all the physical, political, and other factors described, it may be felt that they entirely overshadowed those affecting the economics of operation. These latter, however, were brought continuously to bear in estimating the values of one or another proposed line. The writer is firmly convinced that these economic aspects are important elements which no conscientious engineer can afford to ignore, but the other elements have been set forth to emphasize that both aspects must be given due regard and their relative values properly appreciated.

*Application of Economic Factors.*—As an indication of the use to which these economic factors were put, there are cited here some comparisons made of two lines which were projected between the Hudson County Boulevard and the west side of the Hackensack River.[4] These Lines *A* and *B* are shown on Fig. 8 and the various profiles studied on Fig. 9.

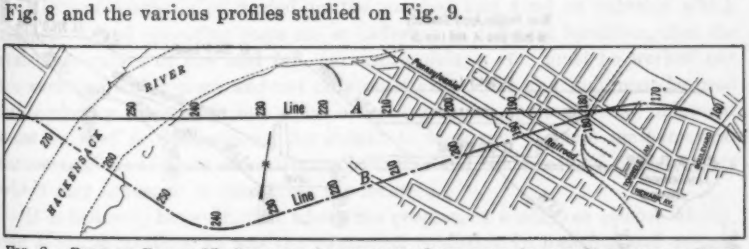

FIG. 8.—PART OF ROUTE 25, SHOWING ALTERNATIVE LOCATIONS ACROSS HACKENSACK RIVER.

Line *A* was a straight line (practically on the location afterward adopted), which, however, required a long skew crossing of the river. Line *B* was deflected to provide a square crossing of the river. Both lines were estimated for high and low levels.

[4] These estimates were made in 1924 and 1925 and applied to conditions assumed at that time. Later, in 1929, conditions, especially in regard to the War Department requirements for a bridge crossing on the skew line, made it necessary to revise the estimated costs of construction.

The high-level lines provided for a viaduct structure from the exit of the crossing under the Hudson County Boulevard, over the Pennsylvania Railroad to a bridge over the river with 35 ft. clear head-room above mean high water.

The low-level lines were in an open cut from the Boulevard under-crossing, under the Pennsylvania Railroad, and with tunnels under the rivers.

The physical characteristics of the four lines were as given in Table 3.

TABLE 3.—Comparison of High-Level and Low-Level Lines.

| | High-Level. | | Low-Level. | |
|---|---|---|---|---|
| | Line *A*. | Line *B*. | Line *A*. | Line *B*. |
| Length, in feet | 12 253 | 13 003 | 12 253 | 13 003 |
| Rise, going west, in feet | ..... | ..... | 86.2 | 83.9 |
| Fall, going west, in feet | 35.70 | 35.70 | 160.4 | 158.1 |
| Curvature, in degrees | 60 | 168 | 60 | 168 |

The estimated costs of construction were:

*High-Level:*

Line *A* ..... $8 898 410
Line *B* ..... 8 085 780

*Low-Level:*

Line *A* ..... $11 694 223
Line *B* ..... 11 099 869

The difference in the lengths of the two lines is about 750 ft., and it will be recalled that the justifiable expenditure to save 1 000 ft. in distance on this line, and for its expected traffic, was estimated at $6 670 000. It is clearly evident, therefore, that, for either level, Line *A* is preferable to Line *B*.

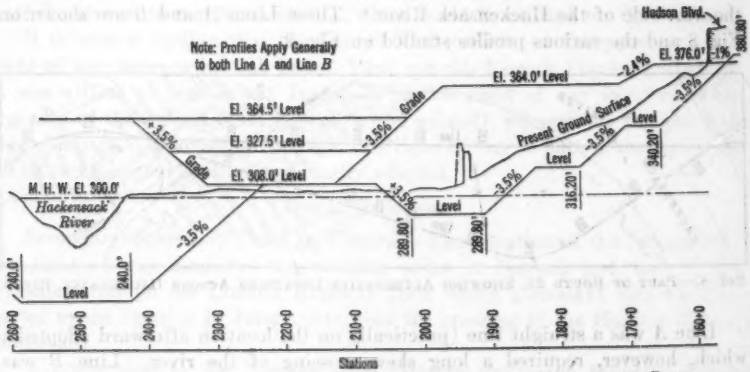

Fig. 9.—Profiles Showing Studies for Lines Crossing Hackensack River.

There was then to be made the comparison between the high and low levels (bridge or tunnel) for Line *A*. For the low level there was added to the construction cost the capitalized value of the added rise and fall, and to the

high-level line the added operating costs due to delays to be caused by the opening of the drawbridge. The comparison of the two lines on this basis, therefore, was at that time worked out as follows:

| | |
|---|---|
| High level and bridge: Estimated costs of construction. | $8 898 410 |
| Capitalized cost of delays at bridge..... | 8 000 000 |
| Total ..... | $16 898 410 |
| Low level and tunnel: Estimated costs of construction ..... | $11 694 223 |
| Capitalized cost of rise and fall..... | 9 780 000 |
| Total ..... | $21 474 223 |

On the basis of these assumptions, which were made in 1924-25, in connection with the earliest investigations of this problem, the high-level line then seemed to be preferable.

Since writing this paper, the profile of that part of the route across the Valley of the Hackensack and Passaic Rivers between Jersey City and Newark has been changed so as to provide 135 ft. clear head-room above mean high water at the river crossings. This change was brought about as the result of conferences to settle the long controversy as to the relative merits of tunnels for these crossings as compared with drawbridges with 35 ft. clear head-room. The writer is entirely in accord with this final decision.

## Modern Highway Demands

It has been impossible within the limits of a paper of this kind to fully demonstrate all the mathematical processes by which the data adopted for the studies for Route 25 were developed; but it is thought that the brief outline of their application to one section of the route will serve as a sufficient indication to experienced engineers, and no others should attempt to apply or develop them.

Highway traffic is so varied in the number and kind of vehicles which compose it, and operating costs are so different in different localities, that the resistance values of rise and fall, curvature, delays, etc., must be worked out for each particular case; and not only must experience and judgment be used in developing these data, but equal or even greater experience and judgment must be used in determining the weight to be given to these mathematical demonstrations of costs of resistance to traffic and the local and other factors which may influence or determine the location.

It is believed, however, that where the problem is wholly, or almost wholly, one of transportation, as was the governing condition in locating and designing Route 25, these resistance values should be worked out, so that they may be available as at least one factor to be considered in determining the location or in deciding between two or more possible variants.

With highways costing $3 000 000 to $5 000 000 per mile, as was the case with the first 8 miles of Route 25, engineers owe it to their clients or employers to make these demonstrations, and the governing bodies charged with carrying out works of this nature owe it to the taxpayers, not only to see that, for instance, the concrete is properly proportioned, the steel properly designed

and erected, and the pavements adequate and properly laid; but before all this, to ensure that the general design of the route—that is, its location, both in plan and profile—is such that there is a true economic proportion between the costs of its construction and the costs of operation of the vehicles which have to use it.

## Acknowledgments

The writer is indebted to the late A. M. Wellington, M. Am. Soc. C. E., and his "Economic Theory of Railway Location" for the basis of the theory herein applied to the location of Route 25.

The work was carried out under the general direction of the New Jersey State Highway Commission; Gen. Hugh L. Scott, U. S. A. (*Retired*), Chairman; and William G. Sloan, M. Am. Soc. C. E., State Highway Engineer. Great credit is to be given to all of these for their far-sightedness in the original conception of the general features of this highway and their initiative, co-operation, and help in the solution of the problems involved, both these herein referred to and innumerable others.

The writer also gratefully acknowledges the assistance of S. Johannesson, M. Am. Soc. C. E., who not only worked out the mathematical solutions of these problems, but who also was in entire charge, under the direction of the writer, of the design of the structure.

## DISCUSSION

W. W. CROSBY,[5] M. AM. SOC. C. E. (by letter).—The writer has endeavored in the past to point out the fundamental significance of the proper location of highways,[6] Mr. Lavis adduces an outstanding example of the sums involved, and the general interest therein may be proportional to their magnitude.

The author states that,

"* * * for handling large volumes of traffic through congested areas, highways should be designed [and paid for] for the main purpose of transportation rather than as adjuncts of the abutting properties." * * * where congestion of existing city streets interferes with the reasonably free passage of vehicles and pedestrians, highways of the type described are necessary not only to expedite through traffic, but also to restore such streets to their normal uses."

When these statements become generally appreciated, the highway will begin to be established in its proper place as an "element of transportation" comparable to the railway or canal.

It is true that a beginning has been made toward this end. The State highways of Pennsylvania have been largely located (or relocated) since 1924 with full recognition of the principles suggested by Mr. Lavis, although perhaps no single example of remarkable magnitude can be cited. Other States have attempted location more or less along similar lines.

However, the economist is not, and never will be, entirely free from the politician in this field. Perhaps this is just as well because the politician represents the sentimental side, and highways are not after all intended entirely for material purposes.

There are "intangibles" connected with any highway improvement that should not be overlooked even in its location. For example, one can estimate very closely the need for the width of a roadway to accommodate traffic, but to that width must be added, more or less arbitrarily, some further width for uses other than vehicular. Furthermore, it has been proved unwise to be too "economical" in that addition. Mr. Lavis refers to "Factors Other than Economic". "A demand for a new type of road" and a "Need of Special Highways" are also suggested by the author.

At the International Road Congress at Milan, in 1926, the Italian delegates proposed the endorsement of the idea of building such special highways where traffic conditions might justify them (as in certain localities in Italy). They even suggested making them toll roads, provided the eventual return of such roads to the State was assured. The American delegates, probably fearful from their experiences with toll roads in the past, united with the British to block the passage of this resolution. However, this country is actually building similar roads now whether or not the toll factor is evident.

To criticize fairly the location of "Route 25", described by Mr. Lavis, is impossible for the writer at present. Apparently, its alignment is question-

[5] Cons. Engr., Coronado, Calif.

[6] *Transactions*, Am. Soc. C. E., Vol. 91 (1927), p. 1007.

ably indirect, although Mr. Lavis seems to have anticipated this comment by his explanations. Probably here the "political" influence has swayed the economic decision. There seem to have been certain "legislative controls" and the influence of other route connections is mentioned as affecting the line. It is not quite clear, however, why the main route was swung aside to meet these other roads instead of bringing them to it. Neither is it clear to the writer why a roadway width of 50 ft. was selected. Do not most highway authorities condemn an odd number of lanes?

That "time is money" is now generally recognized by transportation authorities, and the author's exposition of the "Value of a Car-Minute" is commendable. His assumptions as to the division of the traffic on the highway are interesting, especially because of their apparent departure from the figures for New Jersey traffic reported in times past by the State Highway Commission. The writer believes that the assumed proportions of heavy trucks, 50%, light trucks, 25%, and non-commercial vehicles, 25%, are almost the reverse of the earlier reported figures.

The author proceeds to use operating-cost figures that may be interestingly compared with those used in Pennsylvania.[7] He concludes his all too brief paper with a statement of "Modern Highway Demands". The writer scarcely needs to reiterate his position in this matter, but he does wish to felicitate Mr. Lavis on the forcible expression of his conclusions, which seem incontrovertible.

WALTER LORING WEBB,[8] M. AM. SOC. C. E. (by letter).—This paper demonstrates the possibility, and even the practical necessity, of applying the principles of economics to the construction of through highways, that new type brought into existence by the motor car—a highway designed to serve the traffic which desires to travel fifty miles or more without stopping and which is best served by avoiding all intermediate cities or obstructions of any kind. When the late Arthur M. Wellington, M. Am. Soc. C. E., brought out his book entitled "Economic Theory of the Location of Railways", he dealt with a subject which seemed very complicated to those who tried to master its principles, and yet Wellington had a subject which was comparatively simple. A railway has the right of eminent domain and can locate its line as it pleases; it has a private right of way on which no one else can travel; it does not stop its trains for highway crossings, and it is only a matter of finance to avoid grade crossings, and possible stops and delays, at intersections with other railways.

It is a comparatively simple matter to reconcile existing physical conditions with the conditions necessary for the economical movement of trains when a railway company has the broad powers of eminent domain and the absolute control of its own right of way; but the problem, as exemplified by the construction of Route 25, described by the author, is infinitely more complicated. The State, several municipalities, and several railroad companies—each with their several powers of eminent domain and their several

[7] "Highway Location," p. 134 *et seq.*

[8] Cons. Engr., Philadelphia, Pa.

conflicting interests, each jealous of their powers to control matters to serve their own special interests—must be harmonized as nearly as possible. When one tries to introduce the added complication of designing a motor highway which will make possible the economical operation of motor vehicles, the problem becomes so complicated that it requires the highest grade of engineering skill and experience for its successful solution.

However, it should be realized that this last mentioned element—the economical operation of motor vehicles—is a vital and essential element in the solution of every such problem. In an address[9] before the Engineers' Club of Philadelphia, Dr. George Otis Smith, Director of the U. S. Geological Survey, emphasized the necessity for the modern engineer to be an economist, or, in other words, that he must avoid all features of construction which necessitate methods of operation that are avoidably wasteful. In so far as the design for such a motor-highway project fails to provide for such economies of operation as are possible, to just that extent the design is a failure and is a waste of the several millions of dollars which are spent on it.

This subject is becoming increasingly important, since the construction of Route 25 in New Jersey is one of the first of many similar projects which will undoubtedly arise in the solution of the fast growing motor-transport industry.

The writer is aware that he has said little or nothing that has not already been well said by Mr. Lavis, but he believes that the matter is so important that it should be reiterated and emphasized until the general public, as represented by State and municipal authorities, who do not look at these matters from the engineer's standpoint, become more conscious of its importance as a matter of public welfare and economy.

It is unfortunate that the data on the actual cost of motor operation, the cost of applying brakes and resuming speed, the cost of stops and starts, and the effect of grade and curvature, are so meager. Undoubtedly, there will be an accumulation of such data in the near future. The necessity for the economical operation of motor-bus and motor-truck lines will probably result in the scientific study of those elements by the managers of those lines, and engineers will probably have a much larger accumulation of data on which to base their calculations than is now available.

Although the writer has no experimental data on the subject, he is of the opinion that curvature, even "easy" curvature, is not as harmless as it is commonly supposed to be. The centrifugal force which must be resisted in some way when a vehicle passes around a curve is measured by the formula, $C = \frac{W v^2}{g r}$. Its magnitude may be estimated by assuming numerical values as follows:

Let $W$ = the weight of a car, or truck, assumed numerically as 15 000 lb.;
$v$ = the velocity, assumed as 30 miles per hour, or 44 ft. per sec.;
$g$ = the acceleration of gravity, or 32.2 ft. per sec. per sec.; and,
$r$ = the radius of curvature, here assumed as 1 000 ft.

Then, $C$, the centrifugal force = 902 lb.

[9] *Engineers and Engineering*, July, 1930.

This stress must be taken up by the friction of the tires on the pavement, except as it would be possible to counteract it, at least partly, by elevating or banking the curve on the outside. In this numerical case, reducing the radius from 1 000 to 300 ft. and still maintaining the velocity at 30 miles per hour, would increase the stress from 902 to more than 3 000 lb.

It would probably be very difficult to determine experimentally the increase in rate of tire wear due to curvature. Part of the deterioration will be due to actual skidding or scraping of the tire on the pavement, thus wearing down the tire shoe; but some will be due to mere stress which, when long continued and repeated, will wear down the resistance even of the rubber, and cause its earlier destruction.

The objection to curvature may be very slight or even negligible, from the standpoint of loss of time or required increase in motive power—and hence in the cost of gasoline and oil—but the effect on tires and on the internal stresses in the car frame, which will cause more rapid deterioration, is certainly very appreciable, even if it is difficult to evaluate.

It is to be hoped that, when problems similar to those involved in the design of Route 25, are brought before the State or municipal authorities concerned, those elements of economy of operation will be thoroughly studied and will be given their due weight in making the final decision.

Of course, every such problem involves conflicting interests of greater or less importance. The public must insist that less important interests must give way (and perhaps be compensated) for a design which will best serve the interests of the majority. The danger lies in the possibility that powerful financial or political groups, whose real financial or public interest is less important, will be able to control the situation.

The profession owes much to Mr. Lavis for his practical demonstration of the possibility of the scientific application of Wellington's fundamental principles to such a complicated problem, and also for his demonstration that it is only by the use of such a general method that such problems can be properly solved.

JAY DOWNER,[10] M. AM. SOC. C. E. (by letter).—This description of the Holland Tunnel-Elizabeth Highway, known as Route 25, is a valuable exposition of the new conception of highway design and construction. In recent years marked improvements have been made in such component elements as grades, alignment, bridge structures, and paving materials. The outlook of planners and designers has now expanded beyond these primary essentials to include two other important elements of comprehensive design. These are the isolation of rights of way from abutting private property and the elimination of grade crossings.

The application of these last named principles in congested regions, such as that traversed by Route 25, even at very heavy costs, becomes justified when overbalanced by the economic pressure of losses due to traffic delays. The rapidly increasing volume of mechanical transport on roads in the United

[10] Chf. Engr., Westchester County Park Comm., Bronxville, N. Y.

States has made evident, the analogous relation of the trunk-line, express highway to the railroad.

Through congested city sections, costly viaducts or tunnels are the principal means of accomplishing both isolation from abutting property and grade separations. In areas where vacant land is still available, this isolation as well as grade separation structures and ramps can be attained more economically by the acquisition of rights of way wide enough to afford flanking strips on both sides of the paved roadway.

This principle has been followed in laying out the Westchester County Parkways. The minimum width adopted for these parkways is 200 ft. and 300 ft. is desirable. The paved roadways which have been laid up to the present time (1930) are 40 ft. wide, but the Hutchinson River Parkway and the Saw Mill River Parkway have been sub-graded to a width of 60 ft. to provide for an additional 10-ft. lane on each side of the initial 40-ft. pavement.

The character of the greater part of the area traversed by Route 25 doubtless precluded the application of the excess right-of-way principle, but in laying out trunk-line express highways there are doubtless broad fields offered for its application, even in the environs of many of the large cities.

Wherever it can be applied, this principle will doubtless commend itself to the designers of such highways, both for the economies in grade-crossing eliminations and the opportunities afforded for the amenities of parkway treatment applied to the flanking strips separating the paved roadway from abutting private property or subsidiary streets. The cost of excess land area may be easily outweighed by lower grade-separation costs and the very tangible economic as well as esthetic value of parkway treatment.

Through metropolitan areas of residential character, the effect of a trunk highway on near-by land values may be of greater economic importance to the immediate region than its value as a transportation route. The parkway type of express highway route invariably enhances near-by property values in contrast with the depression of values that has been experienced in many places along heavily traveled, modern roads in direct contact with private property.

S. JOHANNESSON,[11] M. AM. SOC. C. E. (by letter).—The author states that the highway considered in his paper will cost from $3 000 000 to $5 000 000 per mile. When the length of such highway is measured in miles rather than in feet, the total expenditure becomes so great that the first reaction is likely to be expressed in the question: Is it worth its cost? An affirmative answer is given in the paper, but it is of sufficient importance to warrant a re-statement.

The ultimate purpose of the highway is to decrease the cost of transportation of people and merchandise between the points served by it. This might also be expressed in other terms; for example, it might be said that the reason for building the highway is to relieve the congestion of existing traffic facilities or to decrease the time required to travel from one point to another. These statements are, in fact, only different ways of expressing the same definition.

It is probable that not less than 30 min. is saved in traveling over the new highway from the Holland Tunnel Plaza in Jersey City to the airport at

[11] Designing Engr., State Highway Comm., Jersey City, N. J.

Haynes Avenue, Newark. Using the data given in the paper, the traffic is estimated at 18 360 000 vehicles per annum and is valued at 2 cents per car-min. Therefore, the capitalized value of the savings in cost of transportation would be $183 600 000, or, say, $23 000 000 per mile of highway. It is apparent, therefore, that an expenditure of $3 000 000 to $5 000 000 is entirely justifiable, because it permits a saving several times the cost of construction.

The determination of the feasibility of a new highway should properly be based on an economic balance between the cost of producing the new facilities and the saving gained by them in cost of transportation. Generally speaking, this is directly proportional to the volume of traffic. Consequently, the amount of money that may be spent economically on new highway projects is directly proportional to the volume of traffic. When the traffic is heavy, as in the case considered by Mr. Lavis, this amount may often be found to be surprisingly large.

D. P. KRYNINE,[12] M. AM. SOC. C. E. (by letter).—Modern technology and economics are intimately bound together; this statement is perhaps more true of Highway Engineering than of any other technical branch since the cost of a product moving from the producer toward the consumer is often considerably increased by bad road conditions. Consequently, the necessity of an "economic design" arises, that is, a design in which the needs of transportation are met in the most efficient and, at the same time, the cheapest way.

Nowadays, American engineers build roads in practically all parts of the world. Therefore, it is important for them to take into consideration the economic features of a given country or region in order to be able to design such roads effectively.

It may be observed that, in its economic development, a country or a region passes through the stages of being: (*a*) A colony or undeveloped country, such as America was about 1730; (*b*) a developed country, such as America in 1890 or 1900; and, (*c*) a congested area, such as New Jersey or New York at the present time (1930).

Each of these three steps may be found in different countries of this epoch. In the beginning of Period (*a*) there are practically no roads in a country or a region. Gradually, lanes or earth roads appear that satisfy the elementary needs of the settlers. The road system develops little by little, being adapted to the demands of growing industries. However, such a development of a road system involves technical errors, especially in properly selecting the right of way; and often subsequent generations are obliged to waste considerable sums of money in rectifying such errors.

Obviously, such a situation as that which existed about two centuries or more ago, when road experts had but poor ideas concerning highway technique and economics, cannot be tolerated to-day. A highway designer who deals with the road system in an undeveloped country, should prepare a comprehensive plan of construction. A thorough economic study of the region must precede any technical road survey; the existing volume of traffic should be determined, and the future volume should be estimated. Then, a proper type of each link of

[12] Research Associate in Soil Mechanics, Dept. of Civ. Eng., Yale Univ., New Haven, Conn.

the system should be selected, almost in the same manner as is done by a structural engineer when determining cross-sections of a bridge according to the expected stresses. In highway design the stresses correspond to the volume of the traffic, and the cross-sections to the type of the road.

It must be borne in mind that in an undeveloped country or region the road system is a powerful means of controlling the development of industries, and a foreign consulting engineer called to work in the design of such a road system should have a series of conferences with Government officials and economists.

In an undeveloped country or colony the highways are indubitably elements of transportation. In time, however, railroads and other perfected means of transportation appear and, to them, highways cede their rôle of a means of through transportation. Thus opens an epoch during which many (perhaps a majority) of roads and highways become merely municipal features like the water supply or the fire department.

The third stage is that so brilliantly described by Mr. Lavis. The construction of Route 25 in New Jersey is an introduction into the transportation system of a new kind of link that is something between "highway" and "railway." This new member of the transportation family may be called "super-highway" or "autostrade", as in Italy. Incidentally, Italy has constructed the following autostrades to date: (1) From Milan to Lakes Maggiore and Como; length, about 60 miles; width, 33 and 52 ft.; (2) from Rome to Ostia (a short distance); and, (3) from Naples to Pompeii (a short distance), and a vast program is under construction and consideration.[13]

HAROLD M. LEWIS,[14] M. AM. SOC. C. E. (by letter).—The author has described a modern highway as one which is designed with low grades and curvature and with a maximum elimination of delays from crossings of intersecting waterways, main highways, and local streets. Such is the "express highway" which has come to have an important place in the design for highway transportation in any large metropolitan area. New Jersey State Highway Route No. 25 was a pioneer project in such construction and has fully justified the faith of those who designed it.

*Types of Express Highways.*—That "express highways" are needed seems to be admissible without further discussion, but just what form such routes should take and what their relation should be to the other parts of the highway system and to the development of the adjoining land are questions requiring still further study. That there are various solutions of such problems is shown by examples already available. The "super-highways" radiating out from Detroit, Mich., on 204-ft. rights of way illustrate a type which combines the express highway with a main artery for rail transportation, facilities for local traffic, and the intensive development for business purposes of most of the fronting property. The West Side Elevated Highway, along the Hudson River waterfront of Manhattan, in New York City, utilizes a portion of the air rights above the wide open space composed partly of public streets and partly of

[13] See "Tabula viarum Romani Imperii," Rome, 1930.

[14] Cons. Engr.; Engr., Regional Plan of New York and Its Environs, New York, N. Y.

the marginal wharf or place under the jurisdiction of the Dock Department. The space beneath this highway is still available for street traffic, except where ramps interfere. In no other place in Manhattan could such an elevated highway have been constructed without acquiring large areas, or paying damages to abutting buildings for taking away their light and air.

The City of Chicago has proposed an Avondale Super-highway, 10 miles long, from the heart of the city to its northwestern limits. This highway would parallel the tracks of the Chicago and North Western Railroad and would be elevated above the normal street system to which connections would be provided at intervals of about 1 mile, planned so that left-hand turns would be unnecessary. There would be an adjacent local low-level street, 50 ft. wide, for 9 of the 10 miles of the improvements.

The City of New York is planning a cross-town express highway in Manhattan to be constructed as an extension of a mid-town vehicular tunnel under the East River and to connect with a second vehicular tunnel under the Hudson River projected by the Port of New York Authority. This express highway will be a deep-level tunnel passing beneath all existing or projected rapid transit subways and will have no connections with the street system, except at the two ends—one near Second Avenue on the East Side and the other near Tenth Avenue on the West Side.

In Westchester County, New York, the County Park Commission has planned an express highway for general traffic to be constructed on a new right of way roughly parallel to the New York, New Haven, and Hartford Railroad. The right of way has been acquired, but to date (1930), construction has not been started.

In the Detroit District a 40-ft. elevated express toll highway has been proposed above the Detroit-Pontiac Line of the Grand Trunk Western Railway of the Canadian National System, as part of a $100 000 000 electrification and improvement program. The roadway would be 40 ft. above the rails, and intersecting highways would cross on an intermediate level between the railroad and highway. It is proposed to build the highway in sections and to establish the toll on zone rates.

The foregoing examples indicate the various forms which express highways are taking. In addition, there is the "parkway" which may provide an "express" highway restricted to passenger car traffic. Not all parkways may actually be express highways as some are primarily for local recreational purposes, but when—as in the case of the Bronx River, Saw Mill River, and Hutchinson River Parkways, in Westchester County, New York—they form main highways to or from metropolitan centers, they are closely related to such general traffic highways as those discussed herein.

*Proposed Express Highway System for New York Region.*—The Graphic Regional Plan prepared for New York and Its Environs included a comprehensive system of express highways, of which New Jersey State Highway Route No. 25, and the West Side Elevated Highway and the cross-town tunnel in Manhattan, form important parts. For smaller regions, or those with less geographical complications, it might not be necessary for the express highway system to cross the main business center, but only to skirt its edge. In this

case, however, two lines were shown across the main center in Southern Manhattan. One of these utilized the Holland Tunnel and the other the projected mid-town crossings previously mentioned.

North and south routes were proposed on both the main water-fronts of Manhattan and also on both sides of the Hackensack Meadows, in New Jersey, and a fifth route through Brooklyn and Queens Boroughs parallel to the East River. A total of six radial routes was shown, only one of which (the route described by Mr. Lavis) was extended to the edge of the region. Route No. 25 was officially projected to Philadelphia, Pa. The other five routes extended out from 20 to 25 miles from the metropolitan center. Fig. 10 shows two additional express highways proposed by the New Jersey State Highway Department. One of these is a branch of Route No. 25 through the center of Newark, the other would lead to the west across the congested areas of Essex County.

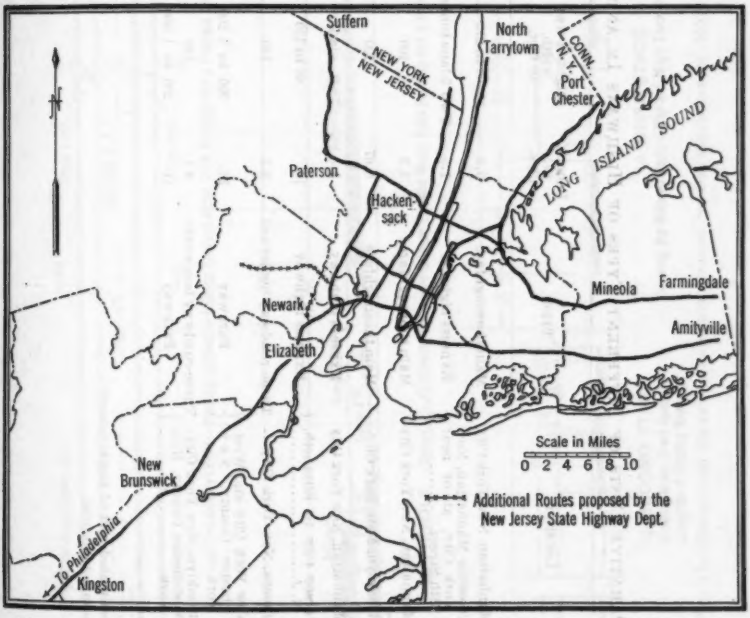

FIG. 10.—PROPOSED SYSTEM OF EXPRESS HIGHWAYS FOR NEW YORK AND ITS ENVIRONS.

*Comparative Costs.*—The cost of such a highway through intensively developed areas of high land values is tremendous, particularly if it becomes necessary to locate it entirely above or below the level of the existing street systems. In suburban territory, an express route may follow the surface of the ground throughout most of its length, and grade separations may be installed only at the main intersecting highways; secondary streets can terminate in part at the highway and in part cross by short offsets along the line of the express highway.

TABLE 4.—COMPARATIVE COSTS OF DIFFERENT TYPES OF HIGHWAYS IN AND ADJACENT TO NEW YORK CITY.

| Name of highway. | Location. | Type. | Length, in miles. | Right-of-way width, in feet. | Cost per mile. | Remarks. |
|---|---|---|---|---|---|---|
| Sixth Avenue Extension. | Manhattan, New York City | Main thoroughfare | 0.6 | 100 to 210 | $14 000 000† | Opened 1930; forms new approach to Holland Vehicular Tunnel. |
| Mid-town Tunnel..... | Crossing Manhattan, New York City, at or near 38th Street..... | Express highway | 1.5 | Two 2-lane tunnels | 11 200 000* | Final plans being prepared. |
| Varick Street Widening and Seventh Avenue Extension..... | Manhattan, New York City | Main thoroughfare | 1.3 | 100 | 6 300 000 | Opened 1918; Varick Street widened from 65 to 100 ft. |
| Flatbush Avenue Extension ..... | Brooklyn, New York City. | Main thoroughfare | 0.67 | 100 | 4 450 000 | Approach to Manhattan Bridge; opened 1909. |
| West Side Elevated Highway ..... | Manhattan, New York City | Express highway | 1.5 | 70-ft. viaduct | 4 300 000 | Section, Canal to 23d Street only; opened 1930; no right-of-way costs required. |
| New Jersey State Highway No. 25..... | Jersey City to Elizabeth, N. J..... | Express highway | 18. | 66 to 120 | 2 200 000* | Partly completed; remainder under construction. |
| Nassau Boulevard..... | Queens, New York City... | Three-roadway boulevard | 2.1 | 160 | 1 171 000‡ | Section, Strongs Causeway to Fresh Meadow Road; includes paving of only a 30-ft. roadway. |
| Bronx River Parkway.... | New York City and Westchester County, New York..... | Parkway | 16. | 200 to 1 200 | 1 060 000 | Final section opened in 1925. |
| Kings Highway..... | Brooklyn, New York City. | Three-roadway boulevard | 4.1 | 160 | 740 000 | Opened 1926; includes paving of central roadway only. |
| Hutchinson River Parkway ..... | Westchester County, New York..... | Parkway | 11. | 200 to 1 000 | 370 000 | Opened 1928. |

* Preliminary estimates.
† Acquisition cost plus estimated cost of improvement.
‡ Estimate based on incomplete figures.

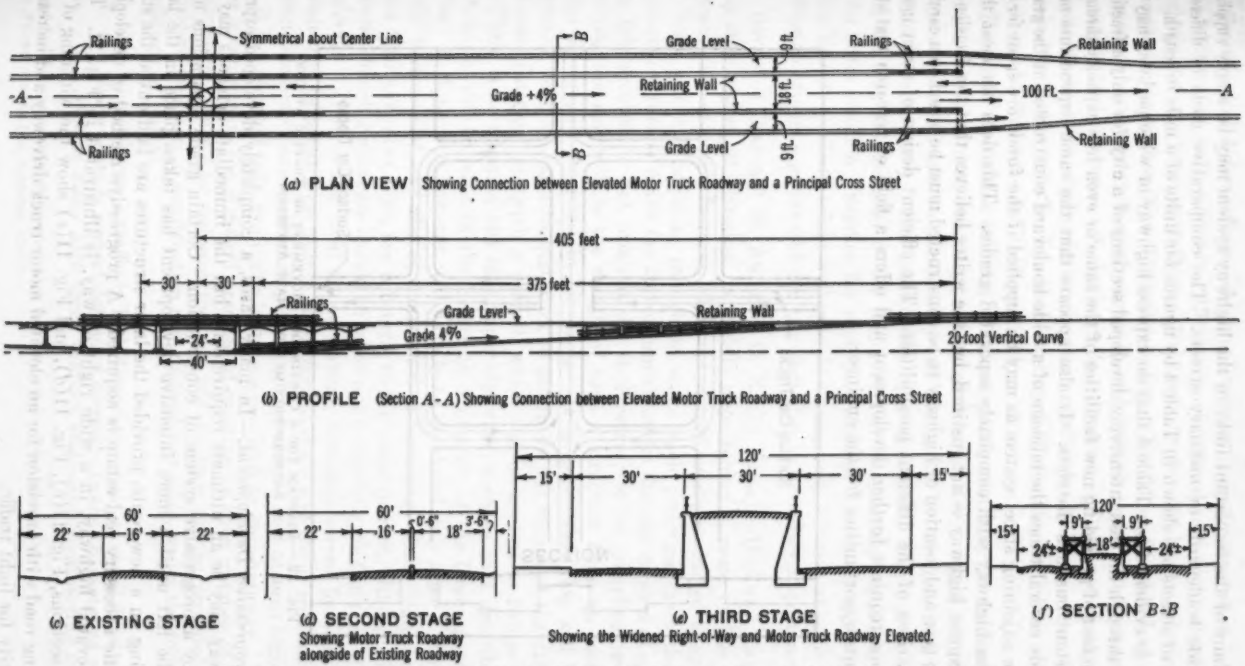

FIG. 11.—SKETCHES SHOWING POSSIBLE STAGES OF DEVELOPMENT OF MOTOR-TRUCK HIGHWAYS.

Many of the important links in the highway system may be amply supplied by wide boulevards or ordinary streets. The comparative costs of different types of streets are shown in Table 4 by figures for units of a mile in length.

It is evident from Table 4 that an express highway or wide parkway may be built through the less intensively developed sections of a city for only a fraction of the cost of providing new facilities of the same or even less capacity through important business districts. It also appears that the same expenditure may provide several times the mileage of a wide boulevard constructed at the grade of the adjoining street system as may be supplied if the funds are spent for an express highway with completely separated grades. This does not mean that the express highway is not justified, but the writer believes that the decision as to the type and location of highway to be constructed must be based on a careful comparison of the different possibilities. The efficient design of street intersections requires further development and offers a field of research that still presents opportunities for the engineer.

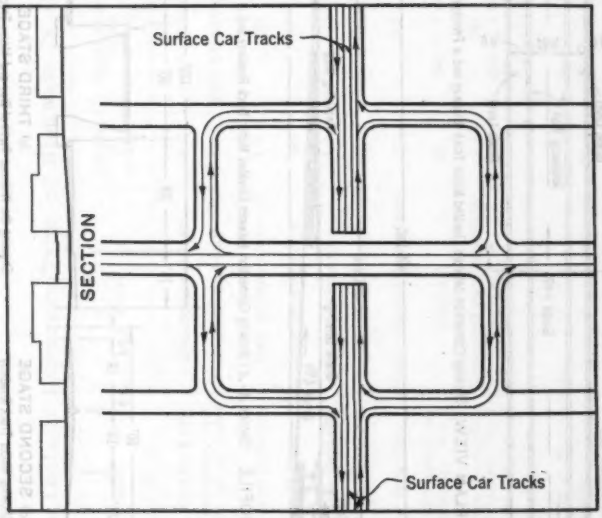

FIG. 12.—DIAGRAM FOR A CONTINUOUS MOVEMENT OF TRAFFIC AT THE INTERSECTION OF TWO MAIN ARTERIES.

*Progressive Development.*—In many cases, a completely developed express highway may be an ultimate requirement, but the immediate demands may be met by a progressive system of construction. Certain grade separations may well be left until a more intensive development has taken place in the land fronting on a new route, provided the later structures are laid out at the start and the necessary real estate is acquired. A progressive method of developing an elevated highway, in a wide right of way, is illustrated in Fig. 11. The road sections, Fig. 11(*c*), Fig. 11(*d*), and Fig. 11(*e*) show the widening of an existing road with provision for an elevated motor-truck driveway and increased capacity for light traffic.

*Treatment of Intersections.*—A complete type of grade separation between two intersecting main highways, offering unobstructed movement along each route and for any turning traffic between them, is provided by the "clover-leaf" intersection as used on New Jersey State Route No. 25, at Woodbridge. This, however, is extravagant of space except in undeveloped country and cannot well be used in business areas. A single grade separation and the use of adjoining streets, however, may approximate the same results in a built-up area. A suggestion for such a solution has been developed by the Regional Plan of New York and Its Environs and is shown in Fig. 12.

The traffic circle is a solution of intersections that may be the only one feasible where several radiating routes of comparatively equal importance intersect. For an intersection of only two routes the writer feels that it will seldom be satisfactory. The substitution of a rectangular area for the circle, with the long axis parallel to the major of two intersecting highways, offers a far better solution. Studies for such intersections have been made by Mr. Fritz Malcher.[15] They might well provide a temporary solution at some intersection points and a permanent one at points of only secondary importance.

DONALD M. BAKER,[16] M. AM. SOC. C. E. (by letter).—Highway planning, like other phases of planning, is rapidly approaching a more or less exact science. The economic features, while not yet sufficiently evaluated to apply to all cases, are still adequate enough to make such planning more than an approximate guess. While the author himself states that the method of attacking this problem is not original, he is, however, to be complimented for applying the approach to the design of such a structure from an economic point of view, as described in his paper. It is hoped that this will be an incentive for more experimental work to determine the values of the different elements entering into such a project, which can be applied to future cases.

There is no question but that super-highways, such as that described by Mr. Lavis, will be built in the future in a number of the larger American cities. Each project, however, will have to be developed only after a thorough study of economics, and also of the method of financing. Such highways, far more than any other type, are a benefit to the users thereof, although in the general financing plan care should be taken not to overlook the fact that, if these highways do relieve the local street systems, residents served by such local streets may be saved large future improvement costs and could reasonably be expected to contribute some small percentage toward the cost of such highways.

It is noted that only five traffic lanes are provided on this highway. While this is contrary to the standard practice of creating an even number of lanes, nevertheless, the writer believes that an odd number can be provided with considerable saving in construction and right-of-way costs, under the following conditions of traffic:

1.—Where the peak traffic in both directions is not of equal density.
2.—Where there is a great degree of diversity in the character of traffic, such as many high-speed vehicles and many slow-moving trucks.

[15] *The American City*, September and October, 1929, and August, 1930.
[16] Cons. Engr., Los Angeles, Calif.

In the first condition traffic studies often show that during morning or evening peaks traffic in one direction will amount to from 150 to 200% of that in the other direction. In this case the odd-numbered lane can be used to accommodate traffic moving in the direction of heaviest flow. If a reversal of this occurs at another time of day, the odd-numbered lane may be used for the traffic in the other direction. A little education is sufficient to adjust the public to this situation, and under these conditions an even number of lanes may normally represent useless expenditure.

Under the second condition in which, say, three or five lanes are provided (particularly three lanes), heavy slow-moving vehicles must be passed by faster and lighter vehicles and the existence of an extra lane used only for such passage will greatly expedite the traffic.

This all points to the fact that, before right-of-way and paving widths are definitely determined, a careful study of existing and prospective traffic should be made, in order to find out whether the extra lane necessary to furnish an odd number of trafficways is, or will be, necessary.

EDWIN F. WENDT,[17] M. AM. SOC. C. E. (by letter).—This paper is a notable contribution to the science of engineering in its relation to transportation. When the late Arthur M. Wellington, M. Am. Soc. C. E., wrote his book entitled "Economic Theory of Railway Location" fifty years ago, the Engineering Profession did not foresee that in 1930 the same principles would be applied to highway design by reason of the growth of traffic due to the extensive use of motor cars.

The author calls attention to the fact that, until recent times, highways were the developments of old trails made by man before the era of wheeled vehicles. The Hon. Henry W. Temple, Representative in Congress of the 25th Pennsylvania District, elaborated this same fact in an address delivered before the Service Clubs of Washington, Pa., September 25, 1930, on the subject "Some Historical Associations of the National Pike". This address contains much interesting information for the engineer.

Mr. Lavis very properly points out that engineering and economics are indissolubly linked together, and this applies to highways as well as railways. He has demonstrated by his thorough analysis of the problem of highway design that the true engineer is an economist, and that economics is essentially a part of engineering. The rise, the development, and the phenomenal growth in the number of motor cars require the design and construction of highways in accordance with scientific principles, so that there will be a true economic proportion between costs of such construction and the cost of operation of the motor vehicles which use the highways. The author is a pioneer in the application of the principles of the economic theory of railway location to the design, construction, and operation of modern highways.

H. W. HUDSON,[18] M. AM. SOC. C. E. (by letter).—The author has referred to a change made in the alignment and profile of Route 25 between the Pennsylvania Railroad crossing in Jersey City and a point west of the Passaic

[17] Cons. Engr., Washington, D. C.

[18] Engr. in Chg. of Constr., State Highway Comm., Jersey City, N. J.

River in Newark, which change was made subsequent to his connection with the project.

The permit issued by the War Department for the construction of the movable bridges having 35-ft. normal clearance, which had been adopted for the crossings of the Hackensack and Passaic Rivers, stipulated that the existing bascule bridge crossing the Hackensack River on Lincoln Highway should be removed following the completion of Route 25. The permit also stipulated that the Passaic River Bridge should be raised to provide a minimum clearance of 35 ft.

Realizing the impracticability of closing Lincoln Highway, due to the removal of the Hackensack River Bridge, as called for by the War Department's permit, the Highway Commission decided to construct a tunnel to take the place of the bridge. This decision led to considerable adverse criticism by interests more or less directly affected. It was appreciated, however, that the cost of this tunnel, as well as the reconstruction of the Passaic River Bridge, required by the War Department permit, would add so materially to the total expenditure that, under these conditions, the adopted plan, involving movable bridges, might not remain the most economical. Further studies, therefore, were made of a proposal involving tunnels under both rivers and an open cut below the meadow level across the Kearny Peninsula, as well as a plan involving bridges with sufficient under-clearance to permit the use of fixed spans.

Either of these proposals would not affect the river traffic, and it was assumed, therefore, that the War Department would not require any changes in the Lincoln Highway bridges in connection with issuing a permit for either of these types of river crossings, and hence no consideration was given to this contingency in preparing the comparative estimates. In the former, it was necessary to consider the possibility of ultimately having to construct a roof over this cut coincident with the development of the contiguous property. In such event, it was realized that the problem of ventilation would be a serious element.

The alignment for both the tunnel and high-level viaduct plans was identical and was found to be several hundred feet shorter than that of the adopted location which contemplated movable bridges with a normal clearance of 35 ft. Either proposal involved a saving in curvature, but increased the rise and fall over the 35-ft. clearance scheme.

The construction and right-of-way costs of the route involving movable bridges (including the raising and reconstruction of the Passaic River Bridge and the construction of tunnels under the Hackensack River, both on Lincoln Highway), was found to be greater than the high-level viaduct route. Similarly, it was found that the construction costs of tunnels under the rivers, with the open depressed cut through the meadows, would be in excess of either the 35-ft. plan, or the high-level viaduct. Investigation of automobile operating costs of the three proposals also indicated the high-level viaduct project to be the least costly.

The Highway Commission, therefore, rescinded its action as regards the 35-ft. level bridge location and adopted the 135-ft. high-level viaduct. The

latter will provide a highway entirely free from any interruptions to its traffic caused by water-borne traffic.

Another change made subsequent to the author's connection with the work was that of the three crossings of the Elizabeth River, in Elizabeth, N. J. As the waterway at this point is under the jurisdiction of the War Department, the permit for the crossings called for the construction of movable bridges. Authority was given to erect these structures as fixed spans until such time as it might be necessary to provide for navigation, when the operating mechanism would have to be installed.

The construction through Elizabeth provided for all streets to intersect or cross the highway at grade. It was evident that a serious traffic hazard would obtain at the crossing of Elizabeth Avenue which is the principal east and west thoroughfare. It was finally arranged to carry the highway over this street on a bridge, and to continue it on an elevated structure southward to, and including, the three river crossings where fixed span bridges with a vertical clearance 22 ft. above mean high water were used. The War Department waived the requirement of movable bridges and approved of the construction of the fixed-span bridges with the clearance mentioned. The wisdom of this viaduct construction has been fully justified.

FRED LAVIS, M. AM. SOC. C. E. (by letter).—The writer appreciates the generally favorable comment on his paper, especially because of the prominence of many of the commentators in the field of modern highway construction along the lines of development which take into due consideration the effects of such highways and the details of their location on the economic operation of the vehicles using them.

The commentators recognize also the nice balance which must be preserved between the bare application of any economic theory in a problem of this kind and the "other" factors which affect the location and design. It is the ability to strike this balance accurately, giving proper weight to economic as well as technical considerations, which marks the true engineer.

The discussion by Mr. Lewis is particularly interesting, as he gives a complete outline of the various types of construction which have been developed thus far in the endeavor of engineers to find solutions of these problems to fit the needs of different localities and conditions.

Mr. Downer also refers only too briefly to the development of the highways of the Westchester County Park System. This project originated primarily as a park development along the Bronx River Valley between the northerly end of New York City and Kensico Reservoir and was the practical realization of a dream for the preservation of scenic beauty, with a highway as an incidental feature. Before the Bronx River Parkway was completed, however, the highway feature had grown to be a most important factor, and fortunately it was realized by Mr. Downer at an early stage in the development that special attention would have to be paid to its design as an "element in transportation".

In the later improvements through the other three valleys running northerly from New York City the landscape features of the parkways have been

developed, as adjuncts of the highways, and the design of these highways has been more and more influenced in these later years by traffic requirements. Mr. Downer and the Westchester County Park Commission deserve the highest congratulations for having achieved that equitable balance between traffic needs and the artistic and other requirements which is so eminently the earmark of true engineering.

It will be realized, however, that the location of Route 25, in New Jersey, through an entirely urban and industrial and manufacturing district, did not permit this type of development, and this all serves to point out the need of the individual study of each problem by properly qualified engineers in order to find the solution best adapted to the needs of each particular case.

Perhaps a word may be permitted in regard to highway widths. On Route 25, New Jersey, the Elevated West Side Highway in New York, and others of this type, no provision is made for other than moving traffic, in which case the writer believes an odd number of lanes (five of 10 ft. each in the case of Route 25) is indicated. The principal reasons for this are pointed out in the discussion by Mr. Baker.

There seems, however, to be a general tendency to establish State Highway widths for main routes at 20 ft., or 40 ft. (two or four lanes). With evenly balanced traffic, and the need of giving some consideration to parking requirements, this may be correct; but the traffic in the vicinity of big cities, especially big terminal cities like New York, is not balanced and, as Mr. Baker points out, the extra lane is justified. This is also more particularly the case when part of the traffic is commercial and is especially noticeable on some roads leading to New York on Sunday afternoons and evenings, with many vehicles carrying produce for the markets at the time that the peak load of tourist traffic is returning to the city.

In regard to Route 25, New Jersey, it was estimated that four full lanes of moving traffic would be required to take care of peak loads, and that it was only ordinary prudence to provide an extra lane for emergencies and passing to keep four full lanes continuously moving.

The discussion by Colonel Hudson, outlining the changes in design on two sections of Route 25, is a welcome contribution and serves to complete the record of the project. Referring to the map and profile, Figs. 1 and 2, the section first referred to is that between Stations 180 and 330. For the four years (1925 to 1929) during which this matter was studied by W. G. Sloan, M. Am. Soc. C. E., State Highway Engineer, and the writer, there were long drawn-out controversies with the municipal authorities and others as to the relative merits of a line on this general location, with crossings of the Hackensack and Passaic Rivers by tunnels or with movable bridges with 40 ft. clear head-room. The writer and Major Sloan were opposed to a tunnel line with the connecting low-level trenches for this distance of nearly 3 miles.

The writer is entirely in accord with the final decision to build this section of the highway as a viaduct with 135 ft. clear head-room over the rivers so long as the War Department and the New Jersey River and Harbor Board

insisted on this as the minimum clearance for fixed spans. It may be pointed out, however, that if such a structure had been proposed in the first place, it probably would have imperiled the entire project, partly because of the expense involved, but largely because of the general impression which would have been created in the minds of the public that it was too grandiose.

In passing also it may be noted that, in the writer's opinion, neither the War Department nor the Board of Commerce and Navigation of New Jersey has an adequate appreciation of the relative or economic value of terrestrial as compared with the water-borne traffic of this area, and, consequently, the taxpayers of the State are unduly penalized, not only in expenditures for unnecessarily costly structures, but in the costs of traffic delays.

In regard to the change at Elizabeth, the project as finally carried out, except for a slightly higher elevation over the Elizabeth River, is almost exactly that recommended by the writer and adopted by the Highway Commission early in 1926. It was strenuously opposed, however, at that time, by almost all the interests in Elizabeth. Many and various proposals for other routes were studied and suggested during the next three years. Agreements were reached only to be thrown over at the last moment, and Colonel Hudson is entitled to a great deal of credit for finally persuading "the powers that be" to agree to the project as finally constructed, which the writer understands is now considered a most acceptable solution of the problem.

The original report of the Advisory Board of the Highway Commission, of which Major Sloan was Chairman, showed an estimated cost of approximately $20 000 000 for the entire 13 miles from the Holland Tunnel to Elizabeth, with bridges over the Hackensack and Passaic Rivers (for tunnels, $28 000 000), and the writer has always felt that the Commission was entitled to the very highest commendation for the splendid manner in which it upheld the report of its engineer and decided to go ahead with a project of this magnitude with little—if any—precedent to guide it.

After the work was finally authorized, more detailed studies showed necessary or desirable developments which brought the estimated cost of the project, as finally worked out under the writer's direction, up to a total of approximately $35 000 000; and the final cost, with the change to the high level as referred to in Colonel Hudson's discussion, to approximately $40 000 000.

To the layman this may appear to be another instance of the inadequacy of engineers' estimates, but consideration should be given to two most important factors. First, the very great number of different interests which had to be served or satisfied. Above all, there was the State, then the counties, the municipalities, the chambers of commerce, the railroads, the public utilities, the navigable waterways interests, individual manufacturing and commercial interests, and, finally, the private citizens, all of which had a voice in determining some detail of the project. The very important change in Newark shown in Fig. 7, which added more than $1 000 000 to the cost of the highway, is a good illustration. Second, this was a pioneer project of its kind. Very few people were able to visualize it or what the plans of the Highway Com-

mission contemplated. In the writer's opinion this perhaps was fortunate, because if its magnitude had been realized it is doubtful whether it would have been carried out.

Finally, the writer feels that, not only is Major Sloan entitled to the highest credit for the original conception of the project as the only reasonable solution of the problem of highway transportation through this area, but in even greater degree for his patience and persistence in insisting that it be carried through on the basis of true engineering principles.

# SILTING AND LIFE OF SOUTHWESTERN RESERVOIRS[1]

By R. G. Hemphill,[2] Assoc. M. Am. Soc. C. E.

With Discussion by T. U. Taylor, M. Am. Soc. C. E.

Synopsis

This paper cites records of the silt load of several of the principal streams of the Southwest to indicate the importance of the silt problem in that region and the necessity for a comprehensive study of it to meet adequately water storage problems which will arise in the future. There follow descriptions of methods used, records obtained, and some tentative conclusions drawn from an investigation of silt in Texas streams, which is now (1929) entering its sixth year.

Erosion is governed by many factors, the more important of which are the amount and intensity of rainfall, and the character of topography, surface cover, and soil. The combination of these factors in the Southwest is favorable in a marked degree to heavy erosion.

Rainfall varies from an annual mean of about 30 in. at the eastern border of the semi-arid area of Texas to an annual mean of less than 5 in. in sections of Arizona and California.[3] Light rains are fairly numerous, but constitute only a small percentage of the total precipitation. As far as erosion is concerned, the significant feature of the precipitation is the large percentage of the total which occurs as torrential rains. The U. S. Weather Bureau reports 23.11 in. in 24 hours in September, 1921, at Taylor, Tex., the highest precipitation ever officially recorded in the United States for that period,[4] and apparently reliable unofficial records for the same storm at points near-by are

[1] Presented at the meeting of the Irrigation Division, Dallas, Tex., April 25, 1929.

higher. Intensity rates of 4 to 6 in. per hour are not uncommon in Texas, and rates for other States of the Southwest are comparable.

Such rainstorms produce a rapid and heavy surface run-off which is very effective in surface erosion; and the quick collection of the run-off in drainage channels produces sharp floods with high velocities which continue the processes of erosion and transportation of silt. As might be expected, the flow of the streams of the region is generally characterized by long periods of low stage and short, sharp floods of relatively great volume. The Colorado River and Rio Grande, which carry spring floods from melting snow in their upper basins, must be noted as exceptions, although in the case of the Rio Grande much of the spring flood is diverted in the San Luis Valley of Colorado.

Except areas in Texas, the topography of the region is predominantly mountainous with steep slopes permitting a rapid run-off. The State of Texas includes a relatively small area of smooth, gently sloping plains and a much larger area of rolling plains with slopes sufficiently heavy to produce rapid run-off.

In general, the surface cover[5] of the region may be classified as sparse. Forests are limited to Central Texas where there are small scattered areas of oak and hickory and to the higher altitudes of Arizona and New Mexico where piñon, juniper, yellow pine, and fir are found. Creosote bush covers a large area in the four States and some sage-brush is also found. The remaining areas are covered by short, tall, or mesquite grass. The effectiveness of the grass cover in checking run-off and erosion has been reduced to some extent by excessive grazing.

The region contains mostly finely divided alluvial soils, in many instances extending to great depths. The tendency to erode is relatively high. While the area of land under cultivation comprises a small part of the total area, doubtless, under present conditions, such land contributes substantially to the silt yield of the region.

## Quantity and Effect of Silt in Streams

To the most casual observer it is apparent that the factors noted are effective in loading the streams of the region with silt. The problems involved were recognized at an early date. Since about 1890, a number of agencies, including the U. S. Geological Survey, the U. S. Bureau of Reclamation, the U. S. Department of Agriculture, the various State experiment stations, and canal managements, have investigated the bearing of silt on some particular existing or proposed project. To cite the results of only a few of these investigations will indicate the extent and character of the problem involved.

*Colorado River.*—The silt load of the Colorado is of particular interest in view of the construction of an immense reservoir in its Lower Canyon Section above the Hoover Dam. Records for 18 years at Yuma, Ariz., show an average annual load of suspended silt of 183 759 000 tons,[6] or, approximately, 0.84% by

[5] "Natural Vegetation," by H. L. Shantz and Raphael Zon, Section E, Pt. I, Atlas of American Agriculture, U. S. Dept. of Agriculture.

[6] "Silt in the Colorado River and Its Relation to Irrigation," by Samuel Fortier, M. Am. Soc. C. E., and Harry F. Blaney, Assoc. M. Am. Soc. C. E., U. S. Dept. of Agriculture, *Technical Bulletin No.* 67, 1928.

weight of the average annual discharge of 16 200 000 acre-ft. Assuming a drainage area of 225 000 sq. miles above Yuma, the average yield of silt per square mile per year was 817 tons.

By comparing records for short periods at Topock and Yuma, Ariz., and on Imperial Valley canals, and assuming that 1 cu. ft. of deposit would contain 85 lb. of dry silt, Fortier and Blaney[6] reached the conclusion that the total load of bed and suspended silt at the lower end of the Canyon Section of the river averages 137 000 acre-ft. per year. For the drainage area of 171 000 sq. miles above Topock, this is equivalent to a silt yield of 0.80 acre-ft. per sq. mile per year.

If this estimate holds good, the capacity of a reservoir formed by a 500-ft. dam[7] at either the Boulder Canyon site or the Black Canyon site will be reduced by one-half in less than 75 years by deposits of silt.

*Gila River.*—Only a few short-term records of silt in the Gila are available to confirm its local reputation of being the muddiest stream in the United States. A Board of Army Engineers in reporting on the San Carlos Project in 1914[8] estimated an average of 1.3% of silt by volume based on 70 lb. of dry silt in 1 cu. ft. of deposit. The equivalent by weight is 1.46 per cent.

Several silt surveys have been made in the Roosevelt Reservoir on Salt River, a tributary carrying less silt than the Gila. In 1925, Cragin[9] reported an accumulation of 101 000 acre-ft. of deposit after 20 years of service. At the average rate of silting shown by the surveys, about 160 years will be required for deposits to reduce the capacity of the reservoir by one-half.

*Rio Grande.*—On the Rio Grande, silt records are available for long periods at El Paso, Tex., and San Marcial, N. Mex. Follett, in his report on silt in this stream,[10] combined the records for these two stations and concluded that at San Marcial, for the period from 1897 to 1912, inclusive, the annual discharge averaged 1 192 000 acre-ft., and contained suspended silt to the amount of 1.41% by weight. Relying on one sample taken under carefully selected conditions, he assumed that 1 cu. ft. of deposit of this silt in a reservoir would contain 53 lb. of dry material. Converting the weight on this basis, he arrived at an estimate of 19 739 acre-ft. of suspended silt per year at San Marcial.

That Follett used good judgment in selecting his volume-weight factor seems to be borne out by the silting of the Elephant Butte Reservoir immediately below San Marcial. Surveys made by engineers of the U. S. Bureau of Reclamation indicate that silt deposits are filling the reservoir at the rate of approximately 20 000 acre-ft. per year.[11] If this proves to be an average

[11] "Elephant Butte Dam," by P. I. Taylor, "Dams and Control Works Constructed by the Bureau of Reclamation," U. S. Dept. of the Interior.

rate, the original capacity of 2 638 860 acre-ft. will be reduced by one-half at the end of 61 years of service.

Follett made no estimate of the silt rolled along the bottom of the stream, but stated his belief that it might possibly amount to as much as 25% of that suspended. Accepting this ratio as the maximum, the measured average annual deposit of 20 000 acre-ft. does not include more than 4 000 acre-ft. of bed silt. The remaining 16 000 acre-ft. of deposit is, therefore, left to be accounted for by the annual average of 22 785 000 tons of suspended silt found by Follett. The combination of this volume and weight of silt gives a unit value of 65 lb. of dry silt to 1 cu. ft. of deposit. It is probable that the 16-year record of suspended silt and the 10-year record of reservoir deposits did not develop true averages, but it is believed that they were accurate enough to indicate fairly that suspended silt in the Rio Grande will form deposits containing from 55 to 65 lb. per cu. ft. of dry silt.

*Pecos River.*—In 1904, a survey of Lake McMillan on the Pecos River near Carlsbad, N. Mex., showed that in ten years of service its capacity had been reduced 42% by silt deposits.[12] This was at the rate of about 1 225 acre-ft. per year. In 1916, a Board of Engineers of the Bureau of Reclamation, on the basis of 21 years of service, arrived at an estimate of an average inflow of 2 400 acre-ft. of silt.[13] This was 0.8% by volume of the estimated annual run-off.

*Colorado River of Texas.*—The silting of the lake on the Colorado River near Austin, Tex., was carefully observed by Taylor[14] from the time of the construction of the first dam. In less than 7 years of service prior to the failure of the dam, silt deposits reduced the capacity of the lake from 49 300 to 25 741 acre-ft., an average of 3 490 acre-ft. per year. At this average rate, deposits would have equalled the total capacity of the lake in 14 years. The drainage area above the dam has been estimated at 38 200 sq. miles, and the annual deposit of 3 490 acre-ft., therefore, was equivalent to a silt yield of 0.09 acre-ft. per sq. mile per year.

The silting of this reservoir is convincing evidence of the necessity for a reasonable relation between the size of a reservoir on a silt-laden stream and the run-off it receives. The mean annual discharge of the Colorado at the dam is 1 900 000 acre-ft., or more than thirty-eight times the original capacity of the reservoir. Since the entire silt load of the stream, during the first years of service at least, was probably retained in the reservoir, it is not surprising that silting proceeded at the rapid rate of 7% of the capacity per year. Had the reservoir been twenty times as large, for instance, and subject to the same run-off and silt yield, silting would have proceeded at a rate of less than 0.4% per year, and approximately 280 years would have been required for the accumulation of deposits equal to the capacity of the reservoir.

[14] "The Silting of the Lake at Austin," by T. U. Taylor, Univ. of Texas, *Bulletin No.* 2439.

*Trinity River.*—In 1928, Taylor made a survey of Lake Worth[15] and found that in 13 years of service 13 837 acre-ft. of silt had accumulated in the reservoir. The average annual deposit, therefore, was 1 065 acre-ft., and amounted to 2.3% of the original capacity of the lake. On this basis, about 45 years would be required for deposits to equal the original capacity of the lake.

The drainage area above the dam is 1 870 sq. miles. The annual deposit of 1 065 acre-ft., therefore, indicates an average annual silt yield of 0.57 acre-ft. per sq. mile.

## Need for Investigation

These examples clearly demonstrate the necessity of a careful consideration of the silt problem in connection with Southwestern reservoirs. While this region has lagged behind other sections of the country in the past, there is now evident a determination to bring about a full utilization of its water resources. In view of the erratic flow of the streams, it is certain that any considerable irrigation or power development must depend on stored water. It follows that one of the chief problems of the engineer of the future project will be to determine the silt load of the stream and to adjust the capacity of the reservoir to other requirements so as to give it the longest effective life within the range of feasible costs.

The best basis for an estimate of the silt load is a long-term record of silt measurements at the site of the reservoir. Such records have been available only in a very few instances, and when a new reservoir is proposed it is seldom practicable to delay the project several years while continuous records of the silt load are being obtained. The result is that estimates are based on short-term or fragmentary records at the site, or on records taken in another locality where conditions are assumed to be comparable.

Either procedure may lead to serious error. Under the circumstances, there can be no question of the real need for an extensive determination of the silt load of Southwestern streams, and the writer is optimistic enough to believe that such an investigation, taken in connection with soil erosion studies made by the U. S. Department of Agriculture and several State agricultural experiment stations, will uncover fundamentals of general application.

## Investigation in Texas

About 1923 the time seemed ripe for a general investigation of the water resources of Texas and of the means by which they might be brought to their maximum development. On the advice of the engineers and other forward-looking men of the State, the Legislature made a substantial appropriation and delegated to the State Board of Water Engineers the duty of carrying out a great part of the program. In addition to increasing the number of stream-gauging stations, and locating and surveying reservoir sites, it was considered necessary to determine the quantity of silt carried by the streams of the State. This silt investigation was inaugurated in 1924 by the State

[15] "Silting of the Lake at Austin, Texas," by T. U. Taylor, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 93 (1929), p. 1681.

Board in co-operation with the Division of Agricultural Engineering of the U. S. Department of Agriculture, with the writer in charge.

Due to limited funds, it was not possible to undertake the determination of the silt load of every stream of the State which offered suitable sites for reservoirs. The Brazos, therefore, was selected as the single basin which best represented in its various divisions the conditions found in other drainage areas. Sampling stations were established at nine gauging stations which were either near reservoir sites or below areas comparable to other drainage basins. Routine daily sampling was begun immediately. These records determined the silt load at any point in the Brazos Drainage Basin and afforded a reasonably sound basis for estimates of the loads of other streams of the State. As a check on such estimates, records were obtained at single stations established on the Colorado, San Antonio, and Nueces Rivers.

*Sampling Device.*—Samples were taken in 8-oz., narrow-mouthed, round, glass bottles. The bottle was placed in a holder on a hanger to which was attached a stream-line current-meter weight varying in size from 7 to 100 lb., according to the velocity of the water to be sampled. Wired to the hanger was a coil spring to which was attached a rubber stopper and a cord by which the stopper might be pulled. The chief purpose of the spring was to counteract the force of the current on the cord and prevent the premature pulling of the stopper. The hanger was suspended by a cable, and, if the current was swift enough to require a heavy weight, a windlass fastened to an A-frame was used to raise and lower it.

*Method of Sampling.*—The difficulty and cost of securing samples and handling them in the laboratory made it necessary to determine the minimum number which could, when averaged, be relied upon to represent accurately the average silt content of the entire cross-section of the stream. To arrive at the desired result, a large number of samples were taken throughout this cross-section for different stages at several stations, the number for each sampling ranging from 30 to 60. In each vertical, samples were taken at every one-tenth or one-fifth of the depth, at the surface, and as close to the bottom as it was possible to go without disturbing the condition of flow to an extent which would have vitiated the result. From these samples, vertical curves of silt percentage were plotted. Thus, it was determined graphically that, within the limits of permissible error, a sample taken at six-tenths of the depth would give the average for the vertical.

In a similar manner the horizontal curve of silt percentage was plotted for each stage at each station, and it was found that the average of percentages at the center of the stream and at distances of one-sixth of the width from each bank would give the average percentage for the cross-section. For routine sampling, therefore, samples were taken at six-tenths of the depth, and at one-sixth, three-sixths, and five-sixths of the width of the stream. The probable error in this method is well within the limit fixed by the degree of accuracy which can be obtained in stream gaugings at stations such as are ordinarily found in Texas.

*Laboratory Methods.*—The three daily samples from each station were forwarded to Austin where the silt content was determined in a laboratory main-

tained for that purpose. The method used involved filtering out the silt, drying it, and obtaining its dry weight. The routine required the weighing of: (1) A dried filter paper; (2) the bottle and sample; (3) the empty bottle; and (4) the dried filter paper and silt. The net weight of the sample and the net weight of the silt, obtained from these weights, gave the percentage.

In order to retain the finest silt, a tight, stout filter paper was used. Drying was done in an automatic electric oven set to maintain a temperature of 110° cent. To overcome troublesome variations in atmospheric moisture, the filter papers, before being used, were dried out at 110° cent., cooled in a desiccator, and taken out one or two at a time and weighed. By following the same procedure with the filter paper containing silt, after drying was completed, the error occasioned by the rapid absorption of atmospheric moisture was reduced to a negligible point.

When the samples showed a large quantity of silt, one of each set of three was first poured into a 40-in. glass tube with a uniform ¾-in. bore, and allowed to settle for one week to determine the percentage by volume for that period of settling. The sample was then passed through the regular routine to determine the percentage by weight. This gave for the same sample the percentage by weight and the percentage by volume after a week of settling.

It is recognized that volumetric percentages determined by seven days of settling in a glass tube do not directly represent the volume the silt will occupy when deposited in a reservoir. It is possible, however, that a proper reduction factor can be found and applied with little, if any, greater chance for gross error than exists in the selection of a factor for converting a given weight of silt to the volume it will occupy when deposited in a reservoir.

*Suspended Silt in Brazos River.*—To indicate the character of the results obtained, tentative data covering the load of suspended silt at four of the Brazos Basin Stations during the first three years of the investigation, are given in Table 1. Three of the stations included are on the main stream: (*a*) Mineral Wells, which is in the upper part of the basin and catches the combined flow of the principal upper tributaries; (*b*) Waco, near the middle of the basin immediately below the junction of the Bosque River; and (*c*) Rosenberg, only a short distance above the mouth of the stream. The station near Aspermont, on the Double Mountain Fork, is included as representing heavily laden branches of the stream near its source. The results involve the silt load for each day, the percentage shown by the three samples being applied to the discharge in order to determine the daily silt tonnage. The average percentages shown are based on the total tonnage and the total discharge for the period.

As was to be expected, the highest average silt content—2.13%—was found at the Aspermont Station on the Double Mountain Fork, which drains an area particularly subject to erosion. At Mineral Wells, the flow includes the discharge of other upper tributaries carrying relatively less silt and the percentage drops to 1.01. Below Mineral Wells, increasing rainfall dilutes the silt content and lowers the percentage to 0.86 at Waco and to 0.43 at Rosenberg. The percentages for 1925 were uniformly much higher than for the

other two years. This is accounted for by the fact that 1925 was a year of unprecedented drouth, during which only two floods occurred, one in May and one in September. These floods, following dry periods of more than three months, carried extraordinarily high percentages of silt. For this reason it is believed that average percentages shown by records over a long period will be appreciably less than those shown by the three-year period.

TABLE 1.—SUSPENDED SILT SHOWN BY PRELIMINARY COMPUTATION OF RECORDS AT FOUR STATIONS IN THE BRAZOS BASIN FOR THE THREE-YEAR PERIOD FROM OCTOBER 1, 1924, TO SEPTEMBER 30, 1927.

| Station. | Drainage area, in square miles. | Annual discharge, in acre-feet. | Annual Load of Suspended Silt. | | Annual yield per square mile, drainage, in tons. |
|---|---|---|---|---|---|
| | | | Tons. | Percentage. | |
| Double Mountain Fork near Aspermont, Tex. | 7 980 | 170 000 | 4 942 000 | 2.13 | 619 |
| Brazos, near Mineral Wells, Tex. | 23 100 | 981 000 | 13 506 000 | 1.01 | 585 |
| Brazos, at Waco, Tex. | 28 500 | 1 629 000 | 19 054 000 | 0.86 | 669 |
| Brazos, at Rosenberg, Tex. | 44 000 | 5 188 000 | 30 528 000 | 0.43 | 694 |

It is interesting to note the rather close agreement in the average yield of silt per square mile of drainage above the four stations. The lowest average—585 tons for the area above Mineral Wells—is more than 84% of the highest average of 694 tons for the area above Rosenberg. By segregating the different areas, however, it is found that for the area which drains into the river between Mineral Wells and Waco the average yield of silt was 1 027 tons per sq. mile; and for the area between Waco and Rosenberg, 740 tons per sq. mile. The unusually high yield between Mineral Wells and Waco is believed to have been due partly to sharp floods in the Bosque River, but the general increase of yield down stream is probably due chiefly to increasing rainfall and increasing acreage under cultivation.

Solely for the sake of comparison, the volume of the silt load at each of the stations has been computed on the basis of 70 lb. of silt to 1 cu. ft. of deposit. At this rate, the suspended silt at Aspermont amounted to, roughly, 3 000 acre-ft., or 0.41 acre-ft. per sq. mile of drainage; at Mineral Wells, 9 000 acre-ft., or 0.38 acre-ft. per sq. mile; at Waco, 12 000 acre-ft., or 0.44 acre-ft. per sq. mile; and, at Rosenberg, 20 000 acre-ft., or 0.45 acre-ft. per sq. mile.

*Reservoir Surveys.*—An important phase of the investigation in Texas has been the actual measurement of deposits of silt in reservoirs. It was the intention to find a reservoir where conditions were such that the silt discharge of the stream could be measured for a period of years as it entered the reservoir and where at suitable intervals measurements could be made of the actual deposit in the reservoir, thus establishing for one set of conditions an absolute relation between measured silt in suspension and the corresponding deposit in the reservoir. Unfortunately, the required conditions could not be found and thus far (1929) this phase of the work has been con-

fined to surveys of the actual deposits in Medina Lake, near San Antonio, Tex., Lake Worth, near Fort Worth, Tex., and Lake Kemp, near Wichita Falls, Tex.

The survey of Medina Lake showed that in 13 years of service silt deposits to the amount of 2 692 acre-ft. had accumulated. The yearly average was 207 acre-ft., which was equivalent to a yield of 0.35 acre-ft. per sq. mile of the approximately 600 sq. miles of drainage area above the dam. The capacity of the reservoir is 254 000 acre-ft. and, at the rate shown by the survey, deposits will equal the capacity in 1 225 years.

The survey of Lake Worth was made in 1925 and indicated that silting was taking place at the rate of approximately 1 000 acre-ft. per year. At this rate, deposits would equal the capacity of the reservoir in 47 years. This result was checked very closely by Taylor's survey made in 1928. The yearly average deposit of 1 000 acre-ft. is equivalent to a yield of 0.54 acre-ft. per sq. mile of drainage area above the dam. It is interesting to note that, if the average silt yield, in tons per square mile, from the area above this reservoir is comparable to the yield from the near-by Brazos drainage, as shown by records at Glenrose, the deposit in the reservoir contains less than 60 lb. of silt per cu. ft.

A complete survey of deposits in Lake Kemp was attempted in its second year of service; but brush left in the basin was so heavy in certain sections that lines could not be put through. It was not considered advisable to make an estimate of the total silt deposit based partly on such random soundings as could be made in these sections. The maximum depth of silt, 4 ft., was found at the upper end of the lake, but fine silt to a depth of not less than 2.5 ft. was found in the old river channel throughout the reservoir.

Characteristic delta formations, largely of coarse material, were found at the head of these lakes. Below the delta areas, the deposits consisted of fine material and were distributed so as to lead to the belief that the finest silt when deposited will flow along the bottom of the reservoir until blocked by the dam. There seems to be no other explanation for the fact that the thickness of the layer of fine material in the case of each reservoir was little less at the dam than it was 8 or 10 miles above. If this condition proves to be general it indicates a possibility of relieving the reservoir of some silt by making a practice of drawing off water through the lowest outlet gate.

## The Weight of Deposited Silt

The most satisfactory and, in fact, the only practical method of determining the amount of silt in samples of river water is by weight; but since the space the silt will occupy in a reservoir is the important consideration, it is necessary to fix a relation between the weight of the silt and its volume when deposited. There is a wide difference of opinion in regard to this relation, and values have ranged from 120 lb. per cu. ft., used by Humphreys and Abbot[16] in estimating the volume of silt carried in suspension by the Mississippi River, to 53 lb. per cu. ft., used by Follett in connection with the Elephant Butte Reservoir. It seems clear that the volume-weight factor of a deposit will depend

[16] Report upon the Physics and Hydraulics of the Mississippi River, by A. G. Humphreys and H. L. Abbot, Bureau of Topographic Engrs., U. S. War Dept., 1861.

chiefly on the proportions of fine and coarse material, the degree of separation which takes place on deposit, the depth of deposit, and whether it is subject to exposure and consequent drying, consolidation, and mixing by the scouring action of later inflow. The selection of a factor for a given reservoir should be governed by a consideration of all these elements.

The proportions of the different sizes of silt carried by streams vary greatly, and under ordinary conditions there is a substantial separation into different grades when the material is deposited. Silt-laden water entering the quiet water of a reservoir tends to continue its course by pushing aside and upward the clear water of the reservoir, and its velocity is reduced more or less gradually. This action is responsible for the rather high degree of separation which has been noted in actual deposits in reservoirs. A fluctuating water level, drying deposits, and the scouring action of a fluctuating inflow are mainly responsible for such mixing of different sizes of silt as occurs.

Some writers have assumed that increasing hydrostatic pressure may be counted on to compact deposits, but there seems to be little ground for the assumption. The writer believes that, unless exposed, deposits will be compacted to a significant degree only by the weight of the silt itself and the overburden of new deposit. In the surveys of Texas reservoirs, no difference in density could be detected in bottom deposits of fine silt under depths of water ranging from 5 to 125 ft. Deposits of fine silt will compact very little unless exposed. Those in the lake at Austin, Tex., for instance, are so loose that a 1-in. rod can be forced into them with one hand to a depth of 10 to 12 ft. When exposed to air and sunlight, however, they dry out, shrink heavily, and crack, and on being submerged again they do not swell to their original volume.

As a guide in determining the relation of volume to weight under various conditions, a large number of sample cubes were taken from deposits in place in Texas reservoirs and the dry weight of the silt was determined. Exposed bars of coarse silt, such as is found at the head of reservoirs, averaged 92 lb. of dry material to 1 cu. ft. of deposit, while finer silt in much the same location averaged 82 lb. Samples from the surface of deposits near the middle of reservoirs averaged 55 lb. of dry material to each cubic foot. Samples of the finest material taken from submerged deposits in old river channels in reservoirs averaged 31 lb. of dry material to 1 cu. ft.

### Bed Silt

In addition to the silt carried in suspension, a certain quantity is moved along the bottom of the stream; but no investigator has yet devised a satisfactory method of measuring its amount. Estimates vary widely. Humphreys and Abbot, from a study of the movement of bars at the mouth of the Mississippi, estimated the bed load to be 11% of the suspended load by volume;[17] but in arriving at the volume of suspended silt, a volume-weight factor of 120 lb. per cu. ft. was used. It is now generally recognized that a much lower factor should be adopted, in which case the percentage of bed silt would be substantially lower. By the use of traps in the San Carlos River, in Costa

[17] Report upon the Physics and Hydraulics of the Mississippi River, by A. G. Humphreys and H. L. Abbot, Bureau of Topographic Engrs., U. S. War Dept., 1861.

Rica, A. P. Davis, Past-President, Am. Soc. C. E., arrived at percentages of 5.2, 1.7, and 7.1 for June, July, and August.[18] By comparing records at Yuma and Topock, Fortier and Blaney estimated the bed load of the Colorado at Yuma as 25% of the suspended load.[19]

Until more light is thrown on this question, a degree of uncertainty must attach to estimates based on suspended silt alone. Simultaneous vertical curves of silt content and velocity in Texas streams incline the writer to believe, however, that the quantity of silt transported as a true bed load comprises a much smaller percentage of the total load than is generally assumed.

### Removing Silt from Reservoirs

Various plans for the removal of silt from reservoirs have been proposed, but a satisfactory and feasible method has yet to be found. One plan calls for an auxiliary basin at the head of the reservoir to catch the silt and a conduit through which it could be flushed to a point below the reservoir. Such a system, no doubt, would work with some degree of effectiveness, but its cost would be prohibitive. Another method involves stirring up the silt with a jet and allowing it to pass out with water drawn off, but this plan does not work satisfactorily even in the smallest reservoirs.

Dredging will naturally come to mind as a method with possibilities, but under present conditions the cost would be prohibitive. As favorable sites become scarcer and the cost of this method decreases through improvements in methods and machinery, it is possible that in time dredging may become economically feasible.

Some small reservoirs have been partly cleaned by draining off the stored water and permitting the flow of the stream to scour out the deposit. It is doubtful whether this method could be used with any degree of success with larger reservoirs. The stream will cut a narrow channel through the deposits, and scouring action will cease before any considerable proportion of the deposit has passed out of the reservoir. There would be a better chance for the successful use of this plan if satisfactory methods could be devised to direct the flow of water to any point desired. Another objection to sluicing is that where water for irrigation is valuable enough to warrant the construction of extensive storage works it is too scarce and valuable to be used in clearing a partly silted reservoir. At present (1929), the only feasible method of remedying the situation created by a silted reservoir is to secure additional storage capacity by increasing the height of the dam or by building a new reservoir.

### Prevention of Silting

Surface soils and banks of channels under the erosive action of flowing water are the two chief sources of silt. The problem of preventing the silting of reservoirs, therefore, will involve either the elimination of, or a reduction in the quantity of, silt thus produced, or its removal from the stream above the reservoir.

[18] Noted in "Irrigation Practice and Engineering": Vol. II, "Conveyance of Water," by B. A. Etcheverry, M. Am. Soc. C. E., p. 87.

[19] "Silt in the Colorado River and Its Relation to Irrigation," by Samuel Fortier and Harry F. Blaney, U. S. Dept. of Agriculture, *Technical Bulletin No.* 67, 1928.

Under present conditions the outlook for effective measures to these ends is not particularly encouraging. Forest and grass cover on public lands can be maintained, but the private owner is allowed to clear his woodland, over-graze his pasture land, and permit his cultivated land to wash and add to the silt load of the streams. There is, however, a growing tendency among farmers to terrace their lands, to adopt contour plowing, and to check gullying; and as these practices become more widespread there must result eventually a substantial reduction in the quantity of silt which reaches the streams.

For reducing the quantity of silt developed by the erosion of banks, dependence must be placed chiefly on flood control, which, by holding the extreme flow of the stream down to moderate stages, will eliminate the high velocities mainly responsible for excessive erosion. Barriers of brush or other material in the smaller channels and lines of living brush across the flood-plains of larger channels, by decreasing velocities and thus encouraging deposits, should relieve these channels of a part of their load of silt. The effectiveness of a dense growth of salt cedars in desilting the Pecos at Lake McMillan is reported by Walter.[20] This growth immediately above the lake dates from about 1918 and is responsible for a reduction in the rate of silting of the reservoir from an average of 1 930 acre-ft. per year from 1894 to 1915 to an average of 350 acre-ft. per year from 1915 to 1925.

There is a possibility of desilting a stream above a reservoir by diverting the silt-laden water through canals leading out over the flood-plain and permitting the silt to deposit in natural or artificial basins before the water is returned to the channel of the stream. Such a system would be costly, but might prove feasible in particular cases.

The problem of preventing the silting of reservoirs is one which should be handled by an organization qualified to deal with a stream as a whole. Each of the desilting works or reservoirs that such an organization would construct, would be required to absorb only a part of the silt burden of the stream, and costs could be spread on an equitable basis over all those benefited. Otherwise, each reservoir would profit without cost from any desilting works or reservoirs in the stream above it.

## Estimating the Effective Life of a Reservoir

In a study involving the effective life of a storage reservoir the first step is to determine the average silt load carried by the stream at the site. Then a consideration of the fineness of the silt, the manner in which it may be expected to be deposited, and the exposure and scouring to which the deposits will be subjected, will permit a conclusion as to the volume the yearly load of silt will occupy. The problem then becomes one of adjusting the size of the reservoir to meet the requirements for a long life at a feasible cost. In this connection, attention should be called to deposits above the flow line, the quantity of silt which may pass over the spillway, the quantity which may be removed through outlet gates, and the return seepage.

When silt-laden water strikes the back-water of the reservoir its velocity is reduced, and the coarser material is deposited immediately. This deposit

[20] *Transactions*, Am. Soc. C. E., Vol. 93 (1929), pp. 1722–1723.

continues to grow and extend up stream. When conditions are favorable, it may build up to the point where a substantial volume of deposit, which otherwise would occupy space in the reservoir, is above the flow line.

Samples taken on the spillway of the Austin Dam and for several months on the spillway of Lake Worth indicate that, until silting has gone so far as to produce channel conditions in the reservoir, the quantity of silt which passes over the spillway is negligible. The reservoir at Austin is so filled with silt that channel conditions prevail and the percentage of silt in the water passing over the spillway differs very little from that in the flow above the reservoir. On the other hand, at Lake Worth where silting is only moderately advanced and channel conditions do not obtain, samples taken on the spillway after the inflow of heavy floods carrying large quantities of silt rarely showed a silt content in excess of 0.02% by weight.

It is well known that in some instances when a reservoir is lowered at a relatively rapid rate water from the saturated sides and bottom seeps back into the reservoir and may amount to a substantial quantity. It is believed that deposits of the very fine material which constitutes the greater part of the silt load of Texas streams will give up water at a very slow rate, probably not fast enough to offset evaporation at its surface. These deposits should not be depended upon as an aid in tiding over critical periods.

That water drawn off through low reservoir outlets will carry some silt with it, is certain, but the quantity is doubtful. The scouring effect of the water drawn into the outlet will extend up stream only a short distance, but if the finest silt flows along the bottom of the reservoir, as was indicated at Medina Lake, Lake Worth, and Lake Kemp, there is a possibility that a substantial quantity of this fine silt will reach the area affected by the gate and be carried out.

## DISCUSSION

T. U. TAYLOR,[21] M. AM. SOC. C. E. (by letter).—In describing the silting condition of the Colorado River in Texas the author mentions some observations reported by the writer in 1928.[22] Since that time an aerial photographic map has been made of the dam and the lake at Austin. It covers a stretch of the river 4 000 ft. long, including Bee Creek which is a tributary from the west. Fig. 1 is a sketch drawn with the assistance of that map. The original water surface of 1913 includes all the area bounded by the solid lines. The present channel is confined between the dotted lines when the water is level with the crest of the new dam at Elevation 51.4. The part between the solid lines and the dotted lines shows the accumulation of silt. It indicates that the silt is gradually narrowing the channel and has reduced it from a width of 1 300 ft. in 1913 to 620 ft. in 1929, with the Bee Creek cross-section ½ mile up stream. The area on the right has been reclaimed entirely and consists of about 14.6 acres of silt.

There are several striking points illustrated by this survey. Point *A* (Fig. 1) is in the original river bed where the water in 1913 was 51.4 ft. deep. This depth has all been taken and the space is now a sand beach covered with willows and weeds.

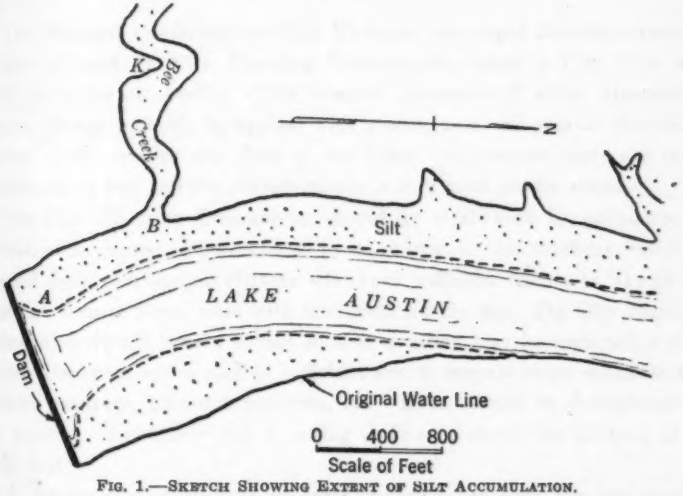

FIG. 1.—SKETCH SHOWING EXTENT OF SILT ACCUMULATION.

At Point *B*, in the mouth of Bee Creek, the water was originally 51 ft. deep in 1913. It has now a bar of silt 2.4 ft. above the lake level, making a depth of 53.4 ft. of silt.

In 1913, a boat-house was anchored at the sharp point, *K*, near the word, "Bee", and a camping party dived off the boat into 30 ft. of water. In 1930

[21] Dean of Eng., Univ. of Texas, Austin, Tex.
[22] "The Silting of the Lake at Austin," Univ. of Texas, *Bulletin No. 2439*.

it has become "high and dry," and Bee Creek from head to mouth is a solid plug of silt varying in depth from 53.4 ft. to zero. On the west shore, a strip of land has been reclaimed or taken from the lake by the encroachment of the silt that extends 5.2 miles up the lake, varying in width from 100 to 300 ft.

Measurements made opposite the mouth of Bee Creek in 1929 revealed a cross-section of 2 400 sq. ft. as compared with 37 300 sq. ft. in 1913. It is thought that the 1929 maximum depth opposite Bee Creek will scarcely be decreased. Other phases of this subject were discussed more fully in connection with another paper.[23]

# CITY PLANNING AS RELATED TO THE SMALLER CITIES

By E. A. Wood,[2] M. Am. Soc. C. E.

With Discussion by Messrs. John L. Starkie, O. H. Koch, Stephen Child, and E. A. Wood

Synopsis

The National Conference on City Planning has urged American municipalities to establish City Planning Commissions, adopt a City Plan and "sell" it to the citizenship. This program embraces all cities, irrespective of size. It can probably be applied with greater ease and greater chances of success to the smaller city than to the larger one, because there are fewer mistakes to correct and the subject-matter is in a more plastic stage.

The City Planning Commission should be established by ordinance, to furnish some degree of permanence to its existence. Its members should be selected from outstanding citizens who have sufficient leisure to attend the meetings, inspect plans, meet with interested owners, etc. The City Planning Commission should have a budget so that quarters may be acquired, a Consultant employed, and a staff of sufficient size to prepare maps, make studies, arrange meetings, give out publicity, etc. Rules should be formulated for the platting of property and a zoning ordinance should be adopted at an early date.

A Master Plan should be prepared covering not only the incorporated area of the city, but the adjacent territory as well. This should show all streets, alleys, blocks, schools, parks, parkways, streams, etc.

Popular support is always necessary for the carrying out of plans. This is particularly true in the smaller cities.

[1] Presented at the meeting of the City Planning Div., Dallas, Tex., April 25, 1929.
[2] City Planning Engr., Dallas, Tex.

## The Program in General

In adopting a comprehensive program for its work the National Conference on City Planning has urged each American municipality to do three things: First, provide a City Planning Commission and an office where the Commission may take part in the City's administrative machinery; second, prepare and adopt an Official City Plan; and, third, secure public support for the administration of the Official Plan. Such a program may be adopted by any municipality irrespective of size, location, or composition. It also clearly shows that the difference in the relationship of city planning in large and small cities is one of size only; the principles are the same and legislation is equally necessary in either case. There is this difference, however, that city planning is easier for the smaller cities to undertake, is more effective, and does not cost nearly as much.

Every city should be as carefully planned as a modern railway terminal, a suspension bridge, or a central lighting plant; but the planning should be done before the city has developed. Further, it should be along regulatory lines before mistakes occur, rather than through the corrective method after errors have been permitted. Therefore, if the Official Plan is prepared in advance of city growth, its enforcement becomes a matter of public support, strengthened by the necessary rules and regulations to make it generally effective.

## City Planning Commissions

As pointed out by the National Conference on City Planning, the establishment of a commission is the first step. Since private property and property rights are involved, a commission is better able to deal with the public than the Mayor and Board of Commissioners. The members of the Board do not have time to devote to the many problems that arise, nor are they politically free to treat the subject dispassionately. The Planning Commission should be created by a properly drawn ordinance to give the required official status. Preferably, the ordinance should be patterned after "A Standard City Planning Enabling Act", as prepared and published by the United States Department of Commerce.

This Act was prepared by an Advisory Committee, members of which have had many years of first-hand experience in coping with local planning problems, both as citizens and in connection with the leading National business, professional, and civic groups which they represent. During the three years' work required to draft the Act, the Advisory Committee made laborious research into legal problems and consulted with expert planners, members of planning commissions, municipal officials, and other interested persons throughout the United States. The Act, therefore, represents the very best thought on city planning, is concise yet brief, and contains the necessary legal phraseology.

## Personnel Required

The relationship of city planning to the smaller city should be real. It should create a lively interest on the part of every citizen. The mem-

bership of the City Planning Commission should be carefully selected and should be composed of outstanding citizens who can devote considerable time to the study of physical conditions on the ground as well as to the numerous meetings that will be required with different groups of individuals. The membership should be varied, and, if the plan is to be comprehensive and include all phases of city life, the public schools, park board, women's clubs, chamber of commerce, and retail merchants should be represented with other organizations.

Representatives from the City Government should be limited to a member of the Council and the City Engineer. The former should act as a liaison agent between the Council and the Planning Commission. The latter is entitled to membership by virtue of his office; he is also charged with the execution of the plan and to some extent with the enforcement of the Commission's rules and regulations. The Mayor and City Attorney should be members *ex officio*, the Mayor by virtue of being the head of the Council, and the City Attorney by reason of his legal training.

The ordinance creating the City Planning Commission should also set up a budget to provide for the establishment of a City Planning Office and the employment of a City Planning Consultant. The former is necessary to provide working quarters for the Commission, a meeting place, and a forum for the creation of interest in the Official Plan. Public interest in the plan is of prime importance, and it is necessary that some one explain it, exhibit maps, and discuss advantages both pro and con, if that interest is to be sustained.

Many people respond by giving counter proposals, and interest is aroused and held if the work progresses expeditiously. In the smaller city, it is easier to create this interest and hold it, because the diversity of objectives common to the large city is lacking. Also, the opportunities for correct planning are more numerous in the smaller city; at least, the physical boundaries are more elastic and are more readily moulded into the Official Plan.

However, one must ever be on the alert for mistakes. A Consultant should be employed, not only to guide and direct the planning, but also to serve as mentor to the Commission and the citizens. It is very easy to make mistakes, and early enthusiasm for city planning benefits may lead to serious errors unless held in check by the Consultant.

## Rules and Regulations

As a preliminary step the City Planning Commission should adopt a number of rules and regulations. The most important of these are the platting requirements and the zoning regulations. The platting of private property is one of the most fruitful sources of errors in city planning because it is so frequently left entirely to the individual owner, who fails to co-ordinate his plans with existing streets, blocks, and alleys. This is largely due to the absence of a Master Plan for the gradual development of the city. By means of certain regulations control of the platting of new additions is

placed in the hands of the City Planning Commission and gives it adequate opportunity to study and adjust the platting to fit existing conditions.

In Texas, cities of 25 000 population, or more, now have the power to control platting, not only within the city's limits, but also for a distance of five miles beyond. In smaller cities, control within the city's limits may be obtained by withholding water, sewer, or other utility connections until plats are approved by the City Planning Commissions.

## Zoning an Essential Feature

Zoning regulations deal with private property and not only restrict the use of land, but also limit the height of buildings and the density of population. They meet a popular demand for protection of home neighborhoods against invasion by undesirable uses. This popularity is shown by the number and class of cities in the United States having zoning regulations, to the extent of 583, as follows;

| Number of Cities with Zoning Regulations. | Population. |
|---|---|
| 53 | Less than 1 000 |
| 144 | 1 000 to 5 000 |
| 102 | 5 000 to 10 000 |
| 103 | 10 000 to 25 000 |
| 79 | 25 000 to 50 000 |
| 47 | 50 000 to 100 000 |
| 55 | More than 100 000 |

This type of regulation is legal, not only in Texas, but in a majority of the States, because it is based on the police power of the Government which seeks to protect the health, safety, morals, and general welfare of the community. This authority was given to Texas cities by the Legislature in 1927.

## The Master Plan

One of the most important duties assigned to the City Planning Commission is the preparation of the Master Plan, or Guide, for the future development of the city. It becomes an easier task after the adoption of the platting rules and the zoning ordinance because these measures afford the necessary means of control. The Master Plan should show not only the incorporated area, but the contiguous area as well, and should include all streets, highways, alleys, parks, school grounds, railways, interurbans, streams, lakes, and water-fronts, if any. The area to be included should be governed by the jurisdiction of the City Planning Commission over the platting of private property. In Texas, this would be a distance of five miles beyond the city limits, but in other States this would depend on the State law.

Other features of the Master Plan would be the continuation of the building lines and set-backs as established in the city proper by means of the zoning ordinance and the street-widening program. This is particularly desirable in the suburban business districts where traffic is heavy and it is essential to keep the thoroughfares as wide as practicable.

### Parks and Parkways

Parks are an essential part of the Master Plan because they provide for recreation. The price of real estate usually requires that they be acquired well in advance of development of adjacent property, otherwise the value of the land is too high. Certain cities now require sub-dividers to dedicate 10% of the area of their sub-divisions for park purposes, a process which materially assists the development of a park system.

Parkways, boulevards, and walkways should be located along creeks or ravines. This is very important in growing cities because it furnishes storm sewers made to order. Too frequently this feature is overlooked, and natural drainage channels are filled to create additional lots or streets. As a result of the parkway adjacent property values are enhanced and natural beauty spots are preserved for future use in a boulevard system.

### Public Support Builds the Future City

Popular support is necessary, and any city plan must be "sold" to the public or the Master Plan will never be carried out. Experience in many cities bears out this statement. It is sometimes said that it is better to have "more selling and less planning". The essential point is to convince the community as to the advantages of planning for the future. Citizens will then demand a plan before they will vote bonds for unco-ordinated work. This is particularly true of the smaller city, where public funds are limited.

## DISCUSSION

JOHN L. STARKIE,[3] M. AM. SOC. C. E.—It seems to be commonly accepted that every city, irrespective of size, is subject to the same general principles in the application of a modern, comprehensive city plan. There are few, if any, problems present in the larger cities that are not also encountered—although most always in lesser degree—in the smaller communities. An economic advantage, however, rests distinctly with the smaller city, in that the earlier in the state of development of a city the plan becomes operative, the greater will be the saving in cost and the simpler the task of the city planner. In meeting an incurable obstacle in the preparation of a city plan or one surmountable only at prohibitive cost, what engineer has not dreamed of the ideal condition in which a city has waxed and expanded from the date of its inception in accordance with a well prepared and well directed city plan? However, such attempts as have been made in that direction may well be termed "noble experiments".

It is fortunate, perhaps, for the progress of the science of city planning in America that the advancement of a city under planless processes must usually reach the point where the resulting chaotic and wasteful conditions awake public consciousness to a realization of the need and economy of an ordered and directed procedure in conformity with a carefully thought out and scientifically prepared plan. This is good because it presents a variety of difficulties to overcome which make for progress in the perfection of the science, and it enlists initially the much-to-be-desired interest of the citizen.

The problem of securing and holding the interest of a larger percentage of the citizens is usually less of a task in smaller cities. However, there is more of a tendency to urge the engineer to incorporate in the plan ideas that are supposedly advanced for the alleviation of existing faults, but with no outlook on the future.

Many merchants in the smaller cities regard a traffic congestion on the streets in the vicinity of their places of business as a sure sign of progress and a condition to be preferred. Fortunately, however, highway engineers in Texas are insisting on locations from a broader viewpoint, so as to by-pass through traffic around population centers and, at the same time, to avoid railroad grade crossings wherever possible.

The traffic problem is present everywhere, in the small as well as in the large city, and the elimination of railroad interference with thoroughfares occupies a very important part in considering that question. From a long experience in railway service the speaker has no hesitancy in stating that practically every reasonable request, equitably made, to share in the expense of grade-crossing separations on existing locations of railways will meet with ready and co-operative response on the part of the railroad so far as financial abilities will permit. There is an alarming increase in the number of new grade crossings being opened, as compared with the number that are being eliminated. The city planning engineer who specifies, with every railroad

[3] Office Engr., G. C. & S. F. Ry., Galveston, Tex.

grade-crossing separation which he proposes, the closing of one or more existing grade crossings, serves humanity in general as well as the city which employs him.

A statement by the Master Plan Engineer of the City of Dallas that "planning should be done along regulatory lines rather than the correction of existing errors", indicates an active interest in the whole success of city planning. The 1927 Enabling Act of Texas also takes cognizance of this viewpoint. Any city plan which proposes in whole or in part for immediate consummation, changes, alterations, or relocations, at a wholesale rate, is untimely. A city plan once adopted should remain in operation perpetually (subject to such modifications as changing conditions demand), and the accomplishment of its objectives should be made a gradual process with its complete realization possibly never fully attained. Thrifty railroad companies are continually changing their standards of various physical properties, but, except in the rarest of instances, the new facilities are not installed until the old ones have completed their useful service life, or until unusual economic conditions warrant a change. Adaptation of this thought to city planning is illustrated in the "set-back building line". The process may be slower, but the transition to the accomplishment of the plan is performed in an orderly manner; it interferes least with the even tenor of the industrial, commercial, social, and moral life of the community, and, in the end, it provides a more enduring continuous and useful service to the greatest number of citizens.

O. H. Koch,[4] M. Am. Soc. C. E.—That city planning is just as vital and important to the smaller cities as to the larger ones has been emphasized by the author. He has outlined a number of principles and recommendations as regards city planning in general. The speaker would like to call attention to a few points wherein planning in the smaller cities differs from that in the larger cities.

A population of less than 50 000 may be considered to define a small city. This is the type that predominates in Texas as well as in other States. Texas has many cities of less than 50 000 inhabitants, but only a few that are larger. The same type of discussion could be very readily carried on as to the difference in planning between cities of 100 000 or 200 000 inhabitants and the great metropolitan centers. In each of these various classes there are many local and individual problems which are peculiar to each classification, and which need to be solved in a different manner. Many people have the impression that city planning, in a town of 25 000 to 50 000 inhabitants, is a comparatively simple matter, but the speaker maintains that a good, sound, sensible, and practical city plan for a town of this size requires a great deal of study and careful consideration.

The first step in preparing a city plan is to take an inventory of the existing conditions. This step in a small city is, of course, much easier and more simple than in the larger cities. The next step is to analyze the projected needs of the community by studying its past record of growth and to attempt to predict the future growth and needs. In this prediction it will be

[4] Cons. Engr. (Koch & Fowler), Dallas, Tex.

necessary to determine the probable type and character of the future of the community. This problem of trying conscientiously to predict the future trend of growth has caused the speaker more concern in plans for the small city than it has for the large one, and that particular decision is one of the most important essentials in preparing any city plan. City planning should be at least 90% preventive and 10% corrective. The accuracy with which the prediction of future growth is made will determine, to a great extent, the ultimate value of that city plan.

It is relatively easier to make such predictions in the large cities because of the availability of a more definite record and tendencies of growth upon which to base predictions. In the small cities this particular information is somewhat limited, and the planner has, as it were, a shorter base line from which to project and predict future tendencies. In the large, more established cities, the trend of growth and type of development is more firmly established and its general character is more permanently fixed. Any unusual development would not change its established characteristics to any great extent compared with the material effect that the same unusual development might have upon the smaller city where the proportion of importance would be much greater. In this type of city it is possible, by the introduction of a large project, to change the entire character of its development.

For example, in a small city, supported primarily by educational institutions, and which has been residential in nature for many years, a satisfactory city plan could be developed based upon such conditions. Suppose that a large manufacturing company should decide to build its factory in this city and to import a great number of factory employees. This unusual development in such small city would tend to unbalance the entire situation; it would change its character and would require a complete change of the plan. In the larger city the introduction of a fair-sized manufacturing plant would not make any appreciable change, since it would probably not be the first manufacturing plant in that city. That phase would have been anticipated to a certain extent, and the city plan could be adapted to meet the situation without materially affecting its character.

Thus, in a smaller city, it is necessary to decide whether or not it would be advisable to prepare a plan providing for such possible industrial developments, thereby furnishing incentives and encouragement for securing additional activities for the city, or whether it would be better to ignore such possibilities and prepare a plan which is limited to developments of its present type, thereby discouraging the possibility of securing such industrial activities.

Finance is always a subject of paramount importance to be considered in the city plan. While the first cost of engineering studies for a plan in the small city is not as great as in a larger city, the per capita cost would probably be more. This expense, however, is not a minor item considering the usual restricted budget of the small city. Even if the per capita cost were the same it would be much more of a burden in the smaller city. The same

thing is true in the matter of corrective city planning. While the property values are not as high and the corrective measures would not total the large amounts which are reached in the greater cities, it is also true that smaller cities have less ability to pay even a smaller proportional cost. This condition is a great stumbling block and a real situation which must be faced. It requires considerable judgment in order to inaugurate and execute what would be thought to be a practical and economical program, both from the standpoint of first cost as well as that of executive cost.

The chief value of city planning lies in anticipating future needs, which is a matter of budgeting the city's facilities, much in the same manner as its financial program is budgeted. If the planner is skeptical in regard to the city's growth and tries to be too conservative in planning for the immediate future only, in order to hold down cost, he will not be securing the full measure of benefit to be derived from city planning. On the other hand, if he is too optimistic and plans for too many years in advance he is apt to cause exceedingly large expenditures for immediate use and to have excess of expense and unused facilities. The excess cost of the superfluous facilities, the overhead carrying charges, and the maintenance of these items, capitalized over a number of years, could very readily exceed what the cost would be with a more conservative plan, even if the additional corrective measures had to be taken after a period of years. It is this choosing of the happy combinations that will determine the comparative value which any city plan may develop.

In the larger city the cost of future corrections, after a long period of years, would be considerably more in proportion than the probable cost of such additional widening would be in a small city. This fact, together with the greater valuations and borrowing power on the part of a larger city, would justify more liberal plans and ambitious programs than it would in the small city. For example, the cost of excessive widths of the streets in a small city might be a burden, even if such cost were limited to present expenditures for excess right-of-way widening only. Even though the paving on such streets was not unusually wide for the present, the cost of paving intersections, extra length of driveway turn-outs and cross-walks for each residence, as well as the additional maintenance for such extra paving and walks, would have to be considered. While these items may seem comparatively insignificant to planners in the larger metropolitan areas, they are a much greater proportion of the original project than in the larger city, and this excess cost, capitalized and put on compound interest over a period of 25 or 30 years, would pay for a great deal of corrective work at that time.

In the larger cities playgrounds, parks, etc., can be provided with much more flexibility because of the greater number to be supplied; whereas in the small cities the matter of first cost per capita again enters into the economic amount which can be spent for such facilities. In the small city the density of population per acre is considerably less than in the larger city. The facilities required for playgrounds and parks would be less and, if sufficient playground space were provided, based upon a liberal estimate of the

density of population, several years in the future, it would add an unnecessary immediate burden upon the city in first cost as well as in maintenance charges.

In the matter of zoning, the areas set aside for business, industrial, and residential purposes would vary considerably in their proportion to one another depending upon whether the problem related to a small or to a large city. In the small one there is not so much possibility of providing transitional property that could be readily changed to permit of the expansion of the business and industrial sections.

In the small city the matter of railroad grade elimination must be handled in an entirely different manner. The small communities are not justified in spending money to eliminate the objectionable grade crossings. This problem, which is often planned in the larger cities as a major operation, must be reckoned with in an entirely different manner in the small city. These same principles are typical of the other phases of city planning.

While city planning is of great value to the smaller cities, the real value will only be obtained by a practical and common sense application of its principles heretofore developed, scaled down to the proper proportions to suit the idiosyncrasies which are peculiar to the small city. City planning in the beginning was born of necessity due to congestion and intolerable conditions in the larger cities. Most of the pioneer work in this field was developed in order to relieve such conditions. These obvious advantages and the favorable results have been made possible through city planning; and these acute and intolerable conditions first gave city planning its importance. The relief gained has encouraged the city planning principles to be applied to the preventive phase, and has educated the public to the realization of the great advantage of planning in advance. This work has been most intensive in the larger cities and the methods and principles adopted were designed to suit conditions there. With the advantages thus favorably established the move naturally is spreading into other cities as well. The success and degree of benefit which the smaller cities will receive, will depend entirely upon the city planner's ability to recognize the slightly different conditions; they will depend on his sense of proportion in adapting the principles, in a practical manner, to suit the differing conditions.

STEPHEN CHILD,[5] M. AM. SOC. C. E. (by letter).—Mr. Wood reiterates the recommendations of the National Conference on City Planning that all American municipalities should establish city planning commissions. He states, furthermore, that provision should be made for the establishment of a City Planning Office and the employment of a City Planning Consultant. Unfortunately, smaller cities frequently become imbued with the idea that it is quite unnecessary to have a consultant, perhaps because a local architect and engineer are members of the commission. This is false economy.

City planning is a never-ending job. Cities cease to need planning only when they cease to grow. There are many methods of procedure and no "hard-and-fast" rules established. A great metropolitan community must adopt the

[5] Landscape Archt.; Consultant in City Planning, San Francisco, Calif.

method best adapted to its own peculiar conditions. However, a large group of cities, ranging in population from 10 000 to 100 000, have much in common as regards the more general features of city planning procedure.

For example, they first need a properly organized city planning commission; then a comprehensive civic survey, to be followed by the preparation of plans for streets, zoning, parks, and other features of growth. Furthermore, and perhaps most important, all these plans and projects must be followed up patiently and continuously, year after year, until finished.

For most of the smaller communities, a separate city planning department would be out of the question. The necessary "follow-up" work is no doubt done best "at home" and not from some expert's office. Recognizing this essential, more or less complete transfer of city planning functions from the expert's offices to some one of the city's departments, it may be best to begin in another way and to proceed with the plan by fundamentally different methods.

As an example of how many mistakes are made in city planning, consider a hypothetical small town. Suppose that, under the stimulus of a campaign carried on by an effective citizens' advisory committee and sponsored perhaps by the Chamber of Commerce, a city planning commission has been organized, a fund appropriated for its work, and a competent consultant employed. For a year or more everything seems to be progressing quite well. A preliminary survey is prepared; an illustrated pamphlet report, containing recommendations for a major street plan and for other important features controlling the city's growth, is published.

Then comes the inevitable slump. Opponents of the zoning plan appear; the Committee declines to appropriate money for a much needed traffic artery; a proposed bond issue to provide for a playground system, park, or civic center is voted down; and, finally, the funds for the city planning commission itself are either not appropriated at all or are radically cut.

By this time the expert has gone on to new fields of endeavor. Possibly some of the valuable data and plans he has prepared are buried in the vaults of the city clerk's office and forgotten. Much material remains in the possession of the expert, whose office is perhaps a thousand miles away. The city then drifts along in practically the same shiftless, inefficient manner that it has for years. Small and large subdivisions continue to be added and haphazard growth goes on, with little guiding or planning.

Then follows another "spasm" of civic righteousness—the result, perhaps, of some grade-crossing accident or other occurrence that arouses public interest. There is a scurrying around in search of mislaid data and the original expert and city engineer are not now near at hand to help in the re-educating work.

The foregoing remarks will serve as an example of conditions that are working against good city planning, particularly in the smaller cities. The ideal steps proposed for the same situation might be analyzed somewhat as follows:

Consider a city of about 30 000 population. Often with the support of the Chamber of Commerce, a Citizens' Advisory Committee is appointed, and this Committee employs a consultant who helps in the preparation and enactment of city-planning ordinances. The ordinances will include the general features

proposed by the Advisory Committee on City Planning and Zoning of the United States Department of Commerce as recommended by Mr. Wood. This step in itself would take a little time and, in the meantime, the Consultant will give some talks on city planning. Ultimately, a city planning commission is authorized and organized.

Under the terms of the ordinance the City Engineer is made an *ex officio* member of the City Planning Commission. Contrary to the example previously cited, the City Planning Commission does not turn the job over to the consultant. On the contrary, it selects an efficient secretary—perhaps a stenographer in the office of the City Engineer. She is to begin immediately to have charge of the data collected. The City Engineer will probably need to employ a city planning assistant. Larger communities might need more than one, and there is the possibility that one of these might become secretary to the Commission. The Commission, again under the advice of its Consultant, proceeds to make a comprehensive civic survey in such a way that every member will be familiar with it. They will be able to amend, extend, and perfect it and they will have all its details available for use in future years.

The next step undertaken by the members of the Commission is to prepare a comprehensive city-planning program. They will endeavor continuously to keep the program of planning up to date. As a whole, the program will need to be flexible enough to permit adjustments to new conditions. One important requisite is the contract drawn between the Commission and the City Planning Expert. This should include such matters as fees, the time to be spent by the Consultant, the extent to which he shall co-operate with the City Engineer, and his duties in respect to directing the civic survey and any field investigations which may be necessary.

Suppose the Council should reject a street-widening proposition, thus upsetting the major street planning; or, suppose the people should vote against a bond issue for parks or a civic center. Every one knows that these are only temporary setbacks. Sooner or later, if the Commission's plans have followed comprehensive civic surveys and are really well considered, these projects will have to be carried out, perhaps in some modified form. If all the data are at hand and the Consultant under the terms of his contract is also at hand, he can insure that these modifications are reasonable and in accord with the general program prepared by the Commission. It is believed that this second proposed method of procedure will go far toward solving the problem of overcoming city-planning inertia which is often a serious matter.

E. A. Wood, M. Am. Soc. C. E. (by letter).—The discussion which has followed the publication of this paper has brought out a number of interesting suggestions. Most of these deserve careful consideration and final adoption by the City Planning Profession. Probably the suggestion having the greatest merit is the one made by Mr. Starkie concerning the separation of grade crossings.

*Grade-Crossing Separation.*—Mr. Starkie suggests that, for every grade crossing shown upon the Master Plan for ultimate separation, additional grade crossings should be shown for closing or complete abandonment. This

seems to be a very efficient and practical manner of dealing with this subject. It also holds out the hope that complete solution is in sight, rather than the inevitable multiplication of future separations or the removal of entire railway lines, as so often suggested in city plans.

Railways have their place in communities in much the same way as highways. Part of their difficulties have come about through improper platting of subdivisions and a demand for grade crossings which have resulted from the frequency of dead-ended streets. City planning can easily take care of this feature in the future, but the work that has already been done must be dealt with in the fashion suggested by Mr. Starkie. Assuming that the railroad is a barrier, it is better to make it a safe barrier and prohibit all crossings except those called for in the Master Plan, than to make it a dangerous barrier and subject to daily loss of life.

*Inventory of the City.*—Mr. Koch stresses the necessity of taking a complete inventory of the city before any planning is done. This is exceedingly important and furnishes the groundwork for city planning. It also furnishes the city planner with the incentive to make each city somewhat different from a preceding city. It is a mistake to attempt to mould American cities after a standard pattern. There is a wealth of history, tradition, and environment to draw upon if the city planner will only take the time for investigation. Each factor should leave a particular stamp upon the Master Plan.

This particular phase of city planning also has a distinct appeal to the average citizen. If properly used, it will furnish a means of contact with the citizenship that will be invaluable to the planner. It will stimulate interest in the plan, increase attendance at meetings, and furnish human interest, subject to development by the press. It will popularize city planning in the smaller cities.

*Regulatory Planning versus Corrective Planning.*—Mr. Koch also stresses the cost of city planning and the inability of the smaller city to pay for parks and street widening. This same cost proves the wisdom of acquiring parks by gift and of widening streets by the set-back line rather than by purchase of property. The control of the platting of property furnishes the means of acquiring, not only park property, but school property as well. It is one of the most valuable means for good city planning. It serves the community, and it serves as a common meeting ground for School Boards, Park Boards, and City Plan Commissions.

By a judicious use of the set-back, practically the entire Master Plan can be protected against encroachment and all streets made ready for widening. This does not have reference to the set-backs established in the zoning ordinance, which are done for the purpose of protecting the health, safety, morals, and general welfare of the community. It means those set-backs which are laid down by ordinance for the express purpose of preventing the erection of buildings on streets that are to be widened at some future time. This type of regulatory planning is well adapted to the smaller city because it does not involve the expenditure of public funds. One of its chief benefits is that it invites co-operation between citizens and the municipality.

*Continuity of City Planning.*—Mr. Child suggests the possibility of the lack of interest in city planning after the completion of the Master Plan and the danger of its utter failure. This possibility is always present in the smaller city, and every means should be taken to guard against it. One of the reasons for making the City Attorney and the City Engineer *ex officio* members of the City Planning Commission is to develop their interest to the point where they will follow city-planning ideals in their municipal work. For the same reason it is well also to have the Mayor as an *ex officio* member of the Commission. As a progressive citizen, he not only can sell city planning to the citizenship, but he can put it into effect as well.

One of the best means for insuring continuity in city planning is to make the various plans effective through ordinances rather than by the expenditure of public funds. For instance, an ordinance requiring the submission of all plats of property to the City Planning Commission before they may be filed for record will at least furnish the opportunity for suggesting gifts of park and school lands. Such gifts may have a string tied to them, such as immediate improvement. This will be within the means of the municipality, whereas the purchase of the property would not. In the same manner the prevention of the erection of new buildings beyond the set-back line on a major thoroughfare is within the means of the municipality, while the immediate widening of the thoroughfare is not. Eventually, the street can be widened because there will be very few buildings to be torn down or moved back. There is even the possibility of the property being given to the city for the widening when the necessity becomes urgent.

*City Planner Must Be a Leader and a Teacher.*—If the city plans for the smaller cities are to be fufilled the Planner must be a leader as well as a teacher. He will find that the average citizen will respond to leadership. He will also find that, when the principles of city planning are thoroughly inculcated in the citizenship, plans will not die, either through neglect or by suffocation through an accumulation of dust. Much will depend upon the City Planner. He must leave his imprint, not only upon the city plan, but upon the citizenship as well. The opportunity for doing this is much greater in the smaller city than in the larger one.

AMERICAN SOCIETY OF CIVIL ENGINEERS

Paper No. 1786

# IMPACT IN HIGHWAY BRIDGES

## FINAL REPORT OF THE SPECIAL COMMITTEE[1]

WITH DISCUSSION BY MESSRS. SEARCY B. SLACK, LLEWELLYN N. EDWARDS, AND THE IMPACT IN HIGHWAY BRIDGES COMMITTEE

TO THE AMERICAN SOCIETY OF CIVIL ENGINEERS:

The Committee was appointed in 1922, and was asked to search for available data on the subject of impact in highway bridges, to encourage experimental work in a more systematic manner than had yet been attempted, and to report to the Society concerning the available information and its application to the design of highway bridges.

Subsequently, progress reports have been presented at each Annual Meeting and published in *Proceedings*.[2] Two of these reports[3] contain pertinent data of value.

This report undertakes to present such conclusions as the Committee has been able to make from the available data; also, in the form of appendices, abstracts of such data as will assist those who are especially interested to make independent applications of the information and to direct future work along the most profitable lines.

The only data published prior to 1922, so far as the Committee could ascertain, consisted of a number of theoretical discussions and the results of experimental work by F. O. Dufour,[4] M. Am. Soc. C. E., made in Illinois from 1910 to 1912. By reason of the revolutionary changes in highway transportation and in the design of highway bridges that have taken place since these experiments were made, the data obtained at that time are of but little value in the present study, and have been utilized only in the construction of Fig. 1. The only other useful information which the Committee has been able to find is from two sources:

[1] Presented at the Annual Meeting, January 16, 1929.

(1) Studies on highway bridge impact at the Iowa State College, Ames, Iowa. These studies were begun in 1922 as a co-operative project between the United States Bureau of Public Roads, the Iowa Highway Commission, and the Engineering Experiment Station of Iowa State College. In 1924, very considerable assistance was rendered directly by the Society, through this Committee, by providing for its use a McCollum-Peters electric telemeter,[5] or strain-gauge, for determining and recording various stress measurements. Reports from this project have been published.[6]

(2) Experiments of the U. S. Bureau of Public Roads on impact on pavements. These results have also been published.[7]

The report is primarily an effort to analyze and correlate the data obtained from these projects and to draw such conclusions as seem to be warranted at this time.

## Nature of the Problem

Obviously, the most direct method of determining dynamic stress and, therefore, impact in a structure is by direct measurement of such stress under moving loads subject to the various conditions met in practice. To a certain extent this is practicable, and much information of this nature was obtained in the tests at Ames, Iowa. This method, however, has its limitations. Not only are the variations of loading, truck design, and tire conditions very great and not easily defined and related, but the structure itself introduces many complications. Smoothness of floor, nature of possible obstructions to be anticipated, the design of the structure itself, and the length of roadway to be loaded for maximum effect, all enter into the problem and seriously complicate it. To cover all these variables by tests in the field is practically impossible. In particular is it difficult to determine the significant impact for those members of a structure that require a considerable load. As a consequence, the tests at Ames were directed primarily to floor-beams and stringers. Impact values were determined in a few truss members of a number of bridges, but the results are of less importance, as in most cases the simultaneous unit stresses were very low.

The greatest impact of a wheel passing over an obstacle may be from shock as the wheel strikes the obstacle, or from drop as it again strikes the floor. According to the available data, drop impact is generally the greatest for heavily loaded trucks. Shock impact was frequently greatest for unloaded trucks, but the resultant stresses were so low as to suggest that shock impact is of theoretical, rather than practical, interest.

As compared to railway bridge impact, the problem is a very different one, especially as regards truss members. In railway bridges, the impact effect arises largely from the rotation of unbalanced drivers; and synchronism of driver rotation and bridge vibration produces dynamic stresses which are subject to certain fairly well-defined laws. Such synchronism of impact can

[5] *Bulletin No. 247*, U. S. Bureau of Standards.

[6] *Bulletins 63* and *75*, Eng. Experiment Station, Iowa State Coll.; *Public Roads*, September, 1924.

[7] *Public Roads*, March and December, 1921, June, 1926, and August, 1928.

hardly occur in highway bridges when heavily loaded with several trucks. Furthermore, the observations necessary to determine the impact due to accidental obstructions when the bridge is loaded in this fashion are almost impossible.

In addition to the direct results by tests on bridges, valuable information can be deduced from impact tests on pavements such as those conducted by the U. S. Bureau of Public Roads. To enable such results to be utilized, it is necessary to determine, first, the relation between the wheel blow on a pavement, and the blow on a bridge floor, under the same surface conditions; and, second, the actual dynamic stresses produced in the bridge member by a given wheel blow. The relative force of a blow, in percentage of static load, delivered by a truck wheel passing over an obstruction depends on the speed, the height of the obstruction, the flexibility of the tires, the percentage of the unsprung to the total weight, and the flexibility of the pavement upon which the wheel drops. It is less on a concrete bridge floor than on a concrete pavement; and limited data indicate that it may be less on certain types of non-rigid pavement than on concrete. The higher the percentage of unsprung weight, the greater will be the ratio of the blow to the static load; and, within certain limits, the greater the speed, the greater the blow. Furthermore, due to inertia and the time element of deflection and deformation, the stresses produced in the bridge member by the force due to a falling wheel is considerably less than would result from a static load of the same amount as this force. All these factors have been taken into account in the analysis of the data and the formulation of the conclusions of this report.

## Definitions

By reason of the numerous quantities and ratios involved in the problem, it is desirable to define carefully some of the terms used, as follows:

*Dynamic Force.*—The dynamic force of a wheel blow is the maximum pressure of a truck wheel upon the pavement or bridge floor when the truck is in motion.

*Impact Increment of Dynamic Force.*—This increment is the amount by which the dynamic force exceeds the weight of the wheel. It is commonly expressed as a percentage of the static weight.

*Impact Increment of Stress.*—This is the amount by which the actual stress due to the moving load exceeds the static stress. It is also commonly expressed in terms of percentage of static stress.

*Stress Ratio.*—Stress ratio is the ratio of the actual dynamic stress produced in a member to the stress that would have occurred if a static load equal in magnitude to the dynamic force were applied at the same place.

*Sprung Weight of a Truck.*—This weight includes all weight carried by the springs.

*Unsprung Weight.*—This consists of the remaining weight: Wheels, axles, housings, and springs.

## Explanation of the Data

On the Ames project, work was done on five steel bridges with concrete floors (four with steel stringers and one with concrete slab between floor-beams) and on seven steel bridges with timber floors on steel stringers. The individual loads with few exceptions were 3½-ton Liberty trucks, which weighed about 5 tons and were loaded with various amounts up to 10 tons, making a maximum total load of 15 tons. The tires were solid dual rubber, worn down so that their deflection was 0.19 in. under a static load of 10 000 lb. Speeds were attained up to 15 miles per hour. Stress measurements were taken on the stringers, floor-beams, and a few truss members by various extensometers; and the force of the blow of the wheel on the floor was determined (part of the time) by accelerometers.

The U. S. Bureau of Public Roads carried on extensive tests in co-operation with the Society of Automotive Engineers and the Rubber Association of America on impact on pavements from trucks equipped with various kinds of tires. The force of the blows was measured by accelerometers, and the load was passed over obstructions of various heights and at various rates of speed. Impacts were determined on smooth concrete pavement and also on old stone block pavement. Tests were also made by the Bureau of Public Roads on the relative impact on pavements of different kinds, including concrete, brick, and various bituminous pavements.[8]

With the assistance of Professor E. B. Smith,[9] an interpretation has been made of the 1921 "copper cylinder" impact data secured, under his direction, by the U. S. Bureau of Public Roads, along lines suggested in his papers[10] descriptive of those results. This interpretation has been made more readily and more clearly by comparison with similar data taken from *Bulletin 75* of the Engineering Experiment Station of Iowa State College.

In order to adapt to the determination of impact on bridges, the mass of data of the Bureau of Public Roads giving impact on pavements, the Engineering Experiment Station of Iowa State College made a few tests during the summer of 1927, in which the force of the blow from the same loads and speeds were determined upon pavements and upon a number of bridges. These latter data have not been previously published, but are included in Appendix D with the consent of the Station.

Appendix A contains a further description of the Ames tests, with abstracts from *Bulletin 75* of the Iowa Engineering Experiment Station. In this appendix are selected diagrams showing the actual results obtained on impact stresses at various speeds and under various conditions; also the impact stress as related to the dynamic force exerted on the bridge floor. The relation between the stress produced by dynamic force and static force of the same amount—the "stress ratio"—is also shown by diagrams. The selected data for impact stresses in trusses show very clearly the relatively small impact where the structure is sufficiently loaded to produce stresses of as much as 5 000 or 6 000 lb.

[8] *Public Roads*, June, 1926, and August, 1928.

[10] *Public Roads*, March and December, 1921.

per sq. in., and illustrate the difficulty involved in this part of the impact investigation.

Appendix B contains extracts from the published reports of the tests of the U. S. Bureau of Public Roads on pavements. These illustrate very well the effect of variations of conditions.

Appendix C contains results of an analysis by the Committee to render possible the approximate determination of impact stresses in floor members in terms of the separate variables involved, namely, the percentage of unsprung weight of the truck, the height of the obstruction, the speed of the truck, the relative tire deformation, and the stress ratio. It is thought that such an analysis, while having no pretention to great accuracy, will assist engineers in making an independent estimate of impact, particularly those who may undertake future experiments.

Appendix D is an analysis of the relation between impact on a concrete pavement and impact on a concrete bridge floor, and helps to relate the work of the Bureau of Public Roads previously mentioned to the Ames impact studies. It is interesting to note that the ratio of impact on a concrete bridge floor to that on a pavement when the bridge members are stressed to 8 000 lb. per sq. in., or more, does not exceed 80 per cent.

## Impact in Floors of Highway Bridges

*Concrete Floors.*—A brief consideration of the variables involved shows how extremely difficult it is to reach any definite conclusions as to what impact factor should be used in the design of highway bridge floors.

The results obtained by application of the analysis given in the Appendices are illustrated in Table 1. The term, "worn solid tires," represents the hardest worn solid tire that has been noted. For it the value of $d$ (the deflection of the tire due to a static load of 10 000 lb.) = 0.1 in.; for "new solid tires", $d$ = 0.6 in.; and for "pneumatic tires", $d$ = 2.0 in. The "normal load" consists of a truck with live load equal to the rated capacity, for which $p$ (the percentage of unsprung weight to total weight) = 25. "Over load" represents an overloaded truck—for example, one weighing 5 tons carrying a live load of 10 tons, making a total of 15 tons and proportioned so that $p$ = 15.

TABLE 1.—Percentage of Calculated Impact Increments of Stress in Highway Bridge Floors for Trucks.

(Speed, 15 Miles per Hour.)

| Obstruction. | Worn Solid Tires. | | New Solid Tires. | | Pneumatic Tires. | |
|---|---|---|---|---|---|---|
| | Normal load. | Over load. | Normal load. | Over load. | Normal load. | Over load. |
| None | 22 | 12 | 8 | 4 | 4 | 2 |
| 1 in. by 2 in. | 210 | 102 | 57 | 30 | 30 | 12 |
| 2 in. by 4 in. | 475 | 275 | 122 | 58 | 50 | 30 |

The values in Table 1 cover a wide range of conditions, and show what high impacts may be expected in some cases. The Committee does not pro-

pose this table as a suggested standard, but presents it as a reasonably accurate picture of the effect of various factors on the impact on highway bridge floors. It has been computed from Equation (1), Appendix C, and the stress ratio curve of Fig. 8, Appendix A.

*Timber Floors.*—The limited work on timber floors with steel stringers indicates that the best of timber floors will compare favorably with clean concrete floors in regard to impact. It also indicates that on the roughest timber floors investigated the impact was about the same as for 1-in. obstructions on concrete floors.

*Recommendations for Impact in Floors of Highway Bridges.*—As a basis for its recommendations, the Committee has considered the following facts:

*First.*—That stresses due to static loads and to impact are important, as regards the safety of the structure, only when they approach design values.

*Second.*—That the percentage of impact increment decreases as the loads increase, and, therefore, as the unit stresses increase.

*Third.*—That the larger impacts observed in the tests were produced by obstructions, such as would be accidental and infrequent under actual traffic conditions.

*Fourth.*—That the actual occurrence, on a bridge, of loads having a magnitude corresponding to those used in the design of modern structures is infrequent.

*Fifth.*—That the simultaneous occurrence on a bridge floor of a maximum truck load and an accidental obstruction capable of producing high impact will be such a rare coincidence that presumably the factor of safety will usually provide safety for this condition.

This Committee recommends, therefore, that for the design of highway bridge floors and floor-beam suspenders, the impact increment of stress be assumed as 25% of the live load stress. It should be used only when the floors are sufficiently smooth to conform to good modern practice; and unusual conditions should be provided for in accordance with the judgment of the individual designer. The Committee believes that this report contains information, with necessary precision, for guidance in unusual conditions.

## Impact in Trusses of Highway Bridges

The published results for impact in the trusses of highway bridges are of interest and value more for the comparison between computed and observed static stresses than for impact. The many experimental results for impact are doubtless correct within a reasonable precision, but they are not representative of the conditions that control in the design of bridges.

The results have been studied in various ways and are reproduced in Fig. 1 for trusses with concrete floors and in Fig. 2 for trusses with timber floors. Evidently, the impact decreases as the unit stresses increase. It is apparent from a practical standpoint that impact is important in design only as the combined stresses due to dead loads, static live loads, and impact approach design stresses. Such stresses have not been reached or closely approached in known experiments.

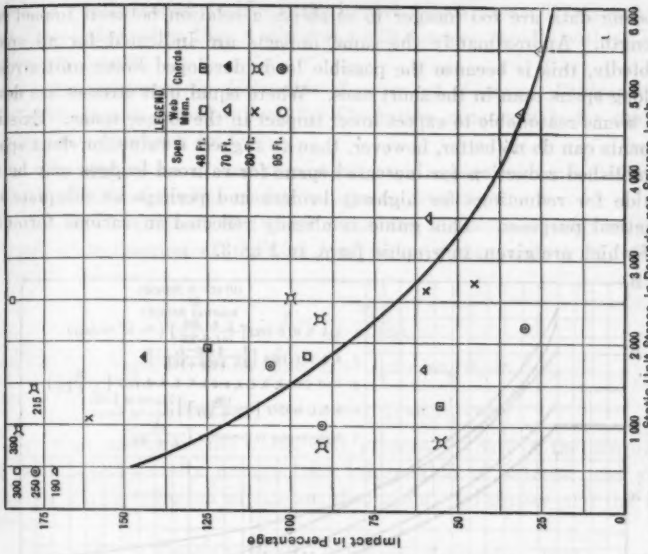

FIG. 2.—IMPACT IN TRUSSES OF HIGHWAY BRIDGES WITH TIMBER FLOORS.

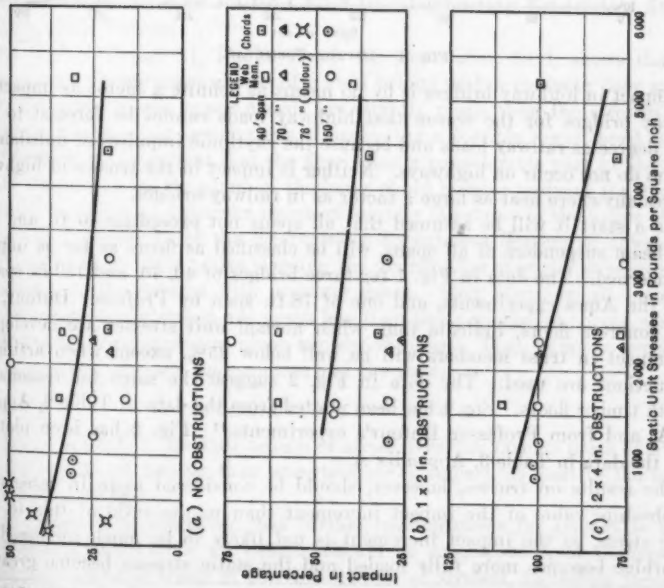

FIG. 1.—IMPACT IN TRUSSES OF HIGHWAY BRIDGES WITH CONCRETE FLOORS.

Existing data are too meager to establish a relation between impact and span length. Approximately the same impacts are indicated for all spans. Undoubtedly, this is because the possible loads developed lower unit stresses in the long spans than in the short ones. Where equal unit stresses are developed, it seems reasonable to expect lower impact in the longer spans. Existing experiments can do no better, however, than to suggest a value for short spans. The established reduction for increased spans for railroad bridges may be the best guide for reductions for highway bridges and perhaps an adequate one for practical purposes. This guide is already reflected in various formulas, some of which are given, in graphic form, in Fig. 3.

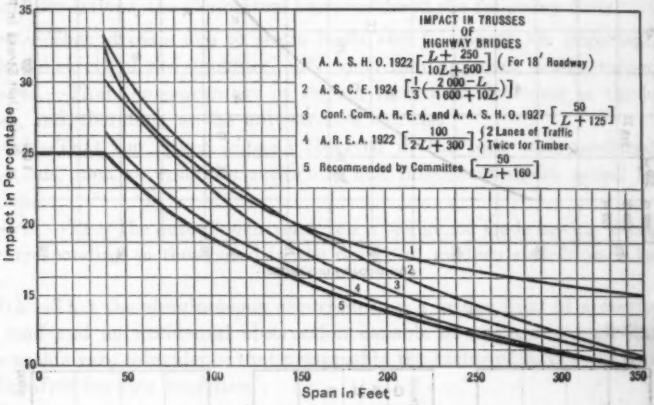

FIG. 3.—IMPACT FORMULAS.

Impact in highway bridges is by no means as definite a factor as impact in railway bridges for the reason that highway loads cannot be forecast to the same degree as railway loads and because the rhythmic impulses of unbalanced drivers do not occur on highways. Neither is impact in the trusses of highway bridges anywhere near as large a factor as in railway bridges.

As a start it will be assumed that all spans not exceeding 40 ft. and the floor-beam suspenders of all spans, will be classified as floors as far as impact is concerned. The data in Fig. 1 for three bridges of 40, 70, and 150-ft. spans, from the Ames experiments, and one of 78-ft. span by Professor Dufour, all with concrete floors, indicate that, when normal unit stresses are developed, the impact in truss members will be well below 25%, except when artificial obstructions are used. The data in Fig. 2 suggest the same for reasonably smooth timber floors. Fig. 1 has been plotted from the data in Table 2, Appendix A, and from Professor Dufour's experiments.[11] Fig. 2 has been plotted from the data in Table 3, Appendix A.

The results on trusses, however, should be considered more in respect to the absolute value of the impact increment than to the ratio of this to the static stress, as the impact increment is not likely to be much increased as the bridge becomes more fully loaded and the static stresses become greater.

[11] *Proceedings*, Am. Soc. C. E., October, 1926, Papers and Discussions, pp. 1737–1742.

Under such fully loaded conditions the impact percentages will be much smaller than those indicated in Figs. 1 and 2 and will decrease rapidly with an increase in the span length.

*Recommendations for Impact in Trusses of Highway Bridges.*—Taking these matters into consideration, the Committee recommends for the girders and trusses of highway bridges:

1.—That for spans of less than 40 ft., the impact increment of stress be assumed as 25% of the live load stress, the same as for floors.

2.—That for spans of 40 ft. and more, the impact increment of stress be assumed as a fraction of the live load stress determined by the following formula:

$$I = \frac{50}{L + 160}$$

in which, $I$ = impact fraction; and, $L$ = span length, in feet.

## By-Products of the Investigation

The stress measurements which were a necessary part of the investigations for impact, incidentally brought out information of interest and value in regard to the distribution of stresses throughout the trusses and the floor, as follows:

1.—In Table 4, page 13, *Public Roads* for September, 1924, a number of instances are cited where the unit stress in one part of a built member is more than double that in other parts of the same member. More instances of the same nature are given in *Bulletin 63* of the Engineering Experiment Station of Iowa State College.

2.—Table 2, page 11, *Public Roads* for September, 1924, shows that the unit stresses in the lower chords of a steel bridge with a concrete floor are far less, and those in the upper chords are slightly more, than the stresses computed under the usual assumptions of neglecting a possible lower chord tension in the floor. It is evident that the floor takes a considerable part of the lower chord tension, raises the plane of the lower chord stresses, reduces the effective depth of the truss, and thereby increases slightly the stress in the upper chords.

3.—In *Bulletin 75* of the Engineering Experiment Station of Iowa State College, there are eight plates showing the distribution of static stresses in the stringers of four bridges with concrete floors. They show, in all instances, that the stresses developed are much less than those computed on the assumption that the steel stringers alone support the load. They point to consistent T-beam action between the concrete and the steel.

## Suggestions for Future Work

Uncertainties in the distribution of stress over the various parts of a truss member are much greater than uncertainties in impact, at least in the trusses of highway bridges.

It would seem, therefore, that further investigations for impact as useful information for a basis for design, should be accompanied, or perhaps preceded, by a general study of the distribution of stresses, including secondary

stresses, stresses due to eccentric connections, etc. Such an investigation should necessarily be of sufficient magnitude to cover a wide range of conditions and to yield conclusions of general application. It would be a worthy companion of the research now under way through the American Society for Testing Materials for studying the distribution of stresses throughout the area of rolled sections. That research is based on the fact that the different parts of a rolled section were really different materials due to unequal working in the process of rolling. Its ultimate effect may be to improve the methods of rolling and to provide material of greater uniformity.

The bridge truss research would give information concerning the degree to which stress is transmitted from one composite part of a riveted (or a welded) member to another. This might possibly lead to better fabrication as well as point out the parts of a structure where the stress distribution is least uniform. In either event, it would contribute to the understanding of some of the factors that must be considered in the determination of unit stresses, a problem which was considered by the Society a few years ago, but regarding which no satisfactory solution was reached.

The bridge truss research should disclose whether there is any need for further work on impact in trusses of highway bridges, and it also might point the way toward the best procedure for the impact investigations if they were found to be desirable.

Respectfully submitted,

Special Committee on Impact in Highway Bridges,

A. H. FULLER, *Chairman*,
ARTHUR R. EITZEN,
E. F. KELLEY,
F. E. TURNEAURE.

December 5, 1928.

## APPENDIX A.

### STRESS AND FORCE MEASUREMENTS FOR IMPACT ON BRIDGES

In order that those who do not have access to *Bulletin 73* of the Engineering Experiment Station of Iowa State College, mentioned in the report, may get a general idea of the manner in which the data of that *Bulletin* were gathered and recorded, a brief description of these factors is given.

The bridges most used were: (*a*) A 150-ft. through riveted steel span, with 6-in. concrete floor on nine lines of 10-in., 25-lb. steel stringers of 18 ft., 9-in. span; (*b*) a 33-ft. I-beam span, with 6-in. concrete floor on nine lines of 15-in., 43-lb. steel stringers; (*c*) a 26-ft. I-beam span, with 8-in. concrete floor on nine lines of 18-in., 54.7-lb. steel stringers; and (*d*) seven light steel spans, with timber floors on steel stringers.

The loads consisted of 3½-ton Liberty trucks with total loads varying from 5 tons for the empty truck to 15 tons, with maximum rear axle load of 12 tons. The unsprung weight of one rear axle was 4 400 lb.

The instruments most used for stress measurements were the McCollum-Peters electric telemeter and the West extensometer.[12]

*Impact in Floors.*—The force of the blows of the truck wheels on the bridge floors was determined by accelerometers which were designed and constructed for the work and described in *Bulletin 75* of the Iowa Engineering Experiment Station. These accelerometers were similar in design and action to those used by the U. S. Bureau of Public Roads.[13]

In the preparation of the *Bulletin* from which these conclusions were taken, the stress measurements were platted on a large number of diagrams, and median lines were drawn. All these lines were then assembled, for a certain stringer (but without the platted points), on a single diagram, as shown on Fig. 4,[14] and other similar diagrams. A study of Fig. 4 brings out certain facts, within the limits of those experiments:

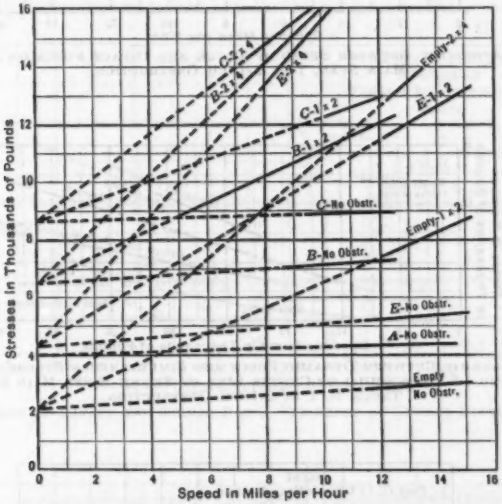

FIG. 4.—RELATIONSHIP BETWEEN SPEED OF TRUCK AND STRESS IN STRINGERS. SIX-INCH CONCRETE FLOORS, SKUNK RIVER MAIN SPAN, STRINGER 7.5 FEET SOUTH OF CENTER LINE.

1.—The increase in stress varies directly with the speed.
2.—The stress increases but slightly with the speed on clean floors (no obstructions).
3.—The stress increases decidedly with the speed when obstructions are used.
4.—The increase in stress, for a given obstruction and speed, is approximately the same for all trucks. This indicates that the impact increment of stress is caused primarily by the unsprung weight of the truck.

[12] *Proceedings*, Am. Soc. C. E., March, 1923, Papers and Discussions, p. 460.
[13] *Public Roads*, December, 1924, pp. 1–9.
[14] *Bulletin 75*, Eng. Experiment Station, Iowa State Coll., Fig. 14.

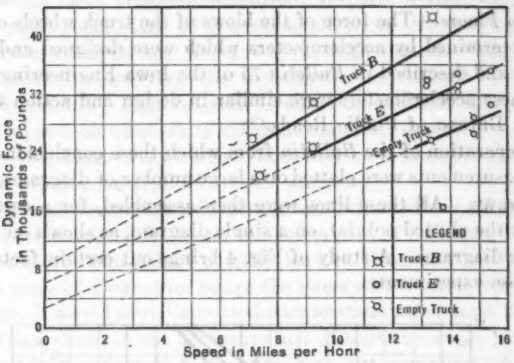

FIG. 5.—RELATIONSHIP BETWEEN SPEED OF TRUCK AND IMPACT FORCE ON SKUNK RIVER MAIN SPAN, 1 BY 2-INCH OBSTRUCTION.

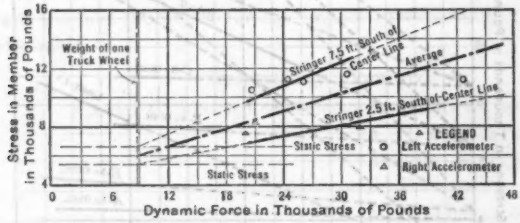

FIG. 6.—RELATIONSHIP BETWEEN DYNAMIC FORCE AND SIMULTANEOUS STRESSES IN STRINGERS 2.5 AND 1.5 FEET SOUTH OF CENTER LINE OF SKUNK RIVER MAIN SPAN, TRUCK B, 1 BY 2-INCH OBSTRUCTION.

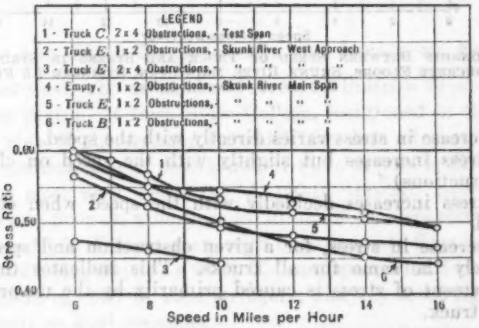

FIG. 7.—RELATIONSHIP BETWEEN SPEED OF TRUCKS AND STRESS RATIO FOR STRINGERS OF CONCRETE FLOOR BRIDGES.

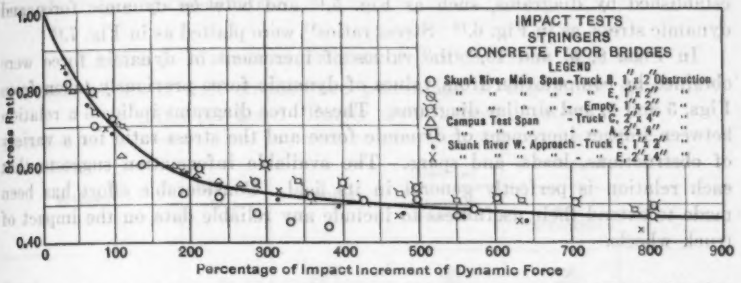

FIG. 8.—RELATION OF IMPACT AND STRESS RATIO, STRINGERS OF CONCRETE FLOOR BRIDGES.

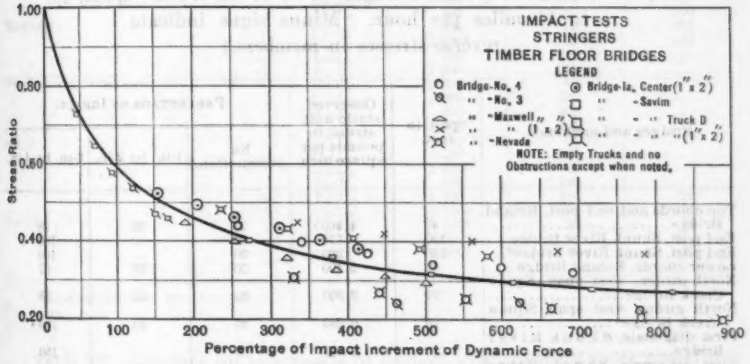

FIG. 9.—RELATION OF IMPACT AND STRESS RATIO, STRINGERS OF TIMBER FLOOR BRIDGES.

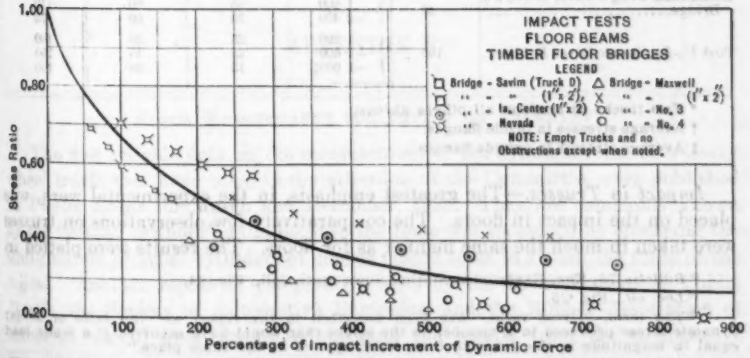

FIG. 10.—RELATION OF IMPACT AND STRESS RATIO, FLOOR-BEAMS OF TIMBER FLOOR BRIDGES.

A relationship between speed and the dynamic force of a wheel blow was established by diagrams, such as Fig. 5,[15] and between dynamic force and dynamic stress, as in Fig. 6.[16] Stress ratios[17] were platted as in Fig. 7.[18]

In Figs. 8, 9, and 10,[19] the values of increment of dynamic force were obtained by computation from values of dynamic force previously taken from Figs. 5 and 6, and similar diagrams. These three diagrams indicate a relation between impact increment of dynamic force and the stress ratio for a variety of obstructions, loads, and spans. The available information suggests that each relation is perfectly general in its field. Considerable effort has been made to extend their usefulness to include any reliable data on the impact of truck wheels.

TABLE 2.—IMPACT IN TRUSSES OF BRIDGES WITH CONCRETE FLOOR.

(Observed static unit stresses and percentage of impact in Skunk River, Squaw Creek, and Roland Bridges. Two 14-ton trucks; speed, 10 to 14 miles per hour. Minus signs indicate reverse stresses in members.)

| Bridges and members. | Span, in feet. | Observed static unit stress, in pounds per square inch. | Percentage of Impact. | | |
|---|---|---|---|---|---|
| | | | No obstruction. | 1-in. by 2-in. | 2-in. by 4-in. |

Table 2[20] gives data for the trusses of bridges with concrete floors, and Table 3,[21] for trusses of bridges with timber floors. The results from Table 2 have been plotted in Fig. 1 and those from Table 3, in Fig. 2.

## APPENDIX B

### FORCE MEASUREMENT FOR IMPACT ON PAVEMENT

The first reliable data on the measurement of the dynamic force of a heavy wheel truck, that have come to the attention of the Committee, were published in *Public Roads* for March and December, 1921. They are commonly known as the "copper cylinder" data, because the force was measured by observing the deformation of small cylinders of copper placed so as to absorb the force of the wheel. Another report of co-operative tests by the U. S. Bureau of Public Roads, the Society of Automotive Engineers, and the Rubber Association of America was of great value in checking the results from the co-operative

[20] Based on Table 4, *Public Roads*, September, 1924, p. 13.
[21] Based on Table 8, *Bulletin 75*, Eng. Experiment Station, Iowa State Coll.

project at Ames, Iowa, and in interpreting the "copper cylinder" impact data.[22] Certain diagrams from the report are reproduced as a means of supplementing and interpreting the data which were obtained from other sources.

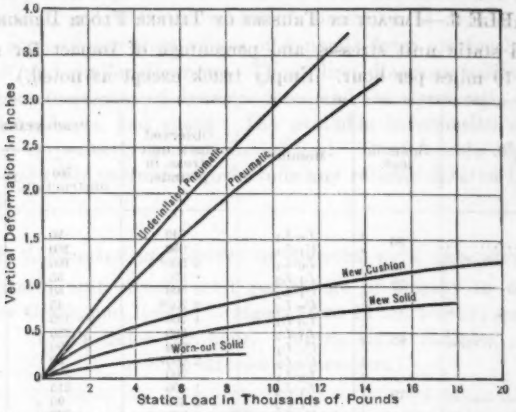

FIG. 11.—TYPICAL CURVES SHOWING TIRE ACTION UNDER STATIC LOAD.

The curves in Fig. 11[23] give some information concerning the flexibility of tires. The curve for "worn out" solid tires indicates a deformation of about 0.25 in. for a load of 10 000 lb. This is slightly softer than the tires used at Ames, Iowa, which had deformations of about 0.19 in. for the same load.

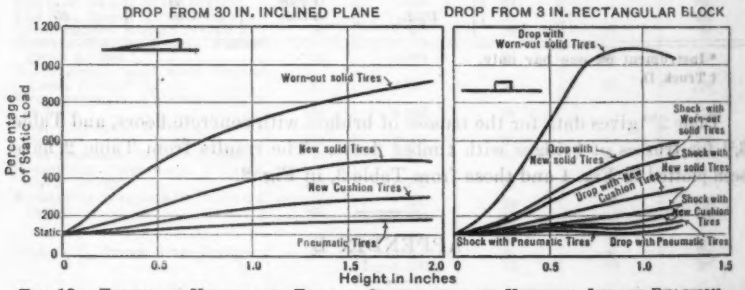

FIG. 12.—EFFECT OF HEIGHT AND TYPE OF OBSTRUCTION ON VERTICAL IMPACT REACTION.

Several results from impact tests are shown in Figs. 12, 13, and 14, all obtained with a 2-ton truck equipped with rated-size dual tires. In Figs. 12 and 13 the wheel loads are those of the tire capacities, and in Fig. 14 the influence of variable load is shown. The speed used in the tests of Figs. 12 and 14 was 12 miles per hour; those of Fig. 13 were variable. Fig. 12[24] shows about the same range of dynamic force of wheel blows as Figs. 8, 9, and 10, and, at the same time, indicates the variation in the intensity of the blows for different tires and obstructions.

[22] "Motor Truck Impact as Affected by Tires, Other Truck Factors, and Road Roughness," by James A. Buchanan and J. W. Reid, *Public Roads*, June, 1926.

[23] *Loc. cit.*, Fig. 2.

[24] *Loc. cit.*, Fig. 14.

Fig. 13[25] shows the relation between the speed and the force of the wheel blow for various tires and obstructions. In comparing these relations with those of *Bulletin 75*, Engineering Experiment Station, Iowa State College, some significant facts are brought out in the form of the curves. A straight line relation between the speed and the blow is indicated in the *Bulletin* for the observed speeds, which were from 5 to 15 miles per hour. The same rela-

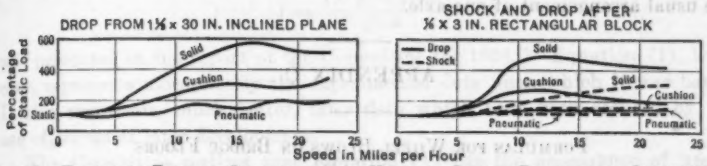

FIG. 13.—EFFECT OF TYPE OF OBSTRUCTION ON VERTICAL IMPACT REACTION AS INFLUENCED BY TRUCK SPEED.

tionship is generally indicated in Fig. 13 for the same speeds, but the latter shows a deviation from a straight line for low speeds (which is not important) and for speeds greater than 15 miles per hour. The data in Fig. 13 make an important contribution in indicating very little, if any, increase in impact for speeds greater than 15 miles per hour, within the limits of known experiments. A tendency toward critical speed at about 15 miles per hour was also indicated in one other instance.[26]

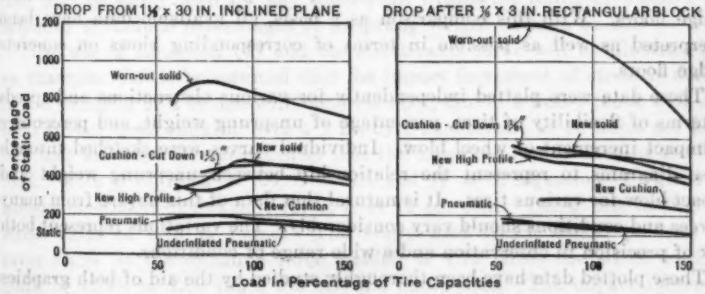

FIG. 14.—EFFECT OF LOAD IN TERMS OF TIRE CAPACITY ON VERTICAL IMPACT REACTION WITH SEVERAL TYPES OF TIRES AND IMPACT.

In Fig. 14[27] is indicated a decreased percentage of impact increment for increased tire loads for various types of tires. This factor is typical of two others mentioned elsewhere in this report: (*a*) That the percentage of impact decreases with an increase in the sprung weight; and (*b*) that the percentage of impact decreases with the flexibility of a structure, or as the unit stresses increase. These two factors suggest that the danger to a structure from an overload on a rubber-tired truck may not be as great as observed values would

[25] "Motor Truck Impact as Affected by Tires, Other Truck Factors, and Road Roughness," by James A. Buchanan and J. W. Reid, *Public Roads*, June, 1926, Fig. 15.

[26] *Public Roads*, August, 1928, Figs. 10, 12, and 13, p. 122.

indicate; also, that for normally stressed and slightly overstressed structures, the impact factors will be less than those observed in the known experiments on bridges.

Other interesting and pertinent factors were brought out—that impact is perceptibly greater when dual, rather than single, tires are used and decidedly less when the rear load is carried on two axles (four wheels) rather than on the usual arrangement of one axle.

## APPENDIX C

### Formulas for Wheel Blows on Bridge Floors

As has been stated in the report, the force of a blow from a given wheel depends on the rigidity of the body that is struck, as well as on the weight and the vertical velocity of the wheel and on the kind and condition of the tire. The blow of a moving wheel on a bridge floor is less than the blow of the same wheel on a pavement, whenever the flexibility of the structure is greater than that of the pavement. This condition exists in most bridges, especially where the load is sufficiently great to produce deflections and unit stresses corresponding to fully loaded conditions.

The data from the experiments of the U. S. Bureau of Public Roads on pavements have been compared with corresponding data on the more flexible bridge floors. With this comparison as a basis, all available data have been interpreted as well as possible in terms of corresponding blows on concrete bridge floors.

These data were platted independently for various obstructions and speeds in terms of flexibility of tires, percentage of unsprung weight, and percentage of impact increment of wheel blow. Individual curves were sketched through these diagrams to represent the relationship between unsprung weight and impact blow for various tires. It is natural that data of this nature from many sources and conditions should vary considerably. The variations represent both lack of precision in observation and a wide range of conditions.

These plotted data have been thoroughly studied by the aid of both graphics and mathematics, and it has been found impossible to evolve a simple equation which will closely represent the experiments. The formula,

$$I = \left(\frac{p\,H^{0.45}\,S^{0.54}}{15\,d^{0.3}}\right)^{a} \qquad (1)$$

does represent them and is presented as an equation which best sums up the available knowledge of the impact of wheel blows of present-day heavy trucks on the surface of concrete floors which rest on steel stringers. In this equation:

$I$ = impact increment of dynamic force of wheel blow expressed as a percentage of the static load.

$p$ = unsprung weight expressed as a percentage of total weight of truck.

$a$ = numerical exponent having the value, $\frac{1}{0.22\,p^{0.2}}$.

$H$ = height, in inches, of any obstruction on the bridge floor. (Equals about 0.1 in. for the bare concrete floors and an average of the best timber floors for which data are available.)
$S$ = speed of truck, in miles per hour.
$d$ = tire deformation, in inches, under a static load of 10 000 lb.

A simpler equation,

$$I = \frac{1.8\,H\,S\,p^{0.625}}{d^{0.45}}$$

was presented in the report of the Committee for 1926.[28] Equation (1), however, represents more closely the experimental data upon which it was based. It also represents, much better, later data which have been secured by the use of trucks of later development.

The Committee realizes that Equation (1) has the appearance of undue precision and that it is cumbersome. Numerous simpler ones have been evolved, but all are complicated and none represents, nearly as well, the results of experiments, especially upon the heaviest trucks; and the heavy trucks are really the only ones that are important in design.

Equation (1) gives directly, not the stress impact, but the impact of the blow of the truck wheel on a concrete bridge floor. In order to transform the effect of the blow into stress impact, it is necessary to make use of the stress-ratio curve for concrete floor in Appendix A (see Fig. 8). Equation (1) and the stress-ratio curve have been used in computing Table 1. It is believed they may be safely used for any conditions, within the limits of Table 1 and extended to include percentages of unsprung weight as high as 40.

The use of Equation (1) and the stress-ratio curve will be illustrated by an example. Let it be assumed that the impact increment of stress is desired in the stringers of a bridge with concrete floor, due to a heavy truck with new solid rubber tires, running over a 1 in. by 2-in. obstacle at 15 miles per hour, and that the truck is overloaded so that the unsprung load is 15% of the total load. With $p = 15$, $d = 0.6$, $S = 15$, and $H = 1$, Equation (1) gives the impact increment of dynamic force, $I$, as 72 per cent. Using this in Fig. 8 a stress ratio of 0.76 is found. The static load which would produce the same stress as the dynamic force (which is 1.72 times the wheel load) is $(0.76 \times 1.72)$, or 1.30 times the original static load. The impact increment of stress is, therefore, $1.30 - 1.00 = 0.30$, or 30 per cent.

## APPENDIX D

### Relation Between Blow upon Pavement and upon a Bridge Floor

Many data are available, mostly through the U. S. Bureau of Public Roads, which give the intensity of a wheel blow, and, therefore, the impact, on pavements. This information may be made available for determining the impact on bridges by establishing a relationship between the intensity of blows on pavement and on bridges under conditions which otherwise are similar.

[28] *Proceedings*, Am. Soc. C. E., March, 1926, Papers and Discussions, p. 448.

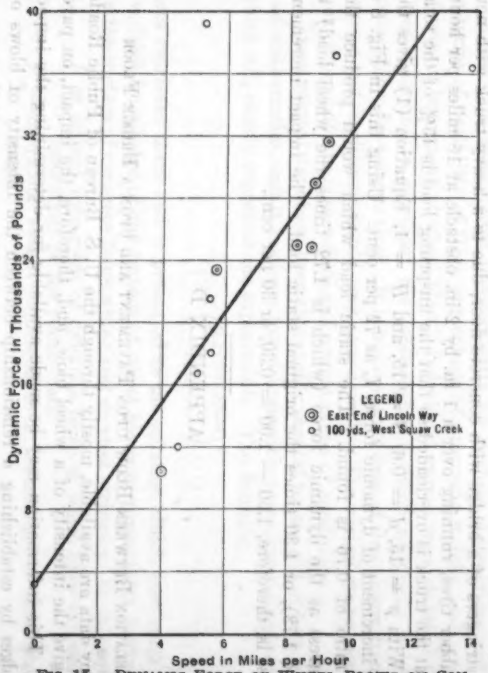

FIG. 15.—DYNAMIC FORCE OF WHEEL BLOWS ON CONCRETE PAVEMENT, EMPTY LIBERTY TRUCK, RIGHT ACCELEROMETER, 1-INCH BY 2-INCH OBSTRUCTION.

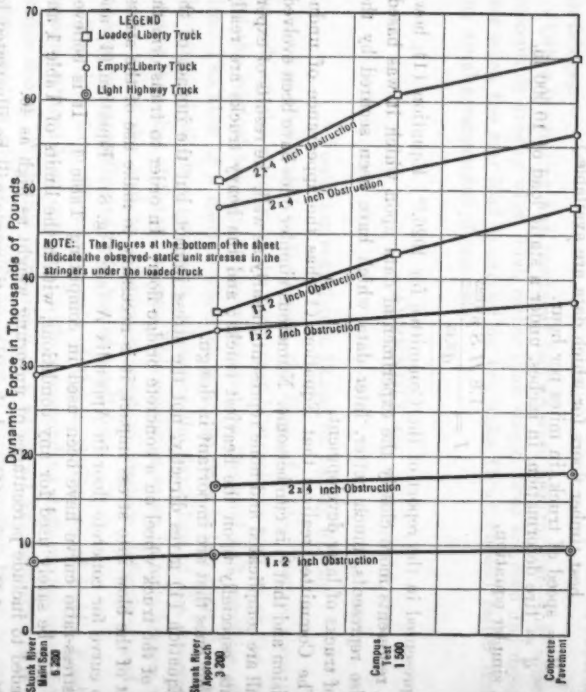

FIG. 16.—COMPARISON OF DYNAMIC FORCE OF WHEEL BLOWS ON PAVEMENTS AND ON BRIDGES.

A number of experiments not only verify the well-known fact that the intensity of the blow from any wheel is dependent on the flexibility of the surface on which the blow is delivered, but suggest a value for the relationship, fairly well in keeping with the variation in road surfaces, tires, etc.

Liberty trucks described in *Bulletin 75* was used, both empty and loaded. A lighter truck with softer tires was also used. More than thirty diagrams were plotted showing the force of wheel blows in terms of speed. One of these is reproduced as Fig. 15.

Table 4 has been made by reading the wheel blows from these diagrams at speeds of 12 miles per hour. Fig. 16, which has been plotted from Table 4, shows a decided variation of wheel blows on different structures and gives the basis for the degree of variation. Fig. 17 shows percentage effects of blows on a bridge to blows on a pavement taken from Fig. 16 and Table 4, plotted against unit stresses in the stringers for the three structures for which observed unit stresses are available. Although the points are small in number and scattering, they give rather definite suggestion that percentages greater than 80 are for such small unit stresses that they would not be significant for design

purposes. The necessary computations for plotting Fig. 17 are given in Table 5.

It is impossible to draw precise conclusions from data such as these; neither would precise conclusions be warranted from any experimental or theoretical studies. The inherent variations in structures and vehicles preclude results of high precision. On the other hand, it seems apparent:

*First.*—That the impact is less on a bridge than on the rigid types of pavements; and,

*Second.*—That the intensity of a blow from a truck wheel on a bridge floor, when the unit stresses in stringers or floor-beams approximate design values, may approach, but will not exceed, 80% of the blow of the same wheel on a reasonably rigid pavement.

## DISCUSSION

SEARCY B. SLACK,[29] M. AM. SOC. C. E. (by letter).—In compiling and considering available information on impact stresses in highway bridges the Committee has rendered a distinct service to all engineers concerned. The allowance made for impact in highway bridge design has varied widely, being different in almost every specification. Some engineers have taken the position that the available data were not conclusive and have made no allowance for impact, while others, through probable misinterpretation of the data, have made allowances which appear unreasonably high. The recommendation of the Committee is a happy medium between these extreme positions.

One of the main criticisms which will undoubtedly be made of the report is that the impact allowance for a given span length is the same for all truss members, whereas maximum stresses in the web members are caused by much shorter loads than the full span length; hence, greater impact allowance should be made. To meet this condition, $L$ of the impact formula has frequently been taken as the loaded length instead of the span length, as suggested by the Committee. The result of taking $L$ as the loaded length is that the allowance made for impact is uniform for the chord members, but varies for the web member in each panel. From the meager test data available this seems to be a needless refinement and the Committee is to be commended for simplifying the practice by recommending a formula which will give a uniform allowance throughout a given span. A further justification of this course is that the sheer weight of a modern highway bridge with concrete floor and paving has a great absorbing inertia, and a large part of the stresses in the members is due to dead load (except of course counters). Varying the impact allowance has comparatively little effect on the members.

In certain cases such as counters or unusual web designs, the formula proposed by the Committee probably does not provide sufficient allowance for impact. These are such special and limited cases, however, that a general formula could hardly be expected to apply to them.

In the interest of uniformity and simplification of highway bridge specifications it is to be hoped that the recommendations of the Committee will be widely adopted.

LLEWELLYN N. EDWARDS,[30] M. AM. SOC. C. E. (by letter).—This report contains instructive and valuable information. However, it seems unfortunate that the research tests and the data secured therefrom, which have been studied by the Committee, did not cover a wider range of highway bridge types, span lengths, and conditions of loading. A large proportion of American highway bridges are short-span structures, or are composed of multiple spans of short length. Incidentally, a considerable percentage of the superstructures of these bridges are constructed of reinforced concrete and are of either the slab or the T-beam type. In general, reinforced concrete slabs are used for spans varying from 2 ft. to 20 ft. in length and T-beams from

[29] Bridge Engr., State Highway Board, Atlanta, Ga.

[30] Care, Div. of Tests, U. S. Bureau of Public Roads, Washington, D. C.

21 ft. to 45 ft., with occasional structures ranging up to 60 ft., in length. The reinforced concrete through-girder type of superstructure is used to a limited extent. The test data studied by the Committee contain little information that can be construed to apply to these structures.

It is mentioned in the report that, apart from the physical irregularities involved in roadway floor surfaces, the design of the structure itself was found to be a factor involved in the determination of impact stresses. From examinations of the physical condition of many bridge structures, the writer has been forced to recognize that not only adequacy in the proportioning of the sections of the main members of bridges, but also an equal liberality in the proportioning of the detail parts forming the connections between the individual members, is of paramount importance in the service functioning of these structures. Until more is known definitely about the ways in which different types of bridge structures and their details of construction function under loadings, it seems hardly proper to predicate impact allowances upon other than a basis that applies to all types of highway bridges. Designers cannot assume with safety that the vehicles which pass over any structure will be equipped with wheels of a kind likely to produce minimum impact effects, nor can they assume that the materials or the methods of construction used will produce structures of an assumed good practice standard, or better. Irregularities in the surfaces of bridge roadways may result from poor workmanship incidental to their original construction, but there are perhaps more instances wherein failures of the surface resulting from traffic wear and tear have produced real obstructions to vehicle movement equal in magnitude and in many cases greater than the 1-in. by 2-in. obstruction used in the bridge impact test. However, apart from these conditions, it is fairly common, in areas where small stones and pebbles abound, to find these obstructions scattered promiscuously upon the surface of the roadway.

For motor trucks and other vehicles provided with springs, the impact effort is evidently produced by the unsprung load and the intensity of the spring pressure; but for other wheeled loads, as, for example, heavy road rollers, shovels, and other heavy portable equipment, there is no sprung load factor involved. In general, the speed rate of movement of these loadings of the latter class is comparatively slow, but frequently the loads are moved by truck traction rather than by their own power and in such cases speed may become a factor.

The Committee recommends "that for the design of highway bridge floors and floor-beam suspenders, the impact increment of stress be assumed as 25% of the live load stress", and suggests that this percentage should be used only when the floors are sufficiently smooth to conform to good modern practice. The designer can have no way of knowing just what will be the character of the roadway surface produced on the bridge for which he, perhaps, does not even prepare the construction detail plans.

The curves shown in Fig. 3 of the report are perhaps misleading in relation to the Conference Committee (A. R. E. A. and A. A. S. H. O., 1927) impact formula since this formula applies to all span lengths, instead of only

to those having effective lengths of 40 ft. and more. In speculations and meditations upon this problem of impact the writer has held rather rigidly to the idea that, in bridge structures, length of span—as a factor tending to provide a means of diffusing, distributing, and absorbing its dynamic effects—is an element to be considered. With this idea in mind he has assumed, naturally enough, the fundamental condition to be that of the impact effect of traffic on a pavement as applying practically without diminution to bridges of short span—in the culvert class—wherein the superstructure is commonly either built monolithically with the substructure, or is very rigidly supported thereon. This seems to be a logical assumption and is quite evidently the basis of the formula promulgated by the Conference Committee. Incidentally, the initial 40% impact increment chosen by the Committee seems to be justified by the tests.

In the investigations of the U. S. Bureau of Public Roads, the tests made with the object of co-ordinating the results secured by the use of the impact machine with results obtained by using motor trucks developed a condition which may be regarded as pertinent to the question under discussion, since they show a relation between rate of speed and height of obstruction, or its equivalent in irregularities of roadway surface. These comparative tests show that, in general, the variations in impact reactions resulting from speeds varying from 4 to 12 miles per hour are practically equal to the variations resulting from obstructions ranging in height from 0.33 in. to 1.38 in. ($\frac{3}{8}$ in. to $1\frac{3}{8}$ in.).

The impact test results studied by the Committee indicate rather sharply how much engineers should know concerning bridge structures, which has not yet been discovered by actual research tests and a study of the information so obtained.

IMPACT IN HIGHWAY BRIDGES COMMITTEE[32] (by letter).—The members of the Committee agree with Mr. Edwards that it is unfortunate that the data upon which the report was based, did not cover a wider range of conditions. However, they are more optimistic than he in believing that the data submitted are distinctly useful in anticipating the impact on reinforced concrete floors. The rigidity of a reinforced concrete floor is doubtless greater than that for a concrete floor on steel stringers and less than that for a concrete pavement. In Fig. 17, the Committee gives the relation between the dynamic force on bridge floors consisting of concrete floor on steel stringers and on concrete pavement. This diagram should be helpful in estimating the dynamic force on a reinforced concrete floor in terms of a known force on either a pavement or steel bridge floor.

The entire investigation shows a distinct reduction in impact with increase in unit stresses or, in other words, with increase in flexibility. Fig. 17 shows that the highest unit stresses observed were 10 000 lb. per sq. in., and indicates that with further increase in unit stresses, the impact would be reduced. The second conclusion of Appendix D of the Committee's report is so conservative

[31] *Public Roads*, Vol. 9, No. 6, August, 1928.

[32] A. H. Fuller, *Chairman*, Arthur R. Eltzen, E. F. Kelley, and F. G. Turneaure. This closing discussion is dated April 27, 1931.

that it may be reasonable to include the reinforced concrete floor in the general statement. For an unusually rigid concrete floor, it may be well to raise the 80% to 85 or 90%, or to another value that may meet the judgment of a designer or specification writer.

Mr. Edwards is correct in pointing out that the Conference Committee (A. R. E. A. and A. A. S. H. O., 1927) impact formula is shown incorrectly in Fig. 3, since the formula applies to all span lengths instead of only to those having span lengths of 40 ft., or more. The formula gives an impact increment of 40% for zero span rather than the 25% recommended by the Committee. He also states that the initial 40% impact increment chosen by the Conference Committee seems to be justified by the tests, and, further, that "designers cannot assume with safety that the vehicles which pass over any structure will be equipped with wheels of a kind likely to produce minimum impact effects, * * *".

Without inquiring as to the derivation of the Conference Committee formula, it is apparent that any opinion as to its superiority must be largely a matter of personal judgment since such experimental data as were available to the Conference Committee were also available to this Committee.

Having in mind the five basic considerations enumerated under "Recommendations for Impact in Floors of Highway Bridges" in the report, and the added fact that pneumatic tires are rapidly replacing other types on heavy trucks and buses, it is the judgment of the Committee that its recommendations provide adequate allowance for impact stresses.

There is an implied discussion of the report by the Society's Special Committee on Specifications for Bridge Design and Construction in the revision of Section 113[33] which was published in pamphlet form under date of June 27, 1929. The revised Section reads:

"*113.—Impact.*—The dynamic increment of the live load shall be added to the maximum computed live load stresses. For floor-beams and stringers, this increment shall be taken as 30%, and for floor-beam hangers as 60%, of the live load stress. For girders and truss members, the increment shall be determined by the formula:

$$I = S\left(\frac{50}{l + 160}\right)$$

in which,

$I$ = impact or dynamic increment to be added to live load stresses;
$S$ = computed maximum live load stress;
$l$ = loaded length of a lane of traffic, in feet, producing the maximum stress in the member. For bridges carrying more than one lane of traffic, the aggregate loaded length of all lanes producing the stress, shall be used.

"Impact shall not be added to stresses produced by longitudinal and lateral forces."

The Section as revised differs from the recommendation of the Committee in two distinct points: First, it retains the previous provision of 30% for floor-beams and stringers and of 60% for floor-beam hangers, while the report of the Committee, based upon later information, recommends 25%

[33] *Transactions*, Am. Soc. C. E., Vol. LXXXVII (1914), p. 1279.

for floor-beams, stringers, and floor-beam hangers; and, second, the Specification Committee accepts the formula for trusses prepared by the Impact Committee, but retains the modified loaded length of the original specifications rather than accept the single-span length, as recommended by the Impact Committee. There is unquestionably some logic in the point of view of the Specification Committee. For practical use, however, the single length apparently represents just as well the available knowledge on the subject. It is surely much simpler to use. Mr. Slack, in his discussion, supports the view of the Impact Committee.

In a discussion of the 1926 progress report of the Committee, F. O. Dufour, M. Am. Soc. C. E., presented some material on impact in highway bridges under light loads observed by him from 1908 to 1912.[34] The results of this work, as well as of other work for light loads observed by the Committee,[35] have very little bearing on the design of modern highway bridges. However, these results are historically interesting and are doubtless correct for the conditions under which they were obtained.

Since the report of the Committee was presented in January, 1929, no additional work on the effect of impact in bridges has been brought to its attention. The U. S. Bureau of Public Roads, however, has been continuing the researches on impact on pavements. Two reports of this work have been published[36] by James A. Buchanan, Associate Engineer of Tests, Division of Tests, U. S. Bureau of Public Roads. One of these reports is entitled "Motor Truck Impact as Affected by Rubber Tread Thickness of Tires". The object of this particular phase of the impact investigation was to determine the effect of reducing the thickness of the tread rubber on the cushioning properties of typical solid and cushion tires. The second report was entitled, "The Inter-Related Effects of Load, Speed, Tires, and Road Roughness on Motor Truck Impact". The experimental work which forms the subject of this report was conducted on five different pavements, with a definition of the roughness of each. Various tires were used, from "pneumatic" to "worn solid", with wheel loads from 2 500 to 10 000 lb., and speeds up to 30 miles per hour. The report presents a number of curves showing the results for the conditions observed and gives directions for interpolating for other conditions.

For the purpose of comparison, the speeds at which each type of tire would cause the same impact reaction as that caused by the pneumatic tire at maximum speed, were determined; and Table 6 gives the recommendations for use.[37]

In both these reports the author states that since the observation of these tests, a thorough investigation of the accuracy of instruments used has been made by the U. S. Bureau of Standards, in co-operation with the U. S. Bureau of Public Roads. As a result of this investigation, a statement is made that the results obtained are, in general, systematically from 10 to 15% too low.

[34] *Proceedings*, Am. Soc. C. E., October, 1926, Papers and Discussions, p. 1737–1742.

[35] *Public Roads*, September, 1924; parts of *Bulletins 63* and *75*, Eng. Experiment Station, Iowa State Coll., Ames, Iowa.

[36] *Public Roads*, September, 1930.

[37] *Public Roads*, September, 1930, Table 9, p. 150.

The results reported by the Committee were taken from previous work by the Bureau of Public Roads and from other work upon which the accelerometers were calibrated by that Bureau. It seems likely, therefore, that the statement also applies to the report of the Committee.

TABLE 6.—SPEEDS AT WHICH APPROXIMATELY EQUAL IMPACT REACTIONS WOULD BE PRODUCED BY VARIOUS TYPES OF TIRE EQUIPMENT.

| Tire equipment | Relative Speeds | | | | | | |
|---|---|---|---|---|---|---|---|
| | In percentages | In miles per hour | | | | | |
| Pneumatic | 100 | 40 | 35 | 30 | 25 | 20 | 15 |
| New cushion | 55 | 22 | 19 | 16 | 14 | 11 | 8 |
| New solid | 40 | 16 | 14 | 12 | 10 | 8 | 6 |
| Worn solid | 20 | 8 | 7 | 6 | 5 | 4 | 3 |

The reports mentioned give information which would be of great assistance in determining a basis for traffic regulation which would be applicable both on pavement and on bridges. If it is found practicable to determine the property of tires on various trucks and to maintain a speed regulation for each type of tire, or to eliminate the use of solid tires, much of the uncertainty of impact in bridges will have been removed.

# FLORIDA HURRICANE

## FINAL REPORT OF THE COMMITTEE OF THE STRUCTURAL DIVISION[1]

WITH DISCUSSION BY MESSRS. F. O. DUFOUR, T. L. CONDRON, E. W. STERN, AND DAVID A. MOLITOR

In enumerating the effects of the Florida hurricane of September 17 and 18, 1926, it may be well to give a brief description of the storm. As in all tropical hurricanes, the wind blew in a circle with an area of calm in the center. F. L. Stearns, Assoc. M. Am. Soc. C. E., who visited Miami on behalf of the Committee soon after the storm, stated that the first half came from the northeast and the second half from a little east of south instead of from an exactly opposite direction. He felt that the explanation for this was that the storm changed form somewhat when it struck the land. He assumed that the center of the storm passed directly over Miami. It can be readily explained, however, by assuming that the center of the storm passed somewhat to the south of Miami. In Fig. 1 is shown a diagrammatic sketch of the storm. Point *A* represents the location of Miami during the first half and Point *B*, the location for the second half. The arrows indicate the direction of the wind. The time between the first half and the second half was about an hour, which indicates that Miami was not far removed from the path of the storm center.

In his report Mr. Stearns gave the storm effects on all the various forms of structures, but as a large part of these were not designed by engineers and are of such a character that they are not susceptible of close mathematical analysis, the Committee can add very little to present knowledge by a study of them. As the damage done to these structures was so many times greater than that done to structures designed by engineers, the necessity of technical design or more careful construction for the smaller structures as well as the larger ones is clearly shown.

It would be of considerable value to the Engineering Profession if an accurate determination of the wind pressure could be made, but the Committee does not deem it possible. On the top of the Meyer-Kiser Building was

[1] Presented at the meeting of the Structural Division, New York, N. Y., January 19, 1928.

a small observation room, about 18 by 21 ft., with four small columns in the corners supporting the roof. The walls were blown out and the four columns bent. It would require a pressure of about 65 lb. per sq. ft. to produce the distortion which occurred and this figure is probably as good as can be determined; but it cannot be taken too seriously because the area of exposure at the time of failure is uncertain.

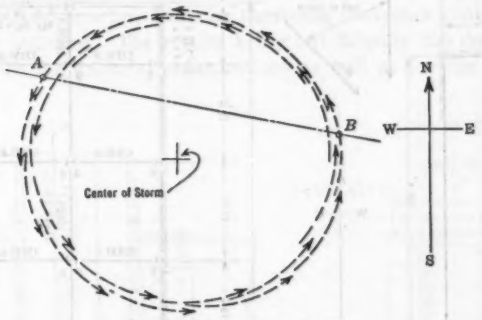

FIG. 1.—DIAGRAM OF STORM.

Professor Morris, of the Committee, has computed that it would have required about 60 lb. per sq. ft. of wind pressure to bend the columns in the front of the Meyer-Kiser Building. It is possible that the failure of the wall allowed the building to sag quickly to leeward and applied a blow of unknown force to the columns, producing a serious effect, although the wind, striking the building at an acute angle, may not have applied a very severe normal pressure. Hence, the static stresses computed may have little relation to the applied pressure. The evidence, however, indicates that for areas of moderate size, the storm probably exerted a pressure of more than 50 lb. per sq. ft., but there is no evidence that this was the case over the entire area of a building.

The two Miami buildings which suffered most from the storm were the Meyer-Kiser Building and the Realty Board Building. A study of the design of these two buildings teaches some interesting lessons. The plan of the Meyer-Kiser Building is shown in Fig. 2 (*a*), from which it can be seen that the south end is about 45 ft. wide and the north end about 39 ft. wide. The length is about 140 ft. The height was about 176 ft., not including penthouses. The dashed line shows the distortion from the storm. On Fig. 3 is shown a typical floor plan. The type of wind braces used is shown on Fig. 2 (*b*) and on Fig. 4. The connection shown is used at points marked *B* in Fig. 3. Based on the number and size of the rivets in the wind braces and assuming the elastic limit of the steel at 36 000 lb. per sq. in., the steel work alone, without any help from the walls, should have resisted a wind pressure of about 15 lb. per sq. ft. at the fifth floor. However, the clip angles were so thin that in bending they did not develop more than 25% of the value of the rivets. These clip angles in many cases bent or broke, thus destroying all the neces-

sary strength; and even if they had not broken they would have been so limber as to have given the building little stiffness. The columns too were not suited to develop the strength for the type of connections used.

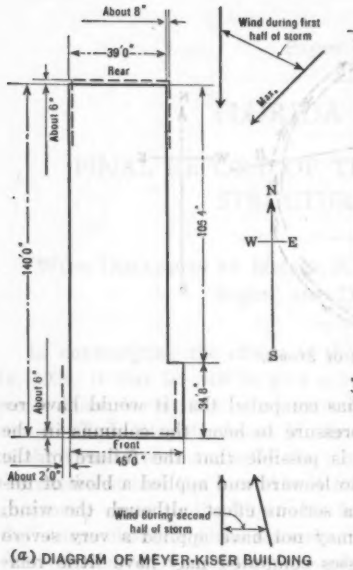

FIG. 2.—PLAN AND DETAILS, MEYER-KISER BUILDING.

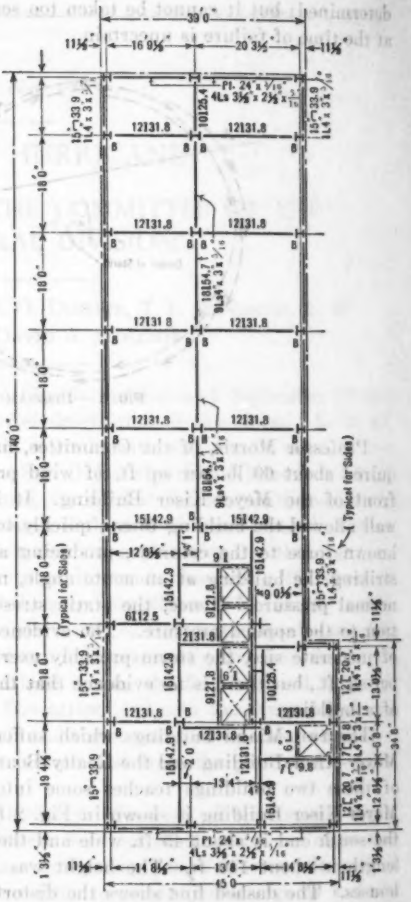

FIG. 3.—TYPICAL FLOOR FRAMING PLAN, MEYER-KISER BUILDING.

The columns were made up of plate and angle sections and in the area that failed they had few cover-plates. The thickness of the angles in the columns was such that the outer rivets connecting the clips to the columns could not develop their full strength before bending the flange angles of the columns. In addition, in the south end of the building, the floor system was broken up with elevator shafts and there was very little bracing. What bracing there

was, was on beams shallower than the 24-in. spandrel girders in the front or south wall. The result was that this wall took nearly all the wind load for this end of the building until it failed. At the north end there was bracing of a similar character, but more bracing in the floor system, which evidently is the reason for less distortion of this end of the building. In conclusion, it is perfectly evident that there was no adequate wind-bracing in this building, and the bracing which was used, was made valueless by the details. It is difficult to understand how any loans or hurricane insurance could have been obtained on this building. The results bring out forcibly the desirability of engineering advice for financial organizations as well as for the owners.

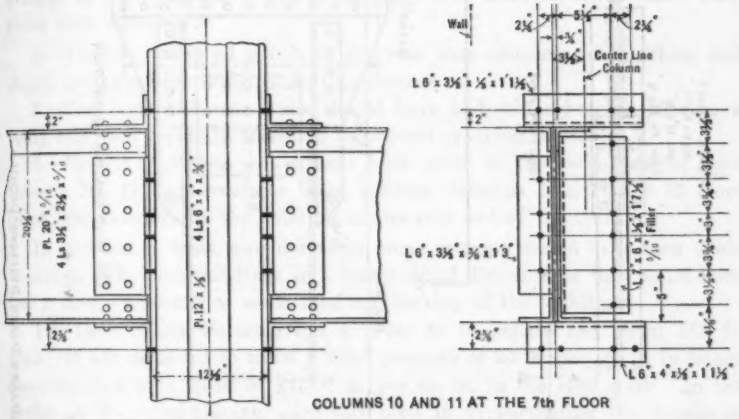

FIG. 4.—WIND-BRACING DETAIL FOR MEYER-KISER BUILDING.

The Realty Board Building also suffered quite severely during the storm. The walls and partitions were much cracked, but the steel framework was not badly distorted. The late E. A. Stuhrman, M. Am. Soc. C. E., who was engineer in charge of reconditioning this building, stated that a careful survey showed that it was only 3⅞ in. out of plumb and part of this may have been due to inaccuracies of erection. There was greater evidence of lack of stiffness than lack of strength, because the structure swayed enough to crack the walls without, seemingly, passing the elastic limit of the steel.

This building has a frontage on the west of 45 ft. and a width in the rear of 34 ft. Its length is 94 ft. It is fifteen stories high and the height of the top of the pent-house is about 166 ft. Fig. 5 (*a*) shows a typical floor plan of this building, and the main bracing connections are shown in Fig. 5 (*b*). All these connections are attached to 15-in. and 18-in. beams. The other transverse beams are 6 in. and 10 in. deep in the typical floors, with very much less rigid connections. It is probable that, on account of their greater stiffness, the beams and connections shown in Fig. 5 (*b*) took practically all the wind stresses. The connection of the wind brackets to the columns is an important feature of the construction. The second line of rivets

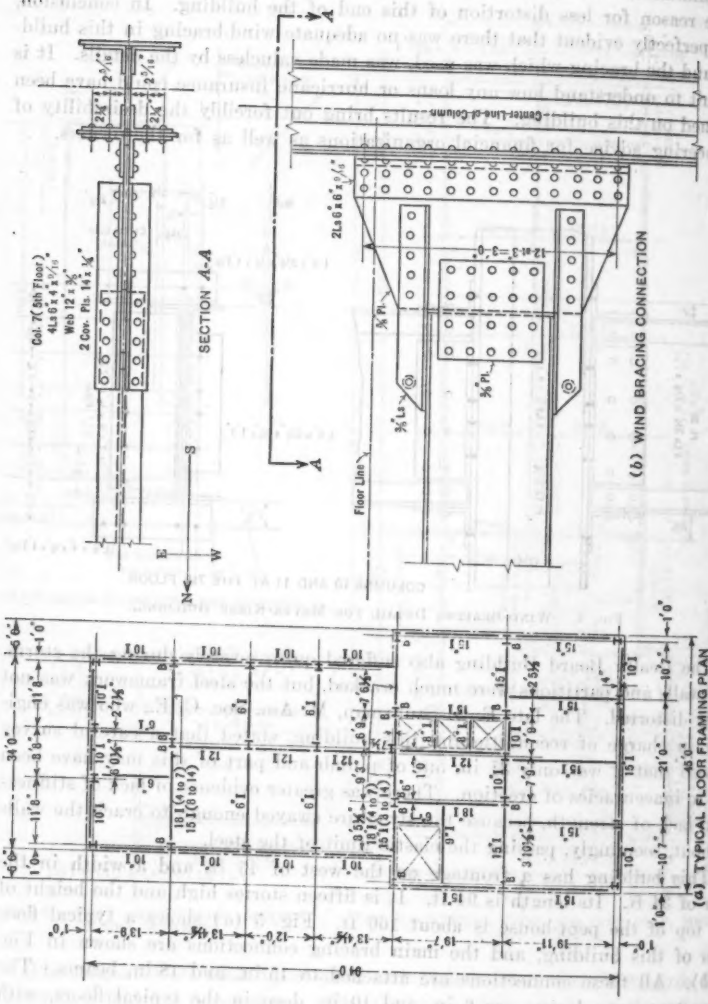

FIG. 5.—REALTY BOARD BUILDING DETAILS.

connecting the brackets to the columns is practically valueless because the connection angles of the thickness used would be weak in bending at the root if the full strength of these rivets was developed. Mr. Stuhrman stated that the steel work was checked and found to comply with the Building Code which calls for a 20-lb. wind load. Probably the combined stresses used were 24 000 lb. per sq. in. Without entering into any controversy on this point, the Committee doubts whether the available strength (before a 24 000-lb. unit stress was reached in some parts) would withstand a full 20-lb. wind load. A study of the design, however, indicates that a genuine effort was made to brace this building properly and any shortcomings should not be attributed to an attempt at false economy. The following points, however, should have been given more attention:

1.—The two unbraced panels in the rear were elements of weakness and should not have been designed in this manner.

2.—The front and rear walls should have had stiffer bracing because a fairly stiff steel frame is necessary to prevent cracking of walls.

3.—Special provision should have been made at the stair opening near Column No. 14 to prevent the beam between Columns Nos. 14 and 15 from being bent laterally by the twisting of the rear end of the building.

In addition to these considerations, some attempt should have been made to stiffen both these buildings in a longitudinal direction as this would have had a strong tendency to resist torsional racking of the buildings.

The Daily News Building has a tower 40 ft. square and about 255 ft. high. It was designed to resist a wind pressure of 20 lb. per sq. ft. in either direction at a unit stress of 24 000 lb. per sq. in. in the steel work. In the design of the wind-bracing, care was used in proportioning the details as well as the main members. There was a special effort to make the connections stiff as well as strong. Besides this, heavy interlocking tiles were used for the walls instead of partition tiles. This building suffered no structural damage. Based on these facts, the building should not show signs of failure before the elastic limit of the steel was reached, which is at about 36 000 lb. per sq. in. This is equivalent to a wind pressure of 30 lb. per sq. ft. over the entire surface without any assistance from walls.

The main lessons to be learned from the foregoing considerations are as follows:

1.—Adequate wind bracing is necessary in the construction of a building.

2.—The details must be carefully designed for the same strength as that for which the main members are calculated.

3.—In designing different types of wind braces for one floor level the designer should take the relative stiffness of the members into account and not depend too much on the arithmetical summation of the total strength of the connections as some members may be greatly overstressed before the others take any large proportion of the stress. On buildings of moderate size, however, it is permissible to take care of this point by the use of an adequate unit wind pressure.

FIG. 5.—REALTY BOARD BUILDING DETAILS.

4.—Stiffness as well as strength is a prime requisite for a good steel design. This is especially realized by the best engineers in designing narrow and high buildings used for living quarters, such as hotels and apartment houses, where the confidence of tenants in the stability of the structure is of the utmost importance.

5.—The effects of the Florida hurricane indicated that the floor system acted as a stiff plate or horizontal girder and that all columns were subject to the same horizontal deflection, except that the entire structure twisted, where one end of the building was stiffer than the other. In designing wind-bracing this must be given full weight and the bracing arranged, if possible, so that no twisting action from the wind can come into play. This means that the wind pressure at one end of a building and the bracing designed to resist it, must balance the relation between the corresponding pressure and bracing at the other end, so that the structure will deflect about the same amount at both ends. This principle applies especially where one end is higher or narrower than the other.

The following is quoted from a preliminary report made to the Structural Division on January 20, 1927, by the Chairman of this Committee:

"Summarizing the fields that this Committee might well cover are the following:

"1.—A determination of the wind pressure exerted by the storm.
"2.—A standard method for figuring wind stresses in tier building construction.
"3.—Standard details best able to resist wind stresses both from the standpoint of stiffness as well as that of strength.
"4.—A study to determine whether the same requirements for wind should be used for buildings having a low ratio of height to width as for buildings having a high ratio.
"5.—The strength of masonry walls and the bearing they have on wind bracing.

"I feel that there is a good chance of our accomplishing something valuable in connection with a part of these at least though it may entail more work than the Committee as now constituted can find time to perform. I am sure, however, were we able to cover any one item thoroughly, our work will have been well worth while."

Taking up the items mentioned in the order given:

*1.—A Determination of the Wind Pressure Exerted by the Storm.*—The Committee feels that, unfortunately, a strict determination of the wind pressure cannot be made. This has been covered earlier in the report. The results showed, however, that all the tall buildings consistently designed for a wind load of 20 lb. per sq. ft. survived without serious damage.

*2.—A Standard Method of Computing Wind Stresses in Tier Building Construction.*—The results of the storm showed that for buildings of the size and shape found in Miami, the common theory, as given in Fleming's "Manual on Wind Bracing", will produce structures capable of standing up under the most severe conditions. The failures were caused by neglecting to apply the theory consistently. On the other hand, buildings so designed will not necessarily be sufficiently stiff to give the tenants confidence in their safety. More-

over, in the case of very high or narrow structures, the obvious errors involved render the results less secure than is desirable. From a standpoint of strict theoretical determination of wind stresses, an adaptation of the slope deflection method will probably give the best results.[2] Some of the members of the Committee, however, are not entirely convinced that this method can come into universal use on account of the work that it will entail.

A consulting engineer generally has a limited time in which to design a structure, and if a method could be developed which will approach in results the slope deflection method and still entail very much less work, it would be desirable. One of the members of the Committee has used a method apportioning the amount of wind shear taken by the various columns on the basis of the relative moments of inertia of the columns. This is based on the assumption that the length of the column is the same. If the lengths between wind brackets vary considerably, as in the case of deep girders, these shears will have to be corrected to take care of the difference in column lengths. A closer approximation would take into account the effect of variations in the stiffness of attached floor-beams, which would involve practically the method developed by Professor Morris. The Committee feels that some study should be given to this before suggesting a definite method for computing wind bracing.

*3.—Standard Details Best Able to Resist Wind Stresses Both from a Standpoint of Stiffness as Well as That of Strength.*—Such details have been pretty well standardized by a few of the leading consulting engineers in New York, N. Y., and these could be released at any time. It would seem advisable, however, to release such information at the same time that a method for computing wind-bracing is developed and, therefore, no action has been taken in regard to this subject.

*4.—A Study to Determine Whether the Same Requirements for Wind Should Be Used for Buildings Having a Low Ratio of Height to Width as for Buildings Having a High Ratio.*—This item is also related to the method of computing wind-bracing and can well be taken up at such time as Item 2 is considered.

*5.—The Strength of Masonry Walls and the Bearing They Have on Wind Bracing.*—To secure any really valuable information on this subject, it would probably be necessary to have numerous tests made, which would entail considerable expense.

In the preliminary report before quoted, it was stated that to make a complete report might entail more work than the Committee, as now constituted, can find time to perform. To make an investigation along this line requires a very large amount of work, and few men are able to devote sufficient time to get results which entirely satisfy them. One of the members of the Committee, Mr. Miller, feels that a great deal of information as to wind pressure could be secured by means of self-registering barometers.

When the American Insurance Union Building was built in Columbus, Ohio, due to the initiative of Professor Morris, numerous gauge points were

[2] This is covered by the paper entitled "The Design of Tall Building Frames to Resist Wind", by Albert W. Ross, Jr., Jun. Am. Soc. C. E., and Clyde T. Morris, M. Am. Soc. C. E., *Proceedings*, Am. Soc. C. E., May, 1928, Papers and Discussions, p. 1395.

established on the columns and targets were located in the elevator shafts by which it is possible to measure the lateral displacement of the building during a storm for a height of 34 stories. No doubt a great deal of valuable information could be obtained by careful readings made on this building. Generally, owners are afraid to have any such tests made as they think it will cause the public to doubt the safety of the buildings; but in this case as the matter was all arranged when the building was constructed and the public now understands that work such as this is for educational purposes, the ordinary objections do not prevail.

The American Institute of Steel Construction, for several years has endeavored to advance knowledge along engineering lines in the use of steel. This question has been discussed with some of the members of the Institute, and it is possible that if its finances permit, it could be persuaded to establish a fellowship in Ohio State University to study the entire problem of wind bracing. In this case the Institute would probably be glad to have the work done under the general supervision of a committee of the Structural Division of the Society, provided that this would be agreeable to the authorities of the Ohio State University. Such supervision, of course, would involve some expense to the Society. In all probability, the student appointed to this fellowship would work under the direct supervision of Professor Morris, of this Committee. If this should be done, many new facts might be discovered in regard to wind-bracing which are now unknown, and a good student devoting his entire time to the subject under the proper supervision, could carry out many investigations which would entail far more work than any individual member of the Structural Division could devote to the subject.

In conclusion, the Committee hopes that this incomplete report may be of some value to the Engineering Profession in the design of wind-bracing. It wishes, of course, to stress the point that no system of rules, however complete, can take the place of thorough technical knowledge and long experience and judgment in work of this character; and that the work of designing wind-bracing for tall narrow buildings should never be entrusted to novices.

# DISCUSSION

F. O. DUFOUR,[3] M. AM. SOC. C. E.—The report of the Committee is good. It covers all the points in an orderly and concrete manner. The speaker made an inspection of the effects of wind on buildings at Miami shortly after the storm.

The storm was as violent as any that has been registered; and on account of its passing over a city with many modern structures the opportunity for constructive criticism of the effects on usual engineering construction in areas of high wind velocity was exceptional.

What the actual velocities and pressures were appears to be immaterial, but nevertheless interesting. The speaker checked Professor Morris as to pressure when computed from the bending of columns in the front bent of the Meyer-Kiser Building, basing the wind distribution on the usual assumptions. This pressure was 60 lb. per sq. ft. Whether or not this was the pressure or whether the effects were due to synchronous behavior or those of impact due to sudden failure of the curtain walls is beside the question. The fact that the greatest destruction of the columns of the Meyer-Kiser building came after the walls were out appears to indicate that the bending was not due to the sudden failure of the walls. If the columns of the Meyer-Kiser Building had been designed for a pressure of 60 lb., even with the details used, it is most probable that no material distortion would have occurred.

The fact that wind-bracing in the form of knee-braces was used below the fourth floor and that no column distortion occurred below that floor, appears to indicate that had wind-bracing of this type been used throughout no column distortion would have occurred.

That the floors and ceilings were not even superficially cracked and that the rear of the building "kicked out" in a direction opposite to the front indicates that, as horizontal girders, these floors distributed the wind to the vertical bents in accordance with the usual supposition. Had the vertical wind bents, however, been equally spaced and had the wind pressure been uniform, it is probable that less damage would have occurred. That the wind pressure should have been uniform was, of course, not to be expected; that the strength of wind bents should be proportioned to stand a maximum difference in pressure is evident.

The report most properly calls attention to the insufficiency of details. The speaker noted a few broken connections and clip angles, but not more than three. A few more were cracked; many were bent.

In the case of the broken clip angles, one showed neither reduction of area nor elongation. Evidently, this break was due to causes other than the storm. Most of the bent connection angles showed no scaling. This indicated that the material was not stretched beyond the elastic limit. The partial springing back of the building when the walls were removed also indicated this.[4]

[4] *Engineering News-Record*, the late E. A. Stuhrman, M. Am. Soc. C. E., December 29, 1927.

The stiffness of structures in areas liable to high wind velocity is, according to the report, next to strength, the most important consideration. The Committee has covered this in an efficient manner. Adequate interior wind bents and some construction for interior partitions other than plain partition tiles, together with a type of gusset-plate or knee-brace construction for the spandrel bents, are certainly required, especially when the depths of the spandrel beams are small.

An extended experience in the design of structures requiring stiffness as well as strength prompts the speaker to suggest that a design based on a unit stress of 9 000 lb. per sq. in. in tension, properly decreased for compression and increased for combined loads, will (in cases when the ratio of width to height is one-tenth or less) provide the desired stiffness, due regard being given to details sufficient to develop full strength.

It is believed that buildings designed in accordance with any of the methods commonly used by the leading structural engineers—a wind pressure of 30 lb. per sq. ft. and a due regard to details and wind-bracing—will, even with the present prescribed unit stresses, withstand injurious distortion as far as the steel frame is concerned. Consideration must be given to the element of stiffness, however, to prevent injury to the walls or inconvenience to the occupants. The floors will take care of themselves.

T. L. CONDRON,[5] M. AM. SOC. C. E.—It is stated that if a wind load of 20 lb. produced a stress of 24 000 lb., a 30-lb. wind load would produce a 36 000-lb. stress. The speaker believes that the 24 000-lb. stress was probably due to combined forces and that the difference between the unit stress of 24 000 lb. and 36 000 lb. would be due entirely to the additional wind load.

E. W. STERN,[6] M. AM. SOC. C. E.—The report of the Committee is interesting; it contains valuable information and suggestions, and it is hoped that its recommendations may be carried out so as to establish a fellowship at one of the engineering colleges, for a study of the entire problem of wind-bracing.

In this connection the speaker suggests that a series of tests be made to determine wind pressures on large surfaces. Few such tests are available and most of these were made on comparatively small surfaces, many years ago. In the light of present-day methods of experimentation, it is reasonable to suppose that much more accurate results would be obtained.

The usual type of beam and column connection illustrated in some of the structural handbooks, namely, a seat angle under the beam and a clip angle on top, has again been proved utterly inadequate in the Florida hurricane. The speaker has seen a building designed with such details pulled about 1 ft. out of plumb during erection, due to the thrust of a boom derrick handling a small load. Of course, thin angles in wind-bracing should never be used. They bend and pull away from the rivets and allow the columns to get out of plumb. This same criticism applies to light columns in which the com-

[5] Cons. Engr. (Condron & Post), Chicago, Ill.
[6] Cons. Engr., New York, N. Y.

ponent members are not heavy enough to transmit the load of the wind connections without bending or twisting, as exemplified in the buildings of Miami. All this is a matter of common knowledge among those who have experience in the supervision of the erection of the structural framework of buildings. Wind-bracing details require very careful study and, of course, should be designed with proper care as to stiffness in all directions. The speaker's practice has been to brace every bent longitudinally as well as crosswise with connections having side angles on every beam, even if the height and shape of the building are such that wind-bracing may not be necessary. During the erection of the steel, a framework braced by such details, is rigid, is easily kept plumb, and is not readily distorted by the swinging of boom derricks.

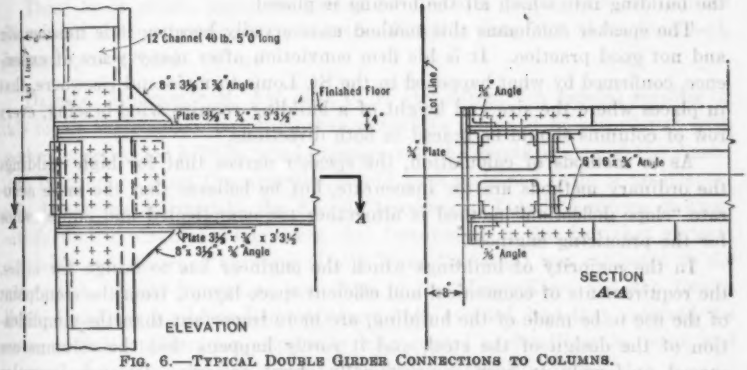

FIG. 6.—TYPICAL DOUBLE GIRDER CONNECTIONS TO COLUMNS.

The speaker offers for consideration the typical design shown in Fig. 6, which he often uses. It has proved to be very efficient in practice developing a large moment without projecting brackets, and the members are easy to erect.

The speaker was in the destructive tornado in St. Louis, Mo., in May, 1896, and has still a very lively recollection of what happened. There were 8 500 buildings damaged, 321 buildings totally wrecked, 255 lives lost, and it all happened within less than 15 min. Walls of the buildings which were wrecked usually fell outward; roofs were lifted and carried very great distances in some cases. The steel frame buildings—either finished or in course of construction—which were well designed, were not damaged, while many of the others with cast-iron columns and no wind-bracing were seriously impaired, some being completely destroyed. One such building was twisted about 1 ft., and another, a six-story building with cast-iron columns and brick walls laid in lime mortar, was pulled about 1½ ft. out of plumb.

The wind velocities were difficult to record because the weather gauges blew away, but it is the speaker's recollection that the highest velocity registered was about 120 miles per hour before the failure of the apparatus. A committee of very able engineers of St. Louis made an investigation immediately after the tornado and evaluated some of the wind pressures, among

which was one derived from the study of a circular brick smokestack, 160 ft. high, which was blown over about 40 ft. above the ground. They found that this stack must have been subjected to a pressure of at least 85 lb. per sq. ft. static over an area 110 ft. high by 14 ft. in diameter. A very valuable paper[7] on the wind pressures in the St. Louis tornado was written by the late Julius Baier, M. Am. Soc. C. E.

There are apparently two different methods of designing wind-bracing that are in use among structural engineers. One of these, only a partial bracing of the bents, is exemplified in the buildings investigated in Miami. Quite a number of buildings in New York City have wind-bracing around the walls only, the theory being that if the floors act as horizontal girders they will transmit the wind pressure on the intermediate columns into the ends of the building into which all the bracing is placed.

The speaker condemns this method unreservedly because it is unscientific and not good practice. It is his firm conviction after many years of experience, confirmed by what happened in the St. Louis tornado and elsewhere, that in places where the size and height of a building require wind-bracing, every row of columns should be braced in both directions.

As to methods of calculation, the speaker agrees that for high buildings the ordinary methods are too inaccurate, but he believes that the more accurate "slope deflection" method is altogether too complicated and cumbersome for the practising engineer.

In the majority of buildings which the engineer has to design for cities, the requirements of economical and efficient space layout, from the standpoint of the use to be made of the building, are more important than the simplification of the design of the steel, and it rarely happens that the columns are spaced uniformly or even symmetrically about an axis. In such irregular cases the problem of calculating the stresses in the wind-bracing by the "slope deflection" method, or by any other accurate mathematical analysis, because of the many unknown quantities would involve so many simultaneous equations as to make the solution of the problem impractical, if not impossible. The case of the 48-story American Insurance Union Building, at Columbus, Ohio[8] is of interest in this connection. This building has six columns crosswise and was almost symmetrical about the axis, and was so assumed for the calculations. Other assumptions were made so that it was possible to get results which were correct for that part of the structure below the fifth floor only. This required, however, the solution of thirty-two simultaneous equations containing thirty-two unknowns. The time and expense involved in making these calculations would be prohibitive to an engineer in active practice even if he were an expert mathematician; and, furthermore, if the structure were not symmetrical about the axis a mathematical solution would be impossible.

For comparatively low buildings with several rows of columns the "cantilever method" is well worth considering. It seems to give safe structures and is quite simple to apply; but for high narrow buildings it is not suf-

[7] *Transactions*, Am. Soc. C. E., Vol. XXXVII (June, 1897), p. 221.

[8] *Proceedings*, Am. Soc. C. E., May, 1928, Papers and Discussions, p. 1401, Fig. 3.

ficiently accurate, and it is necessary, therefore, to find some other way which will prove sufficiently accurate, and at the same time be much easier, more practical, and far less expensive than any mathematical method thus far developed. George E. Beggs, M. Am. Soc. C. E., has developed such a method, using models of cardboard or celluloid, and an interesting modification of this has been offered by Mr. Anders Bull, who uses brass rods in place of cardboard or celluloid models.[9]

As regards the amount of wind load to use, the speaker believes that for tall buildings it is probably more nearly in accordance with actual conditions to use a higher wind pressure at the top than at the bottom, commencing, for example, with 40 lb. per sq. ft. for a 60-story building and reducing this to 10 lb. per sq. ft. at the level of the fourth floor.

These loads might apply to almost all districts throughout the United States, but in the hurricane or tornado districts, they should be increased, perhaps by one-third.

David A. Molitor,[10] M. Am. Soc. C. E. (by letter).—A careful reading of this report leads one to conclude that structures designed in accordance with modern practice for a 20-lb. wind pressure and the specifications of the American Institute of Steel Construction, would have sustained little or no irreparable damage by storms like the Florida hurricane. This is a source of great satisfaction to structural engineers, due fortunately to the fact that at least one fairly well-designed building (Daily News Building) was subjected to the severe test. Such damage as was done to the Meyer-Kiser and the Realty Board Buildings would undoubtedly have been avoided, had they received the same careful consideration, especially with regard to detailing the beam and column connections, as was given to the Daily News Building.

Therefore, the failures recorded cannot be attributed to lack of engineering knowledge respecting methods of wind analysis and designing of connection details, but must be charged to carelessness or ignorance on the part of designers who did not fully consider the information available to them. The writer has treated this subject more fully in a discussion[11] of another paper.

The following comments are offered relative to the five points suggested by the Committee:

*1.—A Determination of the Wind Pressure Exerted by the Storm.*—While this might be impracticable, the actual experience gained from designs based on a 20-lb. wind pressure seems to justify adhering to this practice; but why not use a 25-lb. pressure for this particular storm-infested area in future designs? Each locality has a Weather Bureau record of wind velocity covering a period of 10 to 20 years, from which the maximum can be selected for use, as in designing tall chimneys. From this maximum velocity, the pressure, in pounds per square foot, can be computed from the formula,

$$p = 0.0033\,V^2 \qquad (1)$$

in which, $V$ is wind velocity, in miles per hour.

[9] *Engineering News-Record*, Vol. 99, December 28, 1897.
[10] Detroit, Mich.
[11] *Proceedings*, Am. Soc. C. E., January, 1929, Papers and Discussions, p. 189.

Records show maximum wind velocities ranging from 50 to 120 miles per hour, for various stations in the United States, but it would not seem prudent to use anything less than 60 miles per hour as a basis for computation even if weather reports gave a less value as the maximum. Except in some of the storm-swept areas on the Atlantic Coast and the Gulf of Mexico, 100 miles per hour is considered very conservative, and 87 miles is generally maximum for all inland points.

*2.—A Standard Method of Computing Wind Stresses in Tier Building Construction.*—Such a method has been used by many structural engineers, and it is difficult to understand why less rational methods should be used at all, or why more complicated methods, offering no greater reliability, should be proposed now.

*3.—Standard Details Best Able to Resist Wind Stresses, Considering Both Stiffness and Strength.*—It is in this connection that the most flagrant violations of good practice have been committed, of which examples described in the report are representative. There is no valid reason for this, because insufficiency in design means incompetency on the part of designers. Many important steel frames of to-day represent first attempts by amateurs.

*4.—A Study to Determine Whether the Requirements for Wind Should not Be Made to Depend on the Ratio of Height to Width of a Building.*—When strength alone is considered, the specified unit stresses govern every design. As rigidity is a factor of prime importance, however, and may vary between wide limits, it follows that the load assumptions and allowable unit stresses should bear some relation to the ratio of height to width of the frame. In speaking of rigidity of the steel frame alone, as affected by its width (neglecting the effects of the architectural fill materials), it should be noted that width governs the cantilever stiffness only when complete cross-frames or diagonal systems are used. For the so-called rigid frame, the basal width does not materially affect the cantilever stiffness which latter depends largely on the number of columns and the column details in the wind-resisting bent.

*5.—The Strength of Masonry Walls and the Bearing They Have on Wind Bracing.*—This the writer interprets to mean the effect of the architectural fill materials, including concrete, stone, brick, or tile, etc., composing the spandrel filling, floors, partitions, and fireproofing of the entire building. The inherent rigidity of the steel frame alone, as designed with specifications of the American Institute of Steel Construction, would not afford tenantable tall buildings when subjected to ordinary 60-mile wind. Deflection calculations prove this. However, experience teaches that this practice does produce commercially satisfactory buildings, and, hence, the architectural fill materials must be credited with supplying the extra rigidity required in such structures.

Perhaps in time some measurements of lateral building displacements may become available for the American Insurance Union Building, at Columbus, Ohio, in which instruments for taking such observations were installed during construction. This would be most gratifying, as no reliable measurements of this kind appear to be recorded.

The idea of instituting a fellowship to study the entire problem of wind-bracing, by appointing a good student to work under the direct supervision of

Professor Morris, is rather unique, especially in view of the closing remarks "that the work of designing wind-bracing for tall narrow buildings should never be entrusted to novices." It might have been more fitting to suggest the appointment of a committee of experts, trained by education and experience, to develop a practical and rational method of designing wind-bracing, so that a good student who is most likely a novice, could produce, with some practice, a creditable design.

Paper No. 1788

# ICE AS AFFECTING POWER PLANTS[1]

## FINAL REPORT OF COMMITTEE OF POWER DIVISION

WITH DISCUSSION BY C. M. DAILY, M. AM. SOC. C. E.

At the Annual Convention of the Society held in Chicago, Ill., in July, 1923, a paper was presented to the Power Division by William T. Walker, M. Am. Soc. C. E., on the subject "Ice Problems of Hydro-Electric Plants." In this paper Mr. Walker pointed out the need of the study of ice problems and urged the formation of a committee. At the conclusion of the discussion it was voted to appoint such a committee of the Power Division to study the subject of "Ice as Affecting Power Plants." The Committee appointed by Charles F. Loweth, Past-President, Am. Soc. C. E., (then President, Am. Soc. C. E.), consisted of the following members: Francis C. Shenehon, Minneapolis, Minn., *Chairman*, John R. Freeman, Providence, R. I., John L. Harper, Niagara Falls, N. Y., Daniel W. Mead, Madison, Wis., Louis C. Sabin, Cleveland, Ohio, and William T. Walker, Minneapolis, Minn.

The death of Mr. Harper in November, 1924, reduced the Committee to five. The geographical spread of the membership made meetings of the Committee difficult so that interchange of views has been by letter. The conception of the Committee of its best usefulness involved three elements: Observation, program-making, and compilation of facts as to existing practice. Consideration was given to the desirability of doing some research work, but none was undertaken.

At the Fall Meeting of the Society at Detroit, Mich., in October, 1924, a session of the Power Division was devoted to "Ice as Affecting Power Plants." Mr. Shenehon presented a brief report on the progress of work by the Ice Committee. An interesting talk was given by John Murphy, Electrical Engineer, Canadian Department of Railways and Canals, of Ottawa, Ont., Canada. Mr. Murphy's talk was illustrated by motion pictures and slides showing frazil formation and devices used to combat ice in hydraulic plants. A comprehensive discussion entitled "Ice Problems at Hydro-Electric Plants" was presented by Thomas H. Hogg, M. Am. Soc. C. E., Hydraulic Engineer

[1] Presented at the meeting of the Power Division, New York, N. Y., January 17, 1929.

of the Ontario Hydro-Electric Power Commission.[2] No activity of the Committee appears in the records of 1925.

In 1926 a search was authorized in the Engineering Societies Library under the following specifications:

(*A*) Ice jams in a river approaching a power plant, or jams in a river below, causing back-water rise and loss of head.
(*B*) Floating ice drawn into intakes or approach canals.
(*C*) Sheet ice forming in approach rivers, intakes, canals or forebays, including ice thrust on racks, gates, dams, and control works.
(*D*) Frazil as affecting intakes, control works, racks, and turbines.
(*E*) Snow, slush, or shell ice in ditches, flumes (as in the Sierras), intakes, control works, racks, and turbines.
(*F*) Combinations of Specifications (*A*), (*B*), (*C*), (*D*), and (*E*), in affecting power plants, forming on gates, racks, or dams.

Engineering treatments that have been devised to meet these troubles may be subdivided as follows:

Interception of sheet ice forming and breaking up in a head reservoir or lake (Specifications (*A*), (*B*), and (*C*)). This may be accomplished by the creation of slow current with consequent sheet-ice formation which serves as a barrier; or by intercepting works—as at Massena, N. Y.—formed of cribs and booms. It may also be accomplished by design of entrance of intake, canal, or forebay to by-pass the floating ice. The extent to which heat treatment may apply depends upon many conditions.

The physics of frazil (Specification (*D*)), including water temperatures, etc. (see works of Professor Howard T. Barnes, of McGill University, Montreal, Que., Canada); methods of combatting frazil; heat treatment; and forecasts of approaching trouble through surface temperatures.

Specifications (*E*) and (*F*) involve answers to the following questions: How far has the introduction of higher temperature water into forebays or collecting ponds lessened troubles in flumes or ditches? Will the housing of racks, with a temperature of 70° in the rack room, prevent the clogging of racks with frazil?

The search was completed in February, 1927. (See Appendix.)

In December, 1926, assignments were made to each member of the Committee on Ice as follows:

1.—Mr. John R. Freeman: The use of artificially produced heat, such as steam or warm air, to solve certain ice troubles in power plants.
2.—Mr. Daniel W. Mead: The solution of the problem of racks and their design to avoid ice troubles or to meet them.
3.—Mr. Louis C. Sabin: The ice conditions and troubles of the St. Marys River power plants and devices used in solving these troubles.
4.—Mr. William T. Walker: The ice troubles in the condensing water inlets of big steam plants and their solution.
5.—Mr. Francis C. Shenehon: The use of artificially produced heat, such as steam or hot air, to solve certain ice troubles in power plants.

In August and September, 1927, Mr. Shenehon visited hydro-electric installations in Norway and Sweden. In Sweden he visited the Porjus Devel-

[2] *Canadian Engineer*, November 11, 1924.

opment in Lapland north of the Arctic Circle and observed expedients used by the hydraulic engineers of these countries to meet winter conditions.

At the meeting of the Power Division in New York, N. Y., on January 17, 1929, Professor Barnes presented a paper on "The Constitution of Water and Nature of Ice,"[3] and Mr. Walker presented a paper on "Ice in the Intakes of Steam Power Plants."[3] The Committee on Ice as Affecting Power Plants, following this meeting, submitted its final report and requested dismissal.

Perhaps in the logical sequence of a treatise on ice the fundamental fact is the nature of water and its transformations under heat variation. Professor Barnes has treated this subject in his paper previously mentioned. He has pointed out[4] that,

"* * * water is an associated fluid, that its molecules are not simple $H_2O$ molecules but molecular aggregates of complex form. Steam or water vapor consists of simple molecules which are called Hydrol. Water appears to be composed of double molecules called Dihydrol, while ice of triple molecules is called Trihydrol. From studies of the physical properties of water such as specific heat, density, and viscosity, it has been concluded that the associated water molecules of dihydrol contain varying proportion of the triple molecules trihydrol, and that the amount of the latter increases as the temperature falls from the boiling point. At the freezing point the proportion of trihydrol is estimated to be as high as 37% and at 100° C. about 16%.

"Roentgen as early as 1892 stated that water contained ice in solution above the freezing point, and more recent studies have shown the identity of these ice molecules with the trihydrol. Before congealing, the water contains ice as a solution carries a salt, and the freezing point is the temperature where the solution becomes saturated with the ice and ready to produce the solid when the necessary energy is abstracted to enable the solid to precipitate out. To get this energy to flow out of the solution a small temperature depression is necessary, which we have already described. That the supercooling is not more pronounced is due to the rapid rate at which ice is formed tending to keep up the temperature so long as any water remains to form ice. Water supercooled by laboratory experiments to many degrees below 0° C. is a highly supersaturated solution of ice, and readily precipitates on being agitated or by introducing a small particle of ice. It is exceedingly interesting to observe the nature of this first precipitation. The particles of ice as soon as they can be seen under a microscope are devoid of crystal form and appear as a true colloid in small disc like particles. These flocculate and grow, passing through a crystal colloidal form to a true ice crystal. On allowing to grow slowly in quiet water they assume the form of a branching feathery snow crystal of most beautiful form. In rapidly moving water the crystals never become large, but are broken up and assume more and more a mass of broken spicules or spines. In Nature, we find this first precipitation of ice in water appearing as a cloudy formation throughout the mass of the water. This is the beginning of the fine ice noticed in rapids or open water and called frazil or needle ice. It is the form which gives the most trouble in power house operation, since it is produced all through the mass of the water and is of little or no buoyancy. It is readily carried into the racks and wheels, and adheres to the surface of machinery already cooled below the freezing point by the contact of the chilled water flowing through."

The illuminating statement that the flowing fluid water of a stream as it approaches the freezing point may contain more than one-third of its volume

[3] Abstracts of these papers are published in *Proceedings*, Am. Soc. C. E., March, 1929, Papers and Discussions, pp. 685 and 689, respectively.

[4] "Ice Engineering," Renouf Pub. Co., Montreal. First Edition, April, 1928, pp. 6–7.

in the trihydrol or incipient ice form prepares the mind for a clearer understanding of the amazing phenomenon of the appearance of swarms of frazil, springing into existence when the agitated water drops less than 0.01° cent. below the freezing point. "Before congealing, water contains ice as solution carries salt!" Liquid ice is, therefore, a proper physical conception. The emergence of visible cloudy colloidal ice in water is likened by Professor Barnes to the visibility of mist emerging in an aqueous vapor. The delicate balance in the temperature of water passing from the liquid form to the colloidal and particle form lies safely within 0.01° cent. on either side of the zero line. If water is held to a temperature of 0.01° cent. no ice will form. Ice will form rapidly with a water temperature of — 0.01° cent. and agitation.

The physical constants of ice are essential in this discussion. The density of clear ice may be taken as 0.92 and its weight at 0° cent. as 57.4 lb. per cu. ft. Where air is entrained in ice it is of course lighter. Water is known to increase in density as it is cooled until its maximum is reached at 5° cent. It then expands until its density at the freezing point is the same as its density at 8° cent.

The latent heat of the fusion for ice is 143.5 B. t. u. This means that the transformation of a solid pound of ice takes 143.5 times the heat necessary to raise the temperature of liquid water itself 1° Fahr.; and with 60% efficiency and coal having a heat value of 14 000 B. t. u., 1 lb. of coal will melt 59 lb. of ice; and 1 lb. of petroleum will melt 98 lb. of ice. The heat necessary to raise 1 lb. of water 1° Fahr. is the British thermal unit. This means that with coal of 14 000 B. t. u., 1 lb. of coal will raise the temperature of 14 000 lb. of water 1° Fahr. As a temperature rise of 0.1° will avoid freezing, 1 lb. of coal, therefore, used with 60% efficiency, will treat 1 340 cu. ft. of water. If this water is flowing through a steel siphon at the rate of 40 cu. ft. per sec., 1 ton of coal will serve for tempering to this extent this volume of water for 18 hours. Stated in another way if the temperature of the ditch water approaching a siphon is 32°.0, the addition of 0.1 cu. ft. per sec. of water at 70°, will raise the total volume to 32°.1 Fahr. and will be a safeguard against freezing.

The mechanical equivalent of heat may be taken as 1 h.p.-hour = 2 546 B. t. u. If this be taken in the form of electric current transmitted to the point of use at 70% efficiency this becomes 1 h.p.-hour = 1 780 B. t. u. Therefore, 1 h.p. will serve to raise the temperature of 28.5 cu. ft. of water 1° in 1 hour. The use of mechanically produced heat or electric current must be restricted to the maintenance of temperature of perhaps 32°.1 Fahr. in the metal of racks, gates, or turbine wheels, in order to avoid the adhesion of frazil.

The latent heat of the vaporization of ice is the sum of the latent heats of the melting of ice and the vaporization of water. This is about 143.5 + 1076.5 = 1 220 B. t. u. The bearing of this constant has to do with evaporation from ice.

The specific heat of water is unity at 17°.5 cent., or 63°.5 Fahr. At 0° cent. the specific heat is 1.0094 and at 10° cent. it is 1.0023. The British

thermal unit, therefore, applies strictly to water when its specific heat is unity. About 1% more heat is needed to raise the temperature of water at 0° cent. than at 17°.5 cent.[5]

The thermal conductivity of snow and ice is relevant in a study of water conditions in power streams. The thermal conductivity of ice, snow, and water is expressed in calorie-gramme-second units. For comparison the thermal conductivities of familiar metals are as follows:

| Materials. | Thermal conductivity, in calorie-gramme-seconds. | Materials. | Thermal conductivity, in calorie-gramme-seconds. |
|---|---|---|---|
| Ice | 0.005 | Iron | 0.11 |
| Snow | 0.0003 | Silver | 1.00 |
| Water | 0.0013 | Steel | 0.06 |
| Aluminum | 0.48 | Zinc | 0.26 |
| Copper | 0.89 | | |

The blanket value of a snow-and-ice cover in a forebay pond is obvious.

The coefficient of expansion of ice is given by Professor Barnes as about 0.000 089. In the American Civil Engineers Handbook, Fourth Edition, a value ascribed to Ganot of 0.000 052 is given.

Professor Barnes has discussed[6] other physical elements, such as plasticity, elasticity, viscosity, strength, color, refractive index, electrical properties, and bacteriology. It appears needless and undesirable to include in this report a discussion of the physics of ice. The Committee on Ice in this report has utilized this work of Dr. Barnes on "Ice Engineering" to the fullest extent.

## Surface Formations

It is desirable to suggest definitions for the various forms in which ice is related to power plants.

*Sheet Ice.*—The formation covering the water surface. In its simplest form, it is transparent even when a foot or more thick.

*Cake Ice.*—Solid sheet ice broken up by wind action, or other forces.

*Border Ice.*—Sheet ice forming in marginal bays where the water is shallow and the current slow.

*Shore Ice.*—The formation, along the banks of a stream with brush, driftwood, or débris incorporated.

*Windrow Ice.*—A consolidated aggregation of cake ice with edges up.

*Honeycomb Ice.*—Sheet ice rotting in place and eventually breaking down into long crystal needles.

*Slush Ice.*—Unconsolidated snow floating on the water surface after a snowstorm; or water-penetrated snow, covering and depressing sheet ice by its weight.

*Snow Ice.*—Consolidated slush ice.

*Shell Ice.*—Thin sheet ice forming and breaking up in such streams as the Ohio River above Louisville, Ky.

*Floe Ice.*—Bergs or masses from spray or water action.

[5] "Ice Engineering," by Howard T. Barnes, 1928, pp. 38–40.
[6] *Loc. cit.*, pp. 40 *et seq.*

### Middle Formations

*Frazil or Needle Ice.*—The swarming mass of spicules forming throughout the full depth of open, flowing, agitated, supercooled water. It is the precipitation in needle form of the solid ice, out of the liquid trihydrol element in the water.

*Hanging Ice.*—An agglomeration of frazil, anchor ice, slush ice, shell ice, and cake ice, forming on the bottom of sheet ice at the foot of a stretch of open swift-flowing water.

### Bottom Formations

*Anchor Ice.*—A formation crystallizing on submerged objects, such as boulders, perhaps growing by the agglomeration of frazil.

In considering the adverse effects of ice on power-plant operation, the discussion may be assembled under the following headings.

*A.*—Lessened stream flow from a lake or reservoir because of ice formations in the outflow channel.
*B.*—Ice accumulations in reservoirs.
*C.*—Ice accumulations in approach canals and forebays.
*D.*—Lessened head from back-water caused by ice formation in outflow channels down stream from a power plant.
*E.*—Difficulties of gate operation in sub-zero weather.
*F.*—Ice formations or jams on spillway dams tending to block them.
*G.*—Ice formations on reservoir structures with varying levels in the reservoir.
*H.*—Ice thrust on hydraulic structures.
*I.*—Ice clogging of racks.
*J.*—Ice clogging of valves and turbines.
*K.*—Ice on the intake screens of steam plants.

It should be clearly understood first that the successful operation of a water power plant is not a matter of latitude or of the intensity of cold. The great State-owned power plant at Porjus, Sweden, lies 60 miles north of the Arctic Circle. In the deep lakes or fjords forming the reservoir and forebay pond of this plant, ice forms 3 ft. thick.

The Swedish engineers have built, still farther to the north, a multiple-arch dam—one of the most delicate of hydraulic structures—to conserve and regulate the flow of the Lule River. This river has an ultimate regulated minimum flow of 7 000 sec-ft. The Porjus development utilizes a fall of 184 ft., and has a present installation of 56 500 kw. and an ultimate capacity of 113 000 kw. The current is used for the electrification of the railroads of that region, for the operation of the iron mines at Kiruna and Gallivare, and for chemical industries. The forebay reservoir is deep, with a thick ice-and-snow blanket that keeps the water warm. The water is conducted through a deep, wide, slow-flowing open-rock cut intake canal, then through 1 700 ft. of tunnel in rock to a roof-covered distribution reservoir; then in vertical shafts in the rock, to the turbines in a power house carved out of solid granitic rock. The discharge tunnel 4 200 ft. long in rock leads to the lower levels of the river. The water being carried through rock from intake to tail-water freezing is completely avoided, even in extremely cold weather.

The same situation exists in the great Rjukan development on the Mana River in the mountains of Norway. Here, the water is conducted from a deep reservoir through rock-hewn tunnels to the three power plants; but in a development at Svaelgfoss farther down on the same river, ice troubles are severe. It was said that 10% of the current generated in sub-zero weather was used to solve ice troubles. The fundamental fact in the expectation of ice trouble is conservation of the heat in the water as it exists in deep reservoirs. In such deep reservoirs the bottom water, even in mid-winter, is not far from the temperature of the maximum density of water, 39°.2 Fahr.; and from that temperature it varies to about 32° at the bottom of the ice cover. The snow-covered ice acts as an insulator against the escape of heat and the earth crust temperature radiates from the bottom. Doubtless some heat from the sun penetrates the snow-and-ice insulation, and the freezing of the water on the under side of the sheet ice releases some heat by the process of molecular change. In deep, slow-flowing water, the rotation brings up the bottom strata and the mean temperature of the mass may be as low as 35° Fahr.

The obstruction of the outflow from a reservoir by ice formation in the stream is illustrated by the St. Clair River at the foot of Lake Huron. The normal summer fall in the 40 miles from Port Huron, Mich., to Lake St. Clair is 5.5 ft. When the sheet-ice cover forms in January, this 5.5 ft. of potential energy must serve the friction of the ice perimeter, in addition to the bottom perimeter of the open season. The result is a slower current flowing with lessened cross-sectional area. The outflow volume is at times only one-half the normal summer outflow. This was analyzed by Mr. Sabin, in the report of the Chief of Engineers, U. S. Army, for 1902. In this report, also, the lessened outflow of the great power stream, the St. Lawrence River, is analyzed by Mr. Shenehon, and in the report for 1900 he analyzes the lessened outflow of the Niagara River. The full water-power development of the St. Lawrence River, converting it into a series of slack-water pools where now turbulent rapids exist, may enlarge the winter flow.

The ice formations in a great reservoir like Lake Erie, which pass into the Niagara River in a procession of cake ice and floe ice, cause considerable trouble in the power plants at Niagara Falls. This ice may run up to February 1, when the foot of Lake Erie freezes over and forms a barrier against the entrance to the river of the drift ice of the open middle part of the lake. After the break-up of the sheet-ice barrier—perhaps in late March—the ice may run until mid-May. This run is largely cake ice with some ice floes, which ground in 8 ft. of water. In a paper entitled, "The St. Lawrence Waterway to the Sea",[7] by Mr. Shenehon, a project of breakwaters is suggested to minimize troubles in the Niagara River from Lake Erie ice. At the head of the Gota River in Sweden "an ice boom at the outlet of Lake Vanern prevents snow and ice from entering the river during northerly wind, reducing ice trouble."[8]

The entrance of floating ice into approach canals and forebays leads to many complications and difficulties. Where an approach canal is long, with

[7] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 497.

[8] "Utilization of Water Power and Inland Navigation," by A. Ekwall, World Power Conference, 1926, Section 27, p. 7. .

a definite open-season loss of head, this loss is accentuated by the formation of sheet ice; or by packing with cake ice moving less rapidly than the water; or by the jamming of the ice. The by-passing of river or reservoir ice at the entrance to the canal or forebay is the fundamental solution. The principles of by-passing ice have been discussed[9] by Benjamin F. Groat, M. Am. Soc. C. E. The practice he suggested and utilized for many years is the separation of the surface water for the transportation and by-passing of ice in the direction of the flow of the stream, while the power water is drawn from the middle or bottom strata, preferably at right angles to the stream direction. Guides or vanes in the bottom or gathering tubes may facilitate the cross flow of the lower strata. The power water may pass under a curtain-wall built parallel to the direction of the stream. The velocity of the directed power water must be low enough to avoid pulling the ice under by suction.

The approach to the long penstocks of the Ontario Company at Niagara Falls, built early in the Twentieth Century, illustrates the principle. The surface water carrying the buoyant ice approaching from the head of the rapids is carried past the curtain-wall and discharges with a depth of 2 to 3 ft. over weirs on the gathering-basin walls. A curtain-wall parallel to the Niagara River current guards the entrance to the long Chippewa-Queenston Canal, and the principle of deep-water draft is used, with gathering tubes contemplated. The approach to the ¾-mile canal of the Niagara Falls Power Company, is guarded by booms and by ice formations worked out by the late John L. Harper, M. Am. Soc. C. E., to by-pass the surface ice over the American Fall. At Massena, N. Y., on the St. Lawrence, ice diversion follows the principle of sub-surface intake. At Marseilles, Ill., on the Illinois River, the curtain-wall is utilized less effectively. When ice is running it is necessary to keep a gang of men at work to prevent the cake ice from passing under the wall. At best, some buoyant ice will enter canals and some ice will form in canals, and sluicing is necessary at the power house. A power sluice was used by the Niagara Falls Company. The present device, however, is the endless chain elevator method of mechanically lifting the ice from the water and dropping it into a chute.

It is best, however, to avoid floating ice and frazil by drawing power water from a deep ice-and-snow-covered pool. Mr. Freeman has proposed a dam at the head of the rapids at Niagara Falls below the intakes of the upper three power plants to raise the water 10 ft. This would mean slower current and possible ice cover in the river between Lake Erie and the Falls. When a current exists approaching a power canal, the use of booms may aid in the formation of a surface sheet. This is the practice in the Gota River, Sweden, at the 115 000-kw. power plant, in Trollhättan.

The lessened head caused by a back-water rise is illustrated by the conditions in the Grass River down stream from the power plant at Massena. At the foot of the Lachine Rapids of the St. Lawrence River at Montreal, Que., Canada, a winter rise of 12 ft. is due to ice cover in the river down stream and the formation of huge hanging dams of frazil, anchor, and débris ice. The

[9] "Ice Diversion, Hydraulic Models, and Hydraulic Similarity," *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), p. 1138.

same cause sometimes obliterates the normal 11-ft. summer fall of Rapide Plat at Morrisburg, Ont., Canada, and Waddington, N. Y. The back-water here has been accentuated at times by the farmers along the river swinging a field of sheet ice, formed in a bay, across the current to form a bridge. In the Illinois River below the power plant at Marseilles, the formation of windrow ice and hanging dams at times obliterates the 11-ft. fall. The complete power development of a river by replacing rapids with slack-water deep pools will remedy the back-water. A deepening and straightening of the channel of the Grass River below Massena bettered the back-water conditions.

The difficulties of gate operation under ice conditions are met by the use of live steam—which may be generated in a boiler electrically fired. The use of warm compressed air bubbling against the up-stream side of the gates helps in part and avoids ice thrust. One of the 65-ft. roller gates of the Solbergfoss Plant of the City of Oslo, Norway, is electrically heated for emergency winter operation. This type of gate is readily warmed by a contained heating unit.

The spillway dam appurtenant to a power plant in a stream of heavy ice runs, especially if it be also a flood stream, needs the longest uninterrupted crest length. The roller gate, 20 m. long, previously mentioned, has many advantages over the relatively short-span Taintor or Stoney gates. Better yet are wicket gates which leave when down a clear crest line. The avoidance of ice formation on the crest of the hollow concrete Norrfors Dam is accomplished by steam pipes passing through the chambers, from a boiler electrically fired. At the Hammerfossen Dam the piers, instead of having cut-water prows, have a flat up-stream end, the water cone formed serving effectively to avoid the lodging of logs or ice. These two dams are in Sweden. Robert Fletcher, M. Am. Soc. C. E., has painted[10] a vivid picture of the combination of ice and flood:

"At Sumner's Falls a rocky barrier extends so obliquely across the river that its length is nearly double the direct width of the river. About 50 years ago at this site there was a dam, a canal lock and approach canal for river boats, and a very large saw-mill running seven saws. A spring flood brought down ice which jammed and froze; a second flood increased the jam, piled the ice high on the dam and against the banks, and finally carried the mill down stream, and wrecked the dam and lock, which were never rebuilt. The writer has seen an impressive picture of blocks of ice up to 4 ft. thick (a man standing beside one) wedged together over an extent of many acres, on one side of the Lower Yellowstone Dam, in Montana, as the result of a high flood. This suggests in part the possibilities of destruction by a spring flood carrying ice."

Ice formation in mountain reservoirs in February with continuous pull-down involves the spalling and disintegration under freezing of concrete dams. In a paper[11] by Fred O. Dolson and Walter L. Huber, Members, Am. Soc. C. E., remedies for frost action are stated. For a multiple-arch dam it would appear simple and not too expensive to carry down an insulating wall or diaphragm on the down-stream side, so that the bays are enclosed.

[10] *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), pp. 1161–1162.

[11] "Multiple-Arch Dam at Gem Lake on Rush Creek, California," *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 713.

Maintaining, by salamanders or otherwise, a temperature of 33° Fahr. within the chamber should safeguard the up-stream face against ice adhesion. Heat treatment in such a case will be more effective than super-waterproofing. The heating of the hollow Ambursen type dam at Norrfors, Sweden, has already been mentioned.

Ice thrust on the up-stream faces of dams, unless intercepted, involves great forces. Professor Barnes[12] has given the following values:

| Ice thickness, in inches. | Thrust, in pounds per linear foot. |
|---|---|
| 6 | 28 800 |
| 8 | 38 400 |
| 10 | 48 000 |
| 12 | 57 600 |

These values are based on a crushing strength of 400 lb. per sq. in. Quoting from Mr. George G. Bell, the ice thrust is given for 18 in. as 43 200 lb. per lin. ft. Mr. Bell concludes that a dam exposed to full ice pressure should be designed to resist from 43 000 to 48 000 lb. per lin. ft.[13]

A paragraph on "Ice Thrust" in the American Civil Engineers Handbook[14] is as follows:

"Ice pressure acting at the top of the dam is sometimes required to be taken into account. John D. Van Buren in 1895 advocated the use of 40 000 lb. per lin. ft. The board of experts for the Quaker Bridge dam (report of Aqueduct Com., 1889) recommended that the ice pressure should be taken at 43 000 lb. per lin. ft. of dam. For the design of the Kensico Dam 47 000 lb., for the Cross River dam 24 000 lb., and for the Croton Falls dam 30 000 lb. per lin. ft. of dam have been used. These widely differing specified values of the ice pressure are mostly based on the crushing strength of the ice, but it is obvious that before pressures of such magnitude could be developed, the ice sheet would fail as a long column; moreover the creeping of the ice up the generally sloping shores of the reservoir will prevent any considerable thrust upon the dam. It can be shown (Trans. Am. Soc. Civ. Eng., Vol. 75, p. 164) that the consideration of ice pressure of such intensities as quoted above would result in absurdly large dimensions for low dams while the dimensions of high dams would be only slightly affected. It is believed unnecessary to consider ice pressure in the design of dams unless the reservoir is very short in the direction perpendicular to the axis of the dam and the sides slope abruptly."

The ice thrust assumed in the design of the Lule River (multiple-arch) Dam in Sweden above the Arctic Circle, where the temperature falls to 50° below zero Fahrenheit and ice becomes more than 3 ft. thick, was less than 40 000 lb. per lin. ft. It is desirable to maintain by hand-sawing a gap in the ice sheet parallel to the dam, or to utilize bubbling compressed air. Even where wicket dams are used to keep up the winter head an open slot in the ice sheet avoids thrust.

Where metal racks reaching above the water surface are exposed to sub-zero weather in frazil-forming streams, the probability of complete blocking is great. Wherever this probability exists the racks themselves, or their supporting members, or both, should be designed to support the full load of the static head. Where the racks are enclosed in a heated rack room or rack chamber,

[12] "Ice Engineering," p. 214.

[13] *Proceedings*, Maine Soc. of Civ. Engrs., Vol. I, 1911, p. 41.

[14] Fourth Edition, p. 709.

it is still desirable to design the supports to carry the full static head, since a collapse means a long shut-down for repairs. The heating of the racks in some form so that ice will not fasten to them is desirable. The simplest form is the heated rack chamber made by decking over the rack space. Heat may be supplied best (as it is done in the Norrfors Plant in Sweden) by providing a conduit that carries the hot air from within the generator casing to the rack chamber. A curtain-wall is desirable to by-pass floating ice. In some rack rooms where the air temperature is but little above 32° Fahr., no trouble has resulted. However, in rivers, such as the Gota River in Sweden, where frazil forms and agglomerates and comes to the racks as huge slushy masses it is desirable to utilize additional safeguards. The fine screens are removed during frazil periods. The remaining coarse racks have clear openings between bars of 6 in. or more, and, in addition, electrical heating is ready for emergency use.

The Chief Engineer of Water Power in Sweden, Mr. A. Ekwall, estimates the electric current consumed in heating the racks as that coming from a 2-m. fall of water. Where the operating head on a plant is 20 ft., the energy consumed in heating the racks is 30% of the output; while with a head of 60 ft., it is only 10 per cent. The greatest safety against ice troubles lies in enclosed heated rack chambers, wide spacing in racks, and provision for emergency heating of racks. It should be noted that the use of electrical current is occasional and is likely to be at off-peak times. Should the racks be placed so that they may be flooded with sunshine, the condition is better still. The avoidance of night radiation and the absorption of heat by daylight are the ideal conditions. The complication of anchor ice rising in masses from the bottom, carrying sand, gravel, and boulders, and moving below the surface, complicates by-passing, reliance on curtain-walls, and the removal of the lower level racks.

The clogging of valves and turbine casings by massed frazil, slush ice, or anchor ice, is perhaps present in low-head plants with small units on horizontal axes. Where such clogging occurs, the use of live steam is effective in restoring operation. Mr. Hogg suggests concrete turbine casings "with series immersion electric heaters."[15] The use of electric current in the form of the water rheostat has been effective to break up ice masses. Bubbling warm air is also used. Professor Barnes advocates the use of thermit.[16]

It is understood that compounds more effective than thermit are in course of development. Other forms of chemicals are used, such as calcium chloride. Flooding with heat rays is also in use. It is perhaps desirable to accentuate the higher effectiveness of preventive measures to avoid clogging, rather than the surgical methods of breaking up the ice after a shut-down. So a little heat is needed—perhaps, a few thousandths of a degree—to avoid ice adhesion to metal structures, that the best practice is mild heating of dangerous parts.

Ice troubles in the screens of condensing-water intakes in steam plants and the remedies have been discussed by Mr. Walker[17] who points out the superior

[15] *The Canadian Engineer*, November 11, 1924, p. 497.

[16] In *Engineering Journal*, The Eng. Inst. of Canada, November, 1926, Professor Barnes discusses the nature of thermit ice reaction.

[17] Abstract, *Proceedings*, Am. Soc. C. E., March, 1929, Papers and Discussions, p. 689.

economy of re-circulating the condensing water. The breaking of ice jams in power streams is an art in itself, involving the use of dynamite, thermit, salt, ash, sand, and gravel.[18]

In concluding this report the Committee may summarize by saying that ice troubles are consolidated cold troubles; that heat is the instrument to prevent trouble; that heat is present in the water itself conserved in deep ice-and-snow covered reservoirs; that daylight and sunshine are great heat resources; that the hot air inside the generator casings of power plants is a by-product to be utilized perhaps more effectively than heretofore; that discharged condensing water in steam plants may in part be re-circulated to temper the intake water; and that electric energy itself, in its thermal capacity, is a facile instrumentality—and not too wasteful at off-peak hours of the night or at daybreak.

## APPENDIX

### BIBLIOGRAPHY OF ICE IN HYDRO-ELECTRIC PLANTS

**1881—Francis, J. B.** Anchor Ice. 1881. (In *Transactions*, Am. Soc. C. E., Vol. X (1881), pp. 192-194; part of Presidential Address).
Discusses the nature of anchor ice and its interference in the operation of water power plants.

**1882—Report on Ice Harbor at the Head of Delaware Bay.** 1882. (In Annual Rept., Chf. of Engrs., U. S. A., 1882, Pt. 1, pp. 785-790.)
Several paragraphs on ice pressure, followed by tables on crushing strength of ice, from experiments at Frankford Arsenal, Philadelphia, Pa., and at Fort Tompkins, Staten Island, N. Y.

**1884—Ludlow, William.** Observations on the Crushing Strength of Ice. 1884. (In *Proceedings*, Engrs. Club of Philadelphia, v. 4, pp. 93-99.)
To determine the resistance necessary to be provided against ice in constructing piers for an ice harbor at the head of Delaware Bay.

**1891—Dumble, J. H.** Some Observations on the Expansion and Contraction of Ice on Canadian Waters. 1891. (In *Transactions*, Canadian Soc. C. E., v. 5, pp. 270-308.)
Experience of the effect of ice movement on bridge piers.

——Abstract. Movement of Bridge Piers by Expanding and Contracting Ice. 1893. (In *Engineering News*, v. 29, pp. 41-42.)

——Editorial. 1893. (In *Engineering News*, v. 29, p. 37.)

**1893—Failure of Small Dam.** 1893. (In *Engineering Record*, v. 27, p. 400.)
Failure of dam by ice belonging to Des Moines Water Power Co., during low-water period. Dimensions of dam not given.

**1894—Freeman, John R.** Hoisting Apparatus of the Canal Head-Gates at Sewall's Falls, N. H., 1894. (In *Transactions*, Am. Soc. C. E., Vol. XXXII (1894), pp. 278–294; Discussion, pp. 294-332.)
Pages 295, 304, 306-320 contain data from actual experience on the formation of anchor ice on canal head-gates.

**1897—Hudson, H. B.** Effects of Mississippi River Floods on New St. Anthony Falls Dam. 1897. (In *Engineering News*, v. 37, p. 290.)
Failure of St. Anthony Dam, due to ice. Gorge formed 20 miles up stream, broke. Dam approximately 250 ft. long, of which 110 ft. were swept away by ice pressure. Photographs of the dam, before and after failure.

[18] *Engineering Journal*, The Eng. Inst. of Canada, November, 1926, contains descriptions by Professor Barnes of the "Breaking of the Allegheny Ice Gorge of March, 1926."

**1898—Leonard, R. W.** Masonry Pier Moved by Ice and Replaced. 1898. (In *Transactions*, Canadian Soc. C. E., v. 12, pp. 131-134.)
The thrust of the ice was about 11 tons per sq. ft., considering the ice 3 ft. thick and striking the pier obliquely on a width of 5 ft.

**1899—Failure of a Minneapolis Dam by Ice Pressure.** 1899. (In *Engineering Record*, v. 39, pp. 542-543.)
Plan of Minneapolis Dam given in diagram; width of dam was 12 ft. at base and 5 ft. at top; 250 ft. long and 18 ft. high. Dam owned by St. Anthony Power Co.

——**Rickey, W.** Failure of Dam at Minneapolis Due to Previous Weakening Through Ice Pressure. 1899. (In *Engineering News*, v. 41, p. 307.)
Illustration showing trench cut in ice along face of the dam. Dimensions of dam, 535 ft. long, controlling falls of the Mississippi River, at Minneapolis. Sectional view of dam and mill of the Minneapolis Mill Co.

——**Severe Test of Bridge Masonry.** 1899. (In *Engineering Record*, v. 40, p. 554.)
Effect of a mass of ice sweeping against a bridge, carrying away a span and moving a pier off its foundations.

**1903—Cairns, R. A.** Wigwam Reservoir Masonry Dam of Water-Works of Waterbury, Conn. 1903. (In *Engineering News*, v. 49, pp. 418-419.)
General description of the dam, including dimensions, architectural design, with photograph and plan view. Conditions existing up stream and general description of surrounding territory, character of soil, water movements.

**1905—Canadian Niagara Power To-Day.** 1905. (In *Electrical World*, v. 45, pp. 17-20.)
Illustrates a set of iron ice racks, partly above and partly below the water level at the intake.

**1906—Barnes, H. T.** Ice Formations with Special Reference to Anchor Ice and Frazil. 1906. (Pub. by Wiley, N. Y., 260 pp.)
Discusses physical laws governing the transfer of heat, physical constants of ice, formation and structure of ice; the nature of sheet, frazil, and anchor ice; precise temperature measurements; theories to account for frazil and anchor ice and methods of overcoming the ice problem in engineering work.

——**Patton, W. M.** Practical Treatise on Foundations. 1906. Second Edition. (N. Y., Wiley, pp. 49, 107-113.)
Gives brief description of several cases showing effect of drift ice on the stability of piers.

**1908—Dibos, M.** Glaces de Mer, Glaces de Rivières, Manoeuvres de Preservation et de Deglacage. (Protection from breaking of sea and river ice.) 1908. (In *Memoires et Traveaux* de Société Ingénieurs Civils de France, 1908, Pt. 2, pp. 860-923; Abstract, *Minutes of Proceedings*, Inst. C. E., Vol. 179, pp. 441-442.)
Considerable space is devoted to descriptions of the various forms of ice and the phenomena of freezing. Illustrated descriptions are given of protective mechanism designed by an officer in the Russian Navy. The conclusions reached by the Congress of Navigation at St. Petersburg, regarding the best means of protecting structures from ice, are given. The oxy-hydrogen flame is suggested as a means of thawing grooves in solid river ice. Superficial and submerged charges of dynamite, melinite, black powder, or Favier safety powders may be used. Their advantages are discussed.

**1911—Harrison, C. L.** Provision for Uplift and Ice Pressure in Designing Masonry Dams. 1911. (In *Transactions*, Am. Soc. C. E., Vol. XXXVII (1897), p. 142.)
The question of uplift discussed with reference to types of construction for bridges and dams. Ice pressure on reservoirs and the necessity of considering this factor in connection with bridge or dam design.

**1912—Failure of Dam from Ice Pressure.** 1912. (In *Engineering News*, v. 65, p. 681.)
Failure of dam, 150 ft. long, 21 ft. high, and 15 ft. wide, belonging to Port Henry Light & Power Co., Rockport, N. Y. Ice, 3 ft. thick.

——**Partial Failure of a Masonry Dam, Caused by Ice Pressure.** 1912. (In *Engineering Record*, v. 65, p. 94.)
Partial failure of stone dam, on Saranac River, N. Y., due to ice pressure. Dam, 152 ft. long and 45 ft. high.

——**Wall, E. E.** Ice Trouble at the St. Louis Water-Works. 1912. (In *Engineering News*, v. 67, pp. 212-213.)
Discusses the use of a clamshell bucket to remove ice from the intake of the water-works plant.

**1914—Barnes, H. T., Hayward, J. W., and McLeod, N. M.** Expensive Force of Ice. 1914. (In *Proceedings*, Royal Soc. of Canada, Series 3, v. 8, Section 3, pp. 29–48.)
Table of coefficients of expansion of ice; observations made by the authors on the ice in the Montreal filtration chambers, 1914; conclusions as result of preliminary study of ice expansion, it is found that: (1) the crushing strength of ice is most probably 400 lb. per sq. in.; (2) an ice block will yield under pressure at approximately 200 lb. per sq. in., which is probably due to the slipping of the crystals; (3) an ice sheet will form cracks on the upper and under surface due to unequal strain; (4) that a permanent expansion may result if the cracks become filled and frozen; (5) according to the most trustworthy results of other observers, the ice frozen to concrete develops its full crushing strength, and the tensile strength of ice is less than 200 lb. per sq. in.

——**Fuqua, P. D.** Breaking a Heavy Ice Jam in the Great Miami River. 1914. (In *Engineering News*, v. 71, pp. 997-998.)
Describes the diversion of a serious ice jam from bridge and dam at Hamilton, Ohio, by setting off large explosive charges. Brief data are given on the damage done to structures by ice scour.

——**Hendry, M. C.** Ice Troubles in Hydro-Electric Plants. 1914. (In *Canadian Engineer*, v. 27, pp. 693-694.)
Discusses the nature of sheet, frazil, and anchor ice and the effect of each type on the winter operation of hydro-electric plants.

——**Holtwood Dam Weathers Early Ice Run in Susquehanna River.** 1914. (In *Engineering Record*, v. 69, p. 421.)
The Holtwood Dam is said to have had a deterrent effect on the ice jams in the river below.

——**La Motte, A.** Dynamiting Ice Jams. 1914. (In *Engineering Record*, v. 69, p. 365.)
An effective means of breaking river ice is described. Submerged charges are considered most effective.

——**Winter Operation of Stoney Gates.** 1914. (In *Engineering Record*, v. 70, p. 691.)
Describes the application of steam conduits to the large dam gates at the Shawinigan Water & Power Co.'s hydro-electric plants on the Maurice River. Diagrams show the extent of ice formation on piers and gates.

——**Barnes, H. T.** Crushing Strength of Ice. 1914. (In *Transactions*, Royal Soc. of Canada, Series 3, v. 8, Section 3, pp. 19-22.)
C. A. Mees concluded that the crushing strength of ice might reach as high as 800 lb. in a short column. He says, however, "Wherever the effects of ice expansion have been carefully observed, it has been noted that bending takes place, and this may be expected because we have a long column effect. On this account assuming one-half the crushing strength may be developed before bending, the maximum thrust may equal about 400 lb. per sq. in." The author states: "Probably the best experiments have been made by Mr. George G. Bell; if we neglect his highest result, which appears to be too high, we find values more consistent, ranging from 358 to 783 lb." Details of author's experiments are given.

**1915—Allner, F. A.** Ice Fighting Is Systematized at Holtwood Hydro-Electric Plant. 1915. (In *Engineering Record*, v. 72, pp. 66-68.)
Describes the precautions taken at the Susquehanna River plant to prevent shut-down of main and exciter units due to frazil and anchor ice. Steam is used to warm turbine chamber.

——**Allner, F. A.** Severe Frazil Ice Attack at Holtwood Plant Does not Disturb Service. 1915. (In *Engineering Record*, v. 72, pp. 113-115.)
Some detailed information on the first two onsets of frazil ice and the damage it incurred; at the time of the third occurrence the measures for protection had been put into practice. The situations are compared.

——**Bligh, W. G.** Dams and Weirs. 1915. (Am. Tech. Soc., Chic., 206 pp.)
Discussion concerning the necessity of considering ice pressure in designing dams, bridges, and reservoirs.

——**Smith, C. W.** Construction of Masonry Dams. (McGraw-Hill, N. Y., 272 pp.)
The subject of ice thrust is discussed on pp. 117-126, giving specific example of dams and reservoirs which have been successful and others which have failed.

——**Use of Special Gates to Prevent Ice Formation at Intake Screens.** 1915. (In *Electrical World*, v. 66, pp. 1030-1031.)
Illustrates hand-operated screens installed at the Dundee Falls, Me., plant of the Presumpscott Electric Co.

**1916—Morrison, C. E., and Brodie, O. L.** Masonry Dam Design. 1916. (John Wiley Sons, N. Y., 267 pp.)
Pages 16-19 discuss the question of ice thrust in reservoirs and dams using specific examples. Pages 115-119 work out, according to the formulas, the proper design for dams, allowing for ice pressure.

**1917—Creager, W. P.** Engineering for Masonry Dams. 1916. (John Wiley Sons, N. Y., 229 pp.)
Ice pressure is discussed, pp. 37-39, including the subject of ice thrust and allowances which must be made when designing a structure. A table gives ice pressures adopted for various dams; the design of reservoirs. Pages 78-104 include examples showing the necessary allowances to be made in building to account for ice pressure.

——**Preventing Ice Troubles at a Connecticut Hydro-Electric Plant.** 1917. (In *Electrical World*, v. 69, pp. 184-185.)
Illustrates the arrangements constructed for disposing of ice that clogs the forebay.

——**Smith, J. C.** The Hydro-Electric Power Plant of the Cedars Rapids Manufacturing & Power Co., at Cedars, P. Q. 1917. (In *Canadian Engineer*, v. 32, pp. 211-213; Abstract from *Transactions*, Canadian Soc. Civ. Engrs., article not available.)
A sketch is given to show the general plan and layout of the embankment. A description is given of the power house and the main units, as well as of the method used in diverting ice from the intake.

**1918—Daily, C. M.** Keeping Ice from Ports of Water Intake. 1918. (In *Engineering News-Record*, v. 80, pp. 900-901.)
Describes the plan adopted by the St. Louis Water-Works authorities to protect intake ports. The device illustrated consists of a timber boom with buoyancy cylinders.

——**Davis, A.** Protection of Keokuk Dam Gates from Ice Pressure by the Use of Air. 1918. (In Stone & Webster *Journal*, v. 22, pp. 199-206.)
A history of the ice action at Keokuk, together with some conjectures as to its causes, followed by a description of a very successful air system for dealing with ice blocking.

——**Groat, B. F.** Ice Diversion, Hydraulic Models, and Hydraulic Similarity. 1918. (In *Transactions*, Am. Soc. C. E., Vol. LXXXII (1918), pp. 1138-1151, and discussion.)
An illustrated paper which treats of a new method of diverting surface water and all floating materials carried thereby, for the purpose of preventing jams in canals and rivers.

——**Installing Apparatus to Protect Dam from Heavy Ice.** 1918. (In *Electrical World*, v. 71, p. 778.)
Describes the use of a 5-h.p. air compressor to prevent ice formation on spillways and gates of dams and hydro-electric plants.

——**New Installation Keeps Ice Away from Keokuk Dam.** 1918. (In *Engineering News-Record*, v. 80, pp. 821-823.)
A pipe line across the Misaissippi River supplies a constant current of air up stream and prevents the formation of ice on the gates.

——**Pierce, C. H.** Effects of Ice on River Discharge. 1918. (In *Journal*, Boston Soc. C. E., v. 5, pp. 414-419.)
Stream flow for the canal and weir types of waterways is computed, theoretically. Using these calculations as a basis the effects of frazil, surface, and anchor ice cover are worked out. Graphical results show the effect of ice on river discharge.

——**Purcell, J. M.** Ice in Hydro-Electric Plants. 1918. (In *Power*, v. 48, p. 951.)

——**Slush Ice Prevention at the Denver, Colorado, Water-Works Intake.** 1918. (In *Engineering News-Record*, v. 80, pp. 615-616.)
A sheet-piling channel in the forebay and the maintenance of a steady flow of water through a 60-in. conduit prevents the formation of ice around the intake screens.

**1919—Bromley, C. H.** Operation at Holtwood. 1919. (In *Power*, v. 49, pp. 850-854.)
Describes the manipulation of screens and trash racks to prevent ice clogging at turbine intake. The racks are made in sections, one or two sections being removed. This article discusses at some length the difficulties encountered with débris and how the condition was treated.

——**Russell, S. R.** Method of Breaking Up Ice Gorges with Dynamite. 1919. (In *Engineering and Contracting*, v. 51, pp. 217-218.)
Describes and illustrates three ways of placing dynamite charges for varying types and positions of ice jam.

——**Stickle, H. W.** Monongahela River Navigation. 1919. (In *Proceedings*, Engrs. Soc. W. Pa., 34, pp. 245-266; Discussion, pp. 267-277; Abstract, *Engineering and Contracting*, v. 50, pp. 283-284.)
Pages 252-253 describe methods used in dynamiting ice blocks in the vicinity of Lock No. 5.

——**Wilson, R. M.** Design of Hydro-Electric Plants for Combatting Ice Troubles. 1919. (In *Journal*, Eng. Inst. of Canada, v. 2, pp. 383-395; Discussion in *Canadian Engineer*, v. 36, pp. 237-242.)
An article showing how ice troubles at turbine intakes have been eliminated by the Cedars Rapids Manufacturing & Power Co. A special type of trash rack is described, which is built in sections, allowing a portion to be removed. A considerable amount of railroad ties, stumps, stones, and other débris was found in the runners, but this condition was satisfactorily met. Discussion follows the article.

**1920—Balderston, C.** Ice Inside Cast-Iron Column Raises Floor. 1920. (In *Engineering News-Record*, v. 84, p. 1166.)
Relates a case of ice formation inside a cast-iron column which resulted in lifting the column several inches off its base and pushing a heavy granite sidewalk a like distance.

——**Carpenter, J. S.** Ice Protection for Hydro-Electric Plant. 1920. (In *Power Plant Engineering*, v. 24, pp. 1125-1126.)
Explains methods for deflecting ice jams. Ice forms around speed rings of turbine, causing water passages to become clogged.

——**Concrete Road Uninjured by Weight of Ice Jam.** 1920. (In *Engineering News*, v. 85, pp. 29-31.)
Gives example of Clark's Ferry at junction of Juanita River with Susquehanna, where a concrete pavement remained undamaged after a heavy ice jam.

——**Eckhard, G. F.** Large Highway Bridge Wrecked by Pressure of Cake Ice. 1920. (In *Engineering News*, v. 84, pp. 902-904.)
Gives example of the Brattleboro (Vt.) steel span of 330 ft. pushed off its supports by floating ice. Weight of steel in bridge was 270 tons. Distortion of floor system increased until horizontal deflection of the lower lateral system became at least 2 ft.

——**Groat, B. F.** Ice Diversion for St. Lawrence River Power Co. 1920. (In *Canadian Engineer*, v. 39, pp. 545-552; Abstract in *Engineering and Contracting*, v. 55, pp. 45-46.)
Discusses construction of submerged weir and ice diversion works in South Sault Channel of St. Lawrence River. Ice jams cause high back-water, thus reducing the head on the turbines during such periods, sometimes by as much as 10 ft.

——**Merriman, M.** Ice Pressure. 1920. (In Am. Civil Engr's. Handbook, 4th Edition.)
Example given of a sheet of ice 150 ft. in width tipping a masonry bridge pier weighing 1 000 tons, 2 in. out of plumb (p. 435). Pressures due to ice have been found to be 30 000 lb. per sq. ft. for field of melting ice 1 ft. thick, striking a pier and crushing its way past (p. 709).

**1921—Murphy, J.** Ice Formation and Its Prevention. 1921. (In *Canadian Engineer*, v. 40, pp. 291-292, 294.)
A review of the progress of investigations into methods for the prevention of the formation of ice in hydro-electric practice. States that it is possible to prevent ice from adhering to valves, gates racks, penstocks, turbine runners, and casings by the proper use of heat.

**1922—Gaby, F. A.** Queenston-Chippewa Development of the Hydro-Electric Power Commission of Ontario. 1922. (In *Journal*, Am. Inst. Elec. Engrs., v. 41, pp. 508-526.)
Discusses the design of the intake, taking into account the floating and frazil ice which forms on the Niagara and Welland Rivers. A submerged intake consisting of gathering tubes and a surface intake forming a concrete barrier to ice, are part of the layout which is proving successful.

——**Ice Handling Methods.** 1922. (In *Proceedings*, Nat. Elec. Light Assoc., v. 77, pp. 526-529; Abstract, *Power*, v. 55, pp. 948-949.)
The type of intake rack, designed in two parts and ready for quick removal in case of sudden frazil ice, used at the Cedars Rapids hydro-electric plant in Quebec, is briefly described, but well illustrated on p. 528.

——**Stevens, J. C.** Winter Overflow from Ice Gorging on Shallow Streams. 1922. (In *Transactions*, Am. Soc. C. E., v. LXXXV (1922), pp. 677-696; Discussion, pp. 697-698.)
The facts gathered during the author's study of the winter overflow of the Madison River, Montana, are used as the basis of his paper on the occurrence, in the coldest part of the winter, of frazil ice in streams too turbulent to permit surface ice formation. The effects of this ice on bridges, piers, reservoirs, and channels are described, together with remedial measures.

——**Wegmann, E.** Design and Construction of Dams. Seventh Edition. 1922. (Wiley, N. Y., 555 pp.)
Quaker Bridge Dam is designed to resist an ice thrust of 43 000 lb. per lin. ft. (p. 160). Wachusett Dam will resist an ice pressure of 23.5 tons per lin. ft. (p. 194). Cross River Dam designed to resist ice pressure of 24 000 lb. per lin. ft.; Croton Falls Dam, of 30 000 lb. (pp. 203-204).

1923—**Anderson, C. N.** Ice Prevention on Trash Racks by Electric Heating. 1923. (In *Electrical World*, v. 82, p. 340.)
Illustrates racks adapted for electric heating at the Kykkelsrud Power Station, Norway.

——**Skerrett, R. G.** Reducing Ice Pressures with Compressed Air. 1923. (In *Canadian Engineer*, v. 45, pp. 181-185.)
Describes subaqueous jets of compressed air utilized to prevent ice formation on gates of the Mississippi River Power Co.'s plant at Keokuk, Iowa.

——**Walker, W. T.** Ice Problems of Hydro Plants. 1923. (In *Engineering and Contracting*, v. 60, pp. 1254-1264; Abstract of paper before American Society of Civil Engineers, 1923.)
Suggests methods of relieving gates of ice pressure; shows the importance and necessity of studying the effect of frazil, anchor, and shore ice on piers, canals, and hydro-electric structures.

1924—**Bombing an Ice Jam.** 1924. (In *Aviation*, v. 16, p. 459.)
Reports on the use of planes in dropping bombs on an ice jam in the Platte River, between Columbus and Valley, Nebr.

——**Effects of Ice on River Flow at Keokuk.** 1924. (In *Electrical World*, v. 83, p. 336.)
It is concluded that the flow during any winter will depend on the flow at the time of the first freeze-up. This initial freeze-up will reduce flow to 40% in 6 days and keep it at that for 5 days, after which 75 to 80% is gradually reached. Reasons given.

——**Freeman, John R.** General Review of Current Practice in Water Power Production in America. 1924. (In *Transactions*, First World Power Conference, v. 2, pp. 359-394.)
Discusses ice troubles and their cure (pp. 368-370).

——**Hogg, T. H.** Ice Problems at Hydro-Electric Plants. 1924. (In *Canadian Engineer*, v. 47, pp. 498-500.)
Frazil ice discussed, followed by a description of racks, ice skimmers, and immersion heaters. The specific ice problems of the St. Lawrence District are discussed.

——**Hollow Concrete Bridge Piers Built Like Chimneys.** 1924. (In *Engineering News-Record*, v. 93, p. 757; Discussion, v. 93, p. 924, and v. 94, p. 164.)
Ice pressure on piers of the Kentucky Hydro-Electric Co.'s Kennedy Bridge.

——**Hyatt, R. S.** Preventing Ice Formation on Water Turbines. 1924. (In *Electrical World*, v. 83, p. 386.)
Illustrates a successful arrangement of turbine parts, showing location of heating elements.

——**Kennedy, J. H.** Ice Control Methods at Shelburne Falls. 1924. (In *Power Plant Engineering*, v. 28, pp. 895-896.)
Describes the work which must constantly be carried on to keep the channels of the New England Power Co.'s Deerfield River plant in operation. Ice is held on either side of the channel in solid blocks by its attachment to booms. In this way the ice is melted slowly in the spring and a great deal of damage prevented.

——**Ruths, A.** Ice Troubles in Norwegian Water Power Plants. 1924. (In *Transactions*, First World Power Conference, v. 2, pp. 771-788; Abstract, *Engineering*, v. 118, pp. 73-74; also *Engineering and Contracting*, v. 62, pp. 805-809.)
A complete discussion of the nature of formation and relative danger of frazil, anchor, and sheet ice. Conditions existing at the Vamma Hydro-Electric Plant in Norway are described, together with means used to remove and prevent ice on turbines, gates, and at intakes.

——**Samsioe, A. F.** Measures Taken in Sweden Against Ice Troubles at Water Power Plants. 1924. (In *Transactions*, First World Power Conference, v. 2, pp. 806-811.)
Discusses the damage done by ice jams and ice sludge. Gives some figures on the amount of pressure exerted on dams by ice jams.

## DISCUSSION

C. M. DAILY,[19] M. AM. SOC. C. E. (by letter).—The conclusion of the Committee that ice troubles are "consolidated cold troubles" and that the heat in the water itself may be conserved by storage in protected, deep, stilled reservoirs, presents a logical method for lessening the quantity of "frazil" ice formed and the troubles due to it. The designing engineer's task seems to be only to exercise ingenuity in devising ways and means to accomplish and maintain this condition in his plant.

Another phase of trouble is presented by floating ice, and ice submerged by being weighted with silt in rapid streams and rivers which transport large quantities of sand both in suspension, and by rolling along their beds. This phase has caused the St. Louis Water Department to spend large sums during the thirty-six years since 1894 at its Chain of Rocks Plant, where two intake towers are located in mid-stream. These intakes, like bridge piers, cause violent swirls which carry the ice crushed against the tower into even the lowest ports—at times, more than 15 ft. below the surface of the water.

The swirls prevent bars from forming around the towers, as the sand is carried in suspension past them or into the ports. If it were not for sand-bars periodically passing the towers, the prevention of ice entering the ports would be comparatively simple. No solution of the ice trouble will be effected without giving due consideration to the vast quantity of débris, sand, boulders, and the like, which the Mississippi River playfully rolls along its bed or carries in suspension during periods of high water.

It is very evident that river intakes should be designed to create and maintain a deep and uniform flow of water past them at all stages, and that the ports should be placed far below the surface and be large enough to provide sufficient flow at a low velocity through them. A shore intake with suitable river-regulating works seems to offer the easiest and cheapest method for accomplishing this.

## SECOND PROGRESS REPORT OF THE SPECIAL COMMITTEE[1]

WITH DISCUSSION BY MESSRS. HENRY S. PRICHARD, E. H. SALMON, AND J. H. GRIFFITH

TO THE BOARD OF DIRECTION,
AMERICAN SOCIETY OF CIVIL ENGINEERS:

The study of column test data[2] which the Committee had partly completed and reported upon in January, 1926, made it appear desirable to conduct some experiments along certain lines on relatively small columns before completing its report. Accordingly, certain tests were planned and carried out during the past two years, which have yielded some results of value and which will be considered in this report.

It will be desirable, as a matter of convenience, to describe these tests and present the principal results before going on with the discussion in the order intended in the first report. This report, therefore, will consist of two parts: Part I is a description of the tests referred to, and Part II a continuation of the general report, as outlined in the Progress Report of 1926.

The tests described in Part I were made in the laboratories of the University of Wisconsin, under the direction of Professor M. O. Withey, of the Department of Mechanics, to whom the Committee is much indebted for the care and thoroughness with which this work has been done, and for the preparation of much of the material embodied in the report. Acknowledgment is also made of the valuable services of the following Research Assistants of the same Department: Messrs. R. R. Schrader, K. F. Wendt, E. A. Abendroth, R. T. Homewood, and E. R. Summers. Besides the use of its laboratories, the University of Wisconsin has contributed the test columns and considerable service by its Research Staff. The United States Forest Products Laboratory, through J. A. Newlin, M. Am. Soc. C. E., has assisted effectively by loaning the use of its 1 000 000-lb. testing machine and roller-bearing blocks. Engineering Foundation has co-operated in this work from the beginning, and a considerable part of the budget for 1927 has been secured through that organization.

[1] Presented at the Annual Meeting, January 16, 1929.

## PART I.—TESTS OF COLUMNS MADE DURING 1925-27

*1.—Object.*—The principal object in mind in making these tests was to try out certain promising methods of studying the effectiveness of lacing-bars and other lateral elements. However, as the work developed, considerable valuable information was obtained regarding the stresses in such elements, the crookedness of certain columns, the relation of strength to yield point of material, the properties of the material at various points in a cross-section, the effect of form of section on eccentrically loaded columns, and other features. These various items will be discussed in their proper place after the tests have been described in general.

*2.—Scope.*—These column tests may be conveniently divided into three series, as follows:

(*A*) Eleven columns tested under oblique loading, causing a definite amount of shearing stress on the column.
(*B*) Ten rolled H-columns tested under eccentric loads.
(*C*) Two columns similar to certain columns of Series (*A*), tested under eccentric loads.

*3.—Test Columns.*—The general dimensions and properties of these columns are given in Tables 1 and 2. Details of columns, including location of gauge lines, are given in Figs. 1 to 7. Details of Columns Nos. 4, 5, 5*A*, 5*B*, and 6, which were latticed channel columns, are given in Fig. 4, and details of Columns Nos. 7, 8, and 9, which were batten-plate columns, are shown in Figs. 5, 6, and 7, respectively. Columns Nos. 4, 5, 5*A*, 5*B*, and 6 differ only in the size of the lacing-bars, those used in Column No. 4 being very light, and those in Column No. 6, extra heavy. Fig. 8 gives the locations of gauge lines for the H-columns of Series (*B*). Columns Nos. 5*A* and 8*A* of Series (*C*) were similar to Columns Nos. 5 and 8, respectively, of Series (*A*).

The actual sectional areas were computed from the weights, deducting the calculated weights of rivet heads, lacing-bars, and other details. The values of $r$ were determined by measurement at each end of the column, and the two results were averaged.

All the columns listed in Tables 1 and 2 were contributed by the University of Wisconsin. All fabricated columns were manufactured by the American Bridge Company; and all H-columns were obtained from the Bethlehem Steel Company. The material and shopwork were specified to conform to the General Specifications for Railway Bridges of the American Railway Engineering Association.

*4.—Apparatus.*—Tests were made at the University of Wisconsin, some on a 1 000 000-lb. machine belonging to the United States Forest Products Laboratory, at Madison, and others with the 600 000-lb. testing machine in the Materials Testing Laboratory of the University. An important feature of the testing apparatus without which these tests could not have been readily made was the bearing-block arrangement placed between the ends of the column and the testing machine. These blocks were provided with rollers in

such a manner as to provide nearly frictionless end bearings to the columns. Fig. 9 shows a cross-section of one of the bearing blocks which explains the arrangement. Strain measurements over 8-in. and 20-in. gauge lengths were made with Berry strain-gauges read to 0.0001 in. For 2-in. gauge lines, an Olsen strain-gauge was read to 0.00003 in. Deflections were read by wire-wound dial deflectometers to 0.0001 in. The yield point was determined by the drop of the beam, and checked by the movement of the extensometer dial. The proportional limit was determined by the deviation point of the stress-strain curve from a straight line.

The frictionless character of the end bearings was indicated in various ways throughout the testing program, particularly by the sensitiveness of the column to small changes in position of the ends, and by the very close actual agreement of lateral deflection under eccentric loads with the theoretical, assuming hinged ends. However, in order to assure itself on this point, the Committee obtained direct evidence of the actual amount of the friction. The two blocks were placed face to face in the testing machine and a load applied directly to them. The combination of the two blocks was then turned through a considerable angle by means of a projecting rod attached to the blocks. Assuming that the center of curvature of the roller bearing of each block was precisely at the face of the block, the combination of the two could be turned through an angle with no resistance except friction. The maximum value of the load, $P$, was 500 000 lb., as compared to a maximum load used in the column tests of about 400 000 lb. It was found that up to a certain point the force required to turn the blocks increased with the amount of the movement, but beyond this point, the blocks continued to roll at very nearly constant force. The results of the tests, given in Table 3, are the averages of three to eight sets of readings. The friction coefficient is found by dividing the torque by the product of the diameter of the circle of roller centers times the imposed load, $P$. The angular movement of 0.00006 radians was equal to one division of the bubble used, which was the smallest movement noted.

In the oblique loading tests, it is found from calculation that the angle of rotation for Column No. 4, with $P/A = 14\,570$ lb. per sq. in. ($P = 167\,000$) and 5% shear, was about 0.002; and for Column No. 2, with $P/A = 14\,170$ lb. per sq. in. ($P = 200\,000$), it was about 0.0011. Comparing these values with the results given in Table 3 it would appear that the friction coefficient was in most cases considerably less than 0.002, and this may be taken as about the maximum probable value for any of the tests.

The effect of a friction coefficient of 0.002 can be judged by calculating the eccentricity necessary to overcome this friction. The frictional moment for a single bearing block would be $P \times 6 \times 0.002 = 0.012\ P$, requiring an eccentricity of only 0.012 in.; that is, the effective eccentricity would be 0.012 in. less than that given in the tests. Inasmuch as these values were of the magnitude of 1 in., or more, the error due to friction would be very small—generally less than 1 per cent.

| *H* 10 | 306.9 | 8.92 | 3.42 | 1.94 | 89.7 | 158.2 |

The question has also been raised whether or not in the oblique load tests it could be safely assumed that the applied load is always truly vertical, or whether a horizontal component of considerable magnitude may not be developed as the column becomes distorted, thus giving rise to considerable error in the calculated shear. Inasmuch as the bearing blocks were not free to move laterally, any tendency of the column to take on a horizontal movement of one end with respect to the other would be resisted by the testing machine and thus give rise to a horizontal load component. The analysis of the various kinds of distortion to which the column is subjected—flexure, shear, and direct stress—indicates that such possible effect is very small; but probably the best answer is a comparison of the observed bending stresses (calculated from strain-gauge readings) near the ends of the column, with the values calcu-

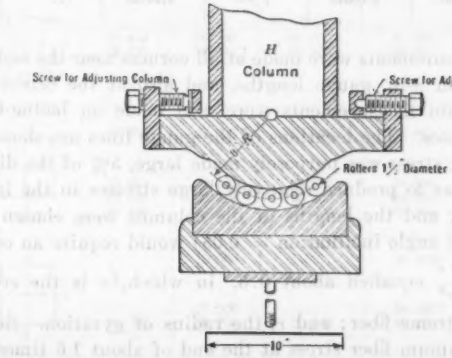

FIG. 9.—ROLLER BEARING BLOCK, FOREST PRODUCTS LABORATORY.

lated from the assumed shear. Such comparison has been made for four columns under an oblique load assumed to give 5% shear (obliquity, 0.05). For a total of seven different loads, the maximum difference between the two methods of calculation, averaging results for both ends, was 14 per cent. Most values were within 3%, some being of one sign and some of the other. The average of the seven was 2.7%, the strain-gauges giving the higher value. Considering the nature of strain-gauge work, this agreement is quite satisfactory.

## Tests of Series (*A*): Oblique Loading

*5.—Procedure in Testing.*—These tests were undertaken to secure information regarding lateral rigidity and strength, but more especially to try out a certain method of testing which it was thought would be particularly well adapted for the study of the various problems connected with lateral strength.

The question of shearing stress and shearing strength of columns is a very important one, and one concerning which the usual test with a central load gives little information. In order to impose a relatively large amount of shearing stress upon these columns, they were loaded obliquely, that is, by placing the load eccentrically at the end, the eccentricities at the two ends being in opposite directions. The bearing blocks were very nearly frictionless, and their behavior indicated that the columns were substantially pivoted end columns. By this arrangement, a definite amount of shearing stress in proportion to the direct stress could be imposed. Fig. 10 shows the manner of placing the column in the testing machine.

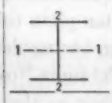
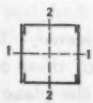
| 500 000 | 2 550 | 0.00043 | 7 400 | 0.00123 | ..... | ..... |

Strain-gauge measurements were made at all corners near the ends, quarter-points, and center, on 8-in. gauge lengths, and also at the center on 20-in. gauge lengths. Strain measurements were also made on lacing-bars, stay-plates, and batten-plates. The locations of the gauge lines are shown in Figs. 1 to 7. The shearing stress was purposely made large, 5% of the direct stress for final loading, so as to produce relatively large stresses in the lateral connections and details; and the lengths of the columns were chosen so that a 5% shear (tangent of angle inclination = 0.05) would require an eccentricity at the end such that $\frac{e\,c}{r^2}$ equalled about 0.6, in which, $e$ is the eccentricity; $c$, the distance to extreme fiber; and $r$, the radius of gyration. Such eccentricity caused a maximum fiber stress at the end of about 1.6 times the aver-





age, or 1.6 times $P/A$. In all cases, the plane of obliquity was parallel to Axis 2-2 (Table 1), the roller axes being parallel to Axis 1-1.

The columns were first centered in the testing machine by measurement and then by trial loadings until the strain-gauge measurements and deflection apparatus showed practically no eccentricity under a considerable load. After being centered, the ends were shifted a calculated amount to produce the desired obliquity.

Some of the columns were tested under 2% shear up to a maximum fiber stress of about 14 000 lb. per sq. in., and then tested to failure under 5% shear. Others were tested only under 5% shear.

*6.—Maximum Stresses at Ultimate Load.*—Table 4 gives the results of these tests relative to the ultimate loads and the maximum fiber stresses at the ends of the columns.

TABLE 4.—ULTIMATE LOADS AND MAXIMUM FIBER STRESSES AT ENDS OF COLUMNS UNDER 5% SHEAR.

* The maximum unit stresses in the batten-plate columns occurred in the unsupported channels near plates, see Table 13.

Columns Nos. 1, 2, 3, and 3*A*, composed of solid rolled or riveted sections, failed in the manner indicated in Fig. 10. The latticed channel columns also failed by over-stressing the channels, except Column No. 4 with the light lacing, which failed both by over-stressing of the channels and by the buckling of the lacing. This is shown very clearly in Figs. 11 and 12. In all these columns, however, the calculated maximum fiber stress at the ends was much beyond the yield point of the material. As Table 4 shows, the first scaling occurred in some cases before the average unit stress on the extreme fiber reached the recorded proportional limit. The batten-plate columns failed as indicated in Fig. 13, as would be expected. The excessive shearing stress caused large bending moments in the individual channels, which led to failure at the first rivet of the end batten-plate. Column No. 9, however, carried an ultimate load almost as great as the maximum sustained by the latticed channel columns.

7.—*Shearing Rigidity and Strength.—Transverse Bending Tests.*—Before testing the columns as columns, they were tested as simple beams under center loads up to calculated fiber stresses of 1 000 to 6 000 lb. per sq. in. By comparing the deflections and sets when bent in different directions, some information was obtained relative to the effectiveness of lateral connections. Table 5 gives important results of these tests.

All the columns when tested with the plane of the load parallel to the web exhibited small sets and the deflections agree reasonably well with calculated values if due allowance is made for shear deflection. When tested with the plane of loading normal to the web, that is, parallel to the lacing or battens, both the laced channel columns, Nos. 4 to 6, and the batten-plate columns, Nos. 7 to 9, showed considerable set as regards deflections after light loads. The elastic deflections of the laced columns so tested agree roughly with calculations, including an allowance for shear deflection. For equal fiber stresses and span lengths, they were approximately equal. The batten-plate columns exhibited much higher deflections. Under this type of loading, basing the comparison on the same fiber stresses, the elastic deflections of Columns Nos. 7, 8, and 9 were, respectively, seven, three, and two times as much as the corresponding deflections of the laced columns.

It is of interest to compare the observed deflections with the calculated values, considering bending distortion only. Table 6 gives some results of such calculation. The calculated values are conveniently obtained from the formula,

$$\text{Deflection} = \frac{1}{6}\,\frac{f\,l^2}{E\,h}$$

in which, $f$ is the bending fiber stress and $h$, the depth of the beam in the plane of bending. When bent in the plane of the webs, the solid riveted and rolled sections showed a deflection somewhat more than the calculated; the laced channel columns, somewhat less. This smaller deflection is doubtless due to the stiffening effect of lacing and stay-plates, which was neglected. The important result is, however, in the relatively large deflections of these columns (from 1.6 to 2.0 times the calculated values) when bent in the plane of the lacing. This excess is due obviously to the contribution of the lacing and

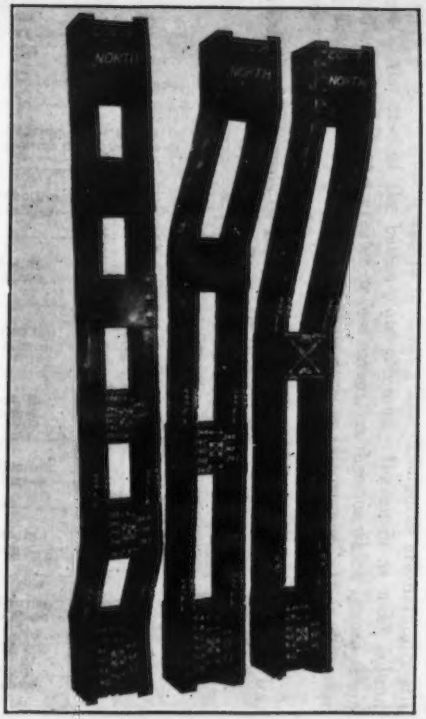

FIG. 13.—FAILURES OF COLUMNS NOS. 7, 8, AND 9.

stay-plates to the deflection, or, as it may be considered, the deflection due to shear; that is, the deflection due to shear is, in this case, from 60 to 100% as much as the deflection due to moment. The differences are naturally still larger in the case of the batten-plate columns. Inasmuch as most column formulas are based, to a greater or less extent, on theories which ignore shearing distortion, this question is of considerable importance. It is discussed further in Part II.

*Member did not have full bearing across knife-edges due to initial wind of approximately 3½ degrees.

*8.—Oblique Loading Tests.*—As regards oblique loading, Fig. 14 shows that, if the column ends are hinged, the mid-section is rotated counter-clockwise by the bending moment and clockwise by the shear. Hence, the net angular rotation of the mid-section, $\alpha$, relative to the column axis is the difference of the shear and bending rotations, $\alpha_S - \alpha_B$. Also, owing to small rotations of the bearings and the machine during loading, the column as a whole suffers a small rotation, $\alpha'$. Hence, the entire rotation of the mid-section, $\alpha_1$, will be $\alpha + \alpha'$. By attaching a pair of spirit-levels to a side-bar supported at the column ends (Fig. 10) the rotation of the column as a whole, $\alpha'$, was

measured. Spirit-levels, termed "shear-minus-moment" levels in Fig. 14, attached at the mid-section measured the entire rotation of that section, $\alpha_1$. Then,

$$\alpha_S - \alpha_B = \alpha_1 - \alpha'$$

TABLE 6.—COMPARISON OF OBSERVED AND CALCULATED DEFLECTIONS, CROSS-BENDING TESTS.

| | | 12.01 | 3 000 | ..... | ..... | ..... | 0.0496 | 0.0198 | 2.50 |

In most of the tests, $\alpha_B$ was calculated from the equation,

$$\alpha_B = \frac{0.05 \dfrac{P\,l^2}{24\,E\,I}}{1 - \dfrac{P\,l^2}{24\,E\,I}} \quad \ldots\ldots\ldots\ldots\ldots\ldots (1)^3$$

[3] From "Modern Framed Structures," Part 2, p. 508, by Johnson, Bryan and Turneaure, the general equation of the elastic curve of such a column is found to be,

$$y = c_1 \sin q\,x + c_2 \cos q\,x - \frac{M_1}{P} - \frac{V_1\,x}{P}$$

in which, $q = \sqrt{\dfrac{P}{E\,I}}$ and $M_1$ and $V_1$ are the moment and shear, respectively, at the end taken as origin. By differentiation the constants may be eliminated and the rotation of the mid-section can be determined from the first derivative of the equation for $y$. By substituting $c = 0.025\,l$ and $V_1 = 0.05$,

$$\alpha_B = 0.05 - \frac{0.05\,q\,\dfrac{l}{2}}{\sin q\,\dfrac{l}{2}}$$

Expansion of the sine term reduces this to Equation (1).

and the net angular shear distortion, $\alpha_S$, was determined from the equation,

$$\alpha_S = \alpha - \alpha' + \alpha_B$$

In tests on Columns Nos. 2*A* and 5*B* the shear distortion was measured more directly by adding rotations measured by "shear-minus-moment" levels to those measured by the "moment" levels (see Fig. 14).

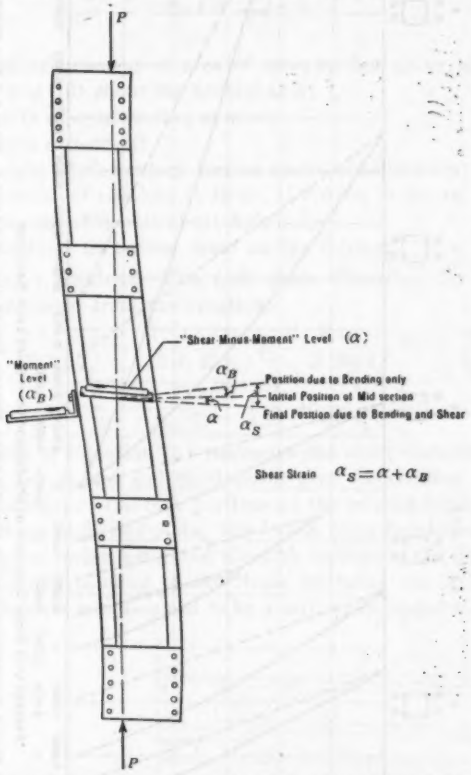

FIG. 14.—METHOD OF MEASURING SHEAR STRAINS IN COLUMNS OF SERIES (*A*).

Typical results of these shear distortion measurements are shown in Fig. 15 for unit loads, $P/A$, up to 15 000 lb. per sq. in. The diagram shows sets after certain loads as well as deformations under load. The solid rolled and riveted sections show little shear distortion and negligible set; the laced channel columns, considerable shear distortion and relatively large sets; and the batten-plate columns, very large distortions and sets.

In the case of the batten-plate columns the shear distortion is, in part, local bending of channels between plates, but the result is a measure of shear flexibility as a whole and of set. The superior rigidity of the solid and riveted sections is marked.

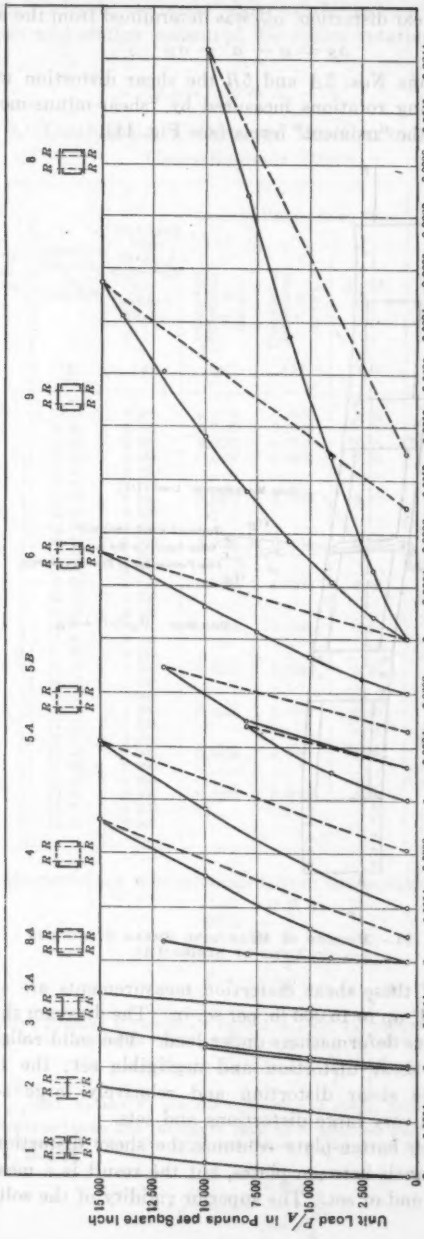

FIG. 15.—UNIT LOAD SHEAR DISTORTION CURVES FOR COLUMNS TESTED UNDER OBLIQUE LOADS. SHEAR 5 PER CENT.

*8(a).—Comparison of Computed and Observed Shear Distortions.*—Calculations of the unit shear distortions of these columns were also made.

Solid Rolled and Riveted Sections.—For these sections the distortions were computed as follows:

$$\alpha_S'' = \frac{V}{E_S\, I\, d} \sum \frac{A'\, y'}{b}\, d\, y \qquad (2)$$

in which,

$A'y'$ = statical moment of area of cross-section above $m$-$m$ (shaded in Fig. 16) about the neutral axis;
$b$ = width of cross-section at $m$-$m$;
$d$ = depth of section;
$dy$ = height of elementary lamina under consideration;
$E_S$ = modulus of elasticity in shear, 11 600 000 lb. per sq. in.;
$I$ = moment of inertia about Axis 1-1;
$V$ = the total transverse shear on the column.

Laced Channel Sections.—The unit shear distortion for laced channel sections was calculated from the equation,

$$\alpha_S'' = \frac{2\, K_1\, V\, l_1}{L\, E_S\, I_1^2} + \frac{V\,(l_0^3\, l_2^3)}{12\, L\, E\, I_2} + \frac{K_2\, V\,(l_0 + l_2)}{L\, E_S\, I_2^2} + \frac{n\, S\, u\, l}{L\, A_1\, E} + \frac{2\, n\, l_3\, V \tan^2\theta}{A_3\, E}\left(\frac{25}{54} + \frac{l_3^2}{40\, r_3^2}\right) \qquad (3)$$

The first term of Equation (3) represents the shear distortion of the stay-plate portion[4]; the second and third terms give the bending and shear distortions, respectively, of the four portions of the column having unsupported channels adjoining each stay-plate; the fourth term furnishes the distortion due to straining of lacing-bars; and the fifth represents the distortion caused by the shearing and bending of the rivets fastening the lacing-bars to the channels. Each rivet was assumed to be a uniformly loaded cantilever.

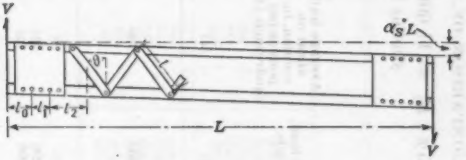

FIG. 17.

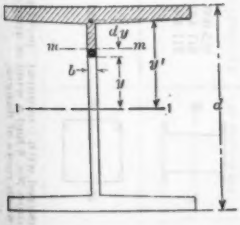

FIG. 16.

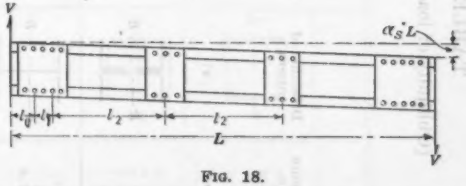

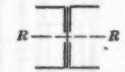

FIG. 18.

[4] The derivation of the general expression for shear deflection may be found in "Strength of Materials," by Maurer and Withey, p. 322.

TABLE 7.—COMPARISON OF THE SHEARING RIGIDITIES OF THE COLUMNS OF SERIES (*A*):

(Obliquity of loading, 5%; $E_s$ = 11 600 000 lb. per sq. in. Columns Nos. 1, 2, 3, 4, and 6 had been subjected to similar loading prior to the runs herein recorded.)

*Measured with "moment" level apparatus.

The significances of the undefined terms are:

$A_1$ = cross-sectional area of a lacing-bar;
$A_3$ = cross-sectional area of a rivet in the lacing-bar;
$I_1$ = moment of inertia of stay-plate portion about a gravity axis parallel to channel webs;
$I_2$ = least moment of inertia of a single channel about its own gravity axis;
$K_1 = \int \frac{(A' y')^2 \, d y}{b}$, a constant for the stay-plate cross-section;
$K_2$ = constant like $K_1$ for a single channel;
$l$, $l_0$, $l_1$, $l_2$, and $L$ are defined in Fig. 17;
$l_3$ = the cantilever length of rivet which was taken equal to twice the thickness of a lacing-bar plus one-half the rivet grip in the channel flange;
$n$ = number of lacing-bars in the column;
$r_3$ = radius of a rivet;
$S = \frac{V}{2} \sec \theta$;
$u = \frac{1}{2} \sec \theta$.

Batten-Plate Columns.—For these columns (Fig. 18), the unit shear distortion was calculated from,

$$\alpha_S'' = \frac{K_2 V l_0}{L E_S I_2^2} + \frac{V l_1^3}{12 L E I_2} + \frac{K_1 V l_1}{L E_S I_1^2} + \frac{K_2 V n l_2}{2 L E_S I_2^2} + \frac{V n l_2^3}{24 L E I_2} \quad \ldots(4)$$

In Equation (4) the first two terms give the shear and bending distortion, respectively, of the two extreme end portions, $l_0$ in length; the third term furnishes the shear distortion of the two stay-plate portions, each $l_1$ in length; and the last two terms, which are of major importance, furnish the shear and bending distortion, respectively, of the several ($n$) portions of the column, each having a length, $l_2$, and containing two unsupported channels. The other symbols have been previously defined.

Comparison of Shear Distortions.—The relation between the measured and calculated shear distortions for the columns of Series ($A$) is given in Table 7. Aside from Column No. 3, which was defective, it will be observed from Column (9) of Table 7, that there is good agreement between the elastic measured unit shear distortions and the values calculated by Equations (1) to (4).

To afford a comparison of the relative shearing rigidities of the various types of columns tested, the ratios of,

$$\frac{\text{Average unit shear stress on column}}{\text{Measured elastic unit shear distortion}}$$

have been entered in Column (10) of Table 7. As would be expected from consideration of Equation (2), Column No. 8 $A$ (with rollers normal to webs) and the riveted box sections exhibited the highest shearing rigidity. The superior shearing rigidity of the laced-channel columns over the batten-plate columns is also noteworthy.

*9.—Stresses in Lacing.*—The tests on laced-channel columns afforded a good opportunity to examine the stresses in the lacing-bars. These were determined both by calculation[5] and by strain measurement for the central and also for the oblique loading tests. At first, the strain measurements were made on the median lines of the outer faces of the bars using 6 or 8-in. gauge lengths. Later, more accurate measurements were made along the median lines of the upper and lower edges of the bars, using 2-in. gauge lengths. Unless otherwise indicated, the calculations herein reported are based on strains measured by the later method. Column (10) of Table 8 shows that for oblique loading and values of $P/A$ of 14 000 lb. per sq. in., or higher, the ratio,

$$\frac{\text{Average stress in lacing-bars calculated from strain}}{\text{Average stress in lacing-bars calculated from load}}$$

is 21 to 24% less than unity. It is of interest to note that the calculated maximum "load" stress, Column (8) of Table 8, at which the thin bars of Column No. 4 buckled, was practically the same as the average ultimate load for three similar lacing-bars tested singly as columns (Column (11) Table 8).*

TABLE 8.—AVERAGE UNIT STRESSES IN LACING-BARS OF COLUMNS NOS. 4, 5, 5*A*, AND 6, UNDER OBLIQUE LOADS.

(Strains measured on 28 to 32 bars in each column.)

* Load at failure of column.
† Bars buckled.

Owing to imperfections in the connections and irregularities in the lacing-bars, the observed average strain for the lacing-bars varied considerably. If one considers variation among the tension bars, or among compression bars, the data in Table 9 indicate that the variation was least among the thin bars of Column No. 4; also, that the stress variation between bars became less as the loads increased. In the test of Column No. 4 the bars carrying

[5] See Equation (32), p. 1242.

compression were the outer bars on both sides of the column; in Columns Nos. 5*A* and 6, the bars carrying compression were the outer bars on one side and the inner bars on the other side of the columns. Comparing the tabulated information for Column No. 4 with that for the other columns, it appears from Column (7) of the lower part of Table 9 that a more equal distribution of stress between the inner and the outer bars was obtained for Columns Nos. 5*A* and 6 than for Column No. 4.

| | | | Outer | 3 710 | 8 850 | 5 370 | 31 | 65 |

Table 10, Column (5), shows that for the high column loads the ratio of:

$$\frac{\text{Average "strain" stress in the most strained lacing-bar}}{\text{Average stress calculated from the load}}$$

in a certain tension bar of Column No. 6[6] reached the high value of 1.65. For compression bars, however, the ratios in Column (6), Table 10, are considerably less. The average "strain" stress in lacing-bars was also calculated for the lacing-bar panel, in which the two most highly strained bars were found. The ratio:

$$\frac{\text{Average "strain" stress in the lacing of the most strained panel}}{\text{Average "load" stress in the lacing}}$$

[6] It should be noted that the strains in the heavy bars of Column No. 6 were considerably smaller than those in the bars of the other columns, and the errors in measurement were proportionately greater.

shown in Column (7), Table 10, indicates that in the worst case one panel of Column No. 6[e] exhibited a ratio of 1.3; for the other columns, the ratio was less than 1.10.

TABLE 10.—COMPARISON OF STRESSES IN LACING-BARS CALCULATED FROM LOAD WITH STRESSES CALCULATED FROM STRAIN, COLUMNS NOS. 4, 5*A*, AND 6.

*10.—Tests of Individual Lacing-Bars.*—Compression tests were made on twenty individual lacing-bars, 10½ in. long, center to center, loaded in the manner indicated in Fig. 19. Measurements of crookedness at mid-length were made on a number of these bars and the results are recorded in Columns (6) and (7), Table 11. In all cases save one, the bars which were appreciably bowed outward, away from the channels, showed lower strength.

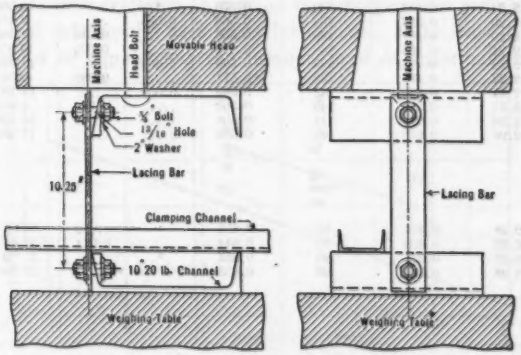

FIG. 19.—METHOD OF TESTING LACING-BARS.

To secure evidence concerning the magnitude of eccentricities in lacing, Bars 27*A*, 52*A*, and 61*A* were tested with Martens mirror extensometers attached to the middle 2 in. of each broad face. Also, in the column tests,

measurements were made on the front faces as well as the top and bottom faces of fourteen bars in Column No. 4, and of ten bars each in Columns Nos. 5*A* and 6. From data obtained in these two types of test, Fig. 20 has been prepared. Apparently, with the same diameter of bolt or rivet, the eccentricity is influenced markedly by the thickness of the bar. The eccentricities found in the bars tested separately under loads approximating 9 000 lb. per sq. in. were somewhat higher than the mean for the outer bars in the column tests. The lower eccentricities of the inner compression bars in the column tests are noteworthy. This evidence indicates that columns laced on two sides will have somewhat more uniform shearing strength and rigidity if the inner bars are sloped in opposite directions on the two sides.

TABLE 11.—Results of Compression Tests on Lacing-Bars.

*No measurements made.

The maximum unit loads from the individual compression tests of lacing-bars have been plotted against corresponding slenderness ratios in Fig. 21. It will be observed that the plotted points lie well above the line representing

the Talbot and Moore equation, $P/A = 21\,400 - 45\,\frac{l}{r}$.[7] It is likely that the discrepancy is partly due to difference in size of fastening bolts. Bolts ½ in. in diameter were used by Talbot and Moore; in the Wisconsin tests they were ⅞ in. in size.

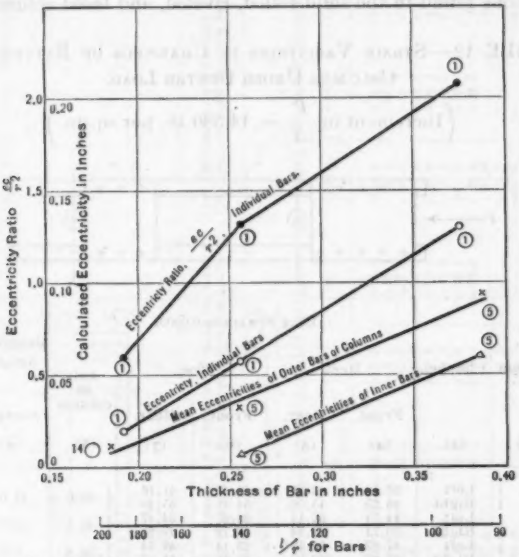

FIG. 20.—ECCENTRICITIES IN LACING-BARS UNDER COMPRESSION.

From the data now available, it appears that compression tests on individual lacing-bars yield safe results as a basis for design. More tests of this nature are much needed to supplement the meager fund of information.

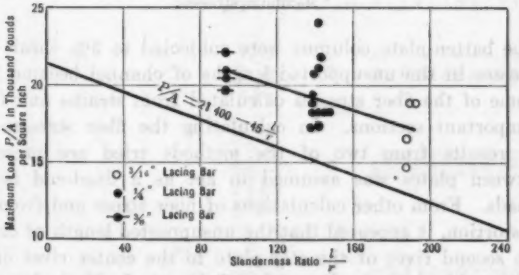

FIG. 21.—COMPRESSIVE STRENGTHS OF INDIVIDUAL LACING-BARS.

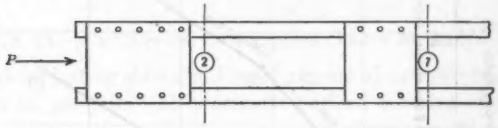

*11.—Stresses in Channels of Batten-Plate Columns.*—In the tests of the batten-plate columns, strains over 2-in. gauge lengths were measured on the

[7] See *Transactions*, Am. Soc. C. E., Vol. LXV (1909), p. 238.

outer fibers of the channel webs and toes at sections close to the lower stays and battens, and in Column No. 8*A*, in the middle of the unsupported channel lengths of the lower panel. The data from the tests made with central loading are assembled in Table 12. These results show that the fiber stress variations for this condition are not unduly large, but are comparable with variations found in the solid rolled, riveted, and laced columns.

TABLE 12.—STRAIN VARIATIONS IN CHANNELS OF BATTEN-PLATE COLUMNS UNDER CENTER LOAD.

* Maximum stresses.

When the batten-plate columns were subjected to 5% shear loadings, the bending stresses in the unsupported lengths of channel became large. Table 13 shows some of the fiber stresses calculated from strains and from loads at the more important sections. In calculating the fiber stresses for the end panels, the results from two of the methods tried are presented. Each channel between plates was assumed to act as a fixed-end beam carrying axial end loads. From other calculations of fiber stress and from calculations for shear distortion, it appeared that the unsupported length of channel should be from the second rivet of the stay-plate to the center rivet of the batten-plate, as indicated by $l_c$ in the diagram of Table 13. In Method (*a*), (Table 13), the inflection points of the channels were assumed to be at the middle of $l_c$. Strain measurements of Column No. 8*A* showed that the inflection point was nearer the first batten. Since the superior restraining influence of the stays over the battens was responsible for this condition, it was assumed in Method

* (*a*) Point of inflection at middle of unsupported length ($l_c$).
(*b*) Point of inflection 0.586 of unsupported length ($l_c$) from second rivet of stay-plate.
(*c*) Point of inflection midway between center rivets of adjacent battens.

† Maximum load.

(*b*), (Table 13), that the segments of the unsupported length of the top and bottom panels were directly proportional to the number of rivets per inch of adjoining plate. Hence, the length of segment adjacent to the stay-plates $= \frac{\frac{5}{13}}{\frac{5}{13} + \frac{3}{9}} l_c = 0.536\ l_c$. If one compares the figures in bold-faced type, Table 13, it is evident that stresses calculated by Methods (*b*) and (*c*) check closely the strain stresses for these highly stressed fibers. To investigate points of greatest fiber stress, calculations at maximum loads by Method (*b*) were made for Sections 1 and 5 through rivets, also by Method (*c*) for Section 6. At the flange toes (*B*) of Section 1, the calculated fiber stress for Column No. 8 is 31 300 lb. per sq. in. tension and at Toes *C* of the same section, 60 000 lb. per sq. in. compression. Under the latter stress, excessive lateral bending occurred which threw more tensile stress on Toe *B*. Finally, the metal necked down and broke in tension. Similar failures occurred in Columns Nos. 7 and 9, although Column No. 9 carried a load nearly as large as the laced-channel columns.

The detailed calculation for stresses at Points *A*, *B*, *C*, and *D* in Section 2 of Column No. 8*A* by Method (*b*) were made as follows: Each channel was assumed to carry one-half the transverse shear and one-half the bending moment (Fig. 22). Then, the distance from the inflection point to Section 2 is (32.75 × 0.536) — 5.625 = 11.92 in.

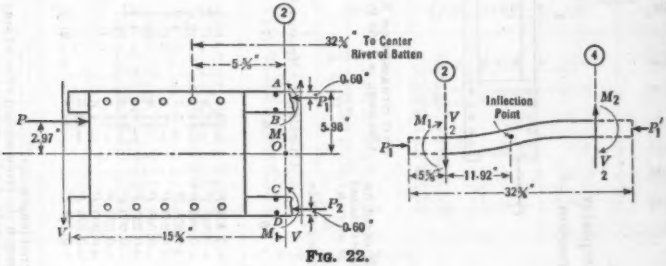

FIG. 22.

Then,

$$M_1 = 11.92\ \frac{V}{2} = 0.298\ P$$

$$\Sigma M_0 = 2.97\ P - (0.05\ P \times 15.75) - 5.38\ (P_1 - P_2) - 0.596\ P = 0$$

Since $P = P_1 + P_2$, $P_1 = 0.647\ P$ and $P_2 = 0.353\ P$.

Using $p = \frac{P}{A} + \frac{M\,c}{I}$ to find the unit fiber stress, $p$, $A = 5.65$ sq. in.; for the heel, $\frac{c}{I} = 0.220$; and for the toe, $\frac{c}{I} = 0.792$. Hence,

$$p_A = -\frac{0.647\ P}{5.65} - (0.298\ P \times 0.22) = -0.180\ P$$

$$p_B = -\frac{0.647\ P}{5.65} + (0.298\ P \times 0.792) = +0.122\ P$$

$$p_C = -\frac{0.353\,P}{5.65} - (0.298\,P \times 0.792) = -0.299\,P$$

$$p_D = -\frac{0.353\,P}{5.65} - (0.298\,P \times 0.22) = +0.003\,P$$

Substituting $P = 96\,700$ lb., the stresses given in Table 13 were obtained.

*12.—Shear Stress in Batten-Plates.*—Strain measurements were made on the stay and batten-plates of Columns Nos. 7 to 9; also on the stay-plates of Columns Nos. 4, 5*B*, and 6, as indicated in Figs. 4 to 7. It was found, however, that the strains on the outer faces of these plates were much larger than the average for the considered gauge line. Hence, in order to secure average strains, measurements on both sides of every plate had to be made. Although difficult, such measurements were made with the 2-in. Olsen gauge on the lower battens and stays of Columns Nos. 8 and 8*A*.

Plate measurements parallel and transverse to the axis of the column showed that these strains were insignificant. The strains on the 45° diagonals in these plates, however, were appreciable. From strains the shear stress in the plates was calculated, assuming Poisson's ratio to be 0.25, by,

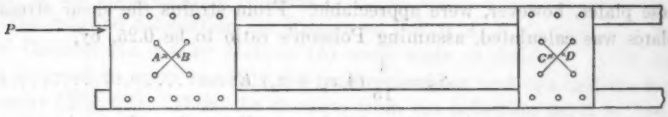
$$S_S = \frac{4}{15}(4\,\varepsilon_1 + \varepsilon_2)\,E \qquad (5)$$

In this expression, $\varepsilon_1$ is the unit strain in one diagonal, and $\varepsilon_2$, that in the diagonal normal to it. The shear stress in the plates was also calculated by the horizontal shear formula for rectangular sections. The stress in each of the two plates will be:

$$S_S = \frac{3}{4}\frac{V}{b\,d} \qquad (6)$$

In Equation (6), $V$ is the stress difference on either side of a batten in one channel, $b$, the thickness of the plate, and, $d$, the length of the plate measured along the column. The results of both calculations are given in Table 14. When one considers the small magnitude of the strains measured, the agreement between the stresses calculated from strain and those calculated from shear is very satisfactory. Hence, the designer may safely use the horizontal shear formula (Equation (6)) to determine the shearing stresses in the battens of such columns.

## Tests of Series (*B*): Eccentric Loads



*13.—Method of Testing.*—These tests were made on solid rolled H-columns having values of $\frac{l}{r}$ from 20 to 158. The purpose of the tests was, in general, to compare the behavior of such columns furnished under ordinary commercial conditions, with that of the ideal column; that is, to ascertain the effect of crookedness, eccentricity of rolling, and other variations, on the strength. The tests also furnished some valuable information on the effect of form on the strength of columns.

All columns were first centered in the machine with reference to the calculated gravity axis of the end sections, taking also into account any

measured crookedness of the columns. Shims were used to secure even bearings in a direction parallel to the axis of the rollers of the bearing blocks. Further correction was made in the setting by applying loads up to about 10 000 lb. per sq. in., observing deflection at the center, and taking strain-gauge readings over the center section. After this careful centering, a center loading test up to 15 000 lb. per sq. in., or when possible up to the Euler load, was run. The columns were then shifted a calculated amount to give the desired eccentricity. Fig. 27 shows Column No. *H*7 ready to be tested.

TABLE 14.—COMPARISON OF CALCULATED AND MEASURED SHEAR STRESSES IN BATTEN-PLATES OF COLUMNS NOS. 8 AND 8*A* UNDER 5 PER CENT. SHEAR LOADS.

* Elongation, +; compression, −.

Columns Nos. *H*2, *H*3, *H*4, and *H*5 were first loaded within the elastic limit with the eccentricity perpendicular to the web, then turned and tested to failure with the eccentricity in the plane of the web. Columns Nos. *H*1, *H*6, *H*7, *H*8, *H*9, and *H*10 were first loaded within the elastic limit with the eccentricity in the plane of the web, then turned and tested to failure with the eccentricity perpendicular to the web. Column No. *H*1 (the shortest) was then straightened and tested to failure with the eccentricity in the plane of

the web. Thus, all the columns were tested within the elastic limit with an eccentricity in each direction, four of the columns to failure by bending perpendicular to the web, six to failure by bending parallel to the web, and one (Column No. *H*1) also to failure by bending perpendicular to the web. To supplement the data for the shortest length tested, Column No. *H*10*B* was cut from the lower end of Column No. *H*10 and tested to failure with an eccentricity in the plane of the web.

Eccentricities were chosen so as to make the value of $\frac{e\,c}{r^2}$ (eccentric ratio) equal to 0.5, 1.0, or 2.0; in this expression, $e$ is eccentricity; $c$, distance to the extreme fiber; and $r$, the radius of gyration. In every case failure tests were made with $\frac{e\,c}{r^2} = 1.00$. With this value, the fiber stress on the concave side of the column (neglecting the effect of deflection) would be twice the average, and on the convex side, zero. Deflections at the center were measured, also strains near the ends, quarter-points, and center, at the four corners (edges of flanges), center of each flange, and each side of the center of the web.

*14.—Fiber Stresses at Maximum Loads.*—A comparison of the calculated maximum unit fiber stresses with the yield point of the metal in these H-columns is given in Table 15. The calculated fiber stresses were computed by the formula:

$$p = \frac{P}{A}\left[1 + \frac{(e + D)\,c}{r^2}\right]$$

in which, $D$ is measured deflection and $e$, eccentricity, including the effect of crookedness. The calculations assumed proportionality of stress and strain across the section and for values beyond the yield point give fictitious rather than real stresses. The results, however, serve for comparative purposes. The following significant results are noted:

(1) The maximum fiber stress is in every case considerably beyond the proportional limit of the material, but at "first scaling" the stress is considerably below the limit.

(2) For a column placed with its web perpendicular to the axis of the rollers (bending parallel to web), the maximum fiber stress averages somewhat greater than the yield point of the material, but is slightly less in two cases.

(3) For a column placed with its web parallel to the axis of the rollers (bending perpendicular to web), the maximum fiber stress is greater (generally very much greater) than the yield point of the material, and, therefore, greater than the maximum stress when tested in the other direction. The excess over the latter amounts to the following percentages: 41, 62, 42, 36, and 21, the last being for the longest column. These large differences are significant, and indicate a very considerable difference in the behavior of columns when the bending is in a plane parallel to an outstanding flange and when perpendicular to such a flange. This may be of importance when considering the application of formulas which take account of the form of section in terms of the ratio of $c$ to $r$. Of course, the effect of the difference in the ultimate fiber stress here shown does not indicate a correspondingly large difference in the ultimate strength of the column. This will be discussed later.

* Estimated.

Table 16 gives some of the stresses from strain measurements as compared to calculated stresses under loads within the elastic limit. Unit stresses were calculated from strains as follows: For Fiber A,

$$p_A = \frac{P}{A}\left(\frac{4\,e_A}{e_A + e_B + e_C + e_D}\right)$$

The 8-in gauges near the top and bottom of the columns were centered 8 in. from the ends. (See Fig. 8.)

Considering all H-columns and unit loads, $P/A$, sufficient to produce stresses of 16 000 to 27 000 lb. per sq. in. on the outer concave fibers at mid-section, the average variation of the average gauge stress was only 2.6% from the calculated stress, and the maximum variation was 11.7 per cent.

A variation between individual and average gauge readings (large only at end sections) indicated the effect of irregularity of end condition in a plane parallel to the axis of the roller (fixed direction), and shows the difficulty of flat end tests.

*15.—Measured and Calculated Deflections.*—Figs. 23, 24, and 25 show comparisons between observed and calculated central deflections, the calculated deflections being determined by the theoretical formula for eccentric load, as follows:

$$D = e\left(\sec\sqrt{\frac{P}{E\,I}}\frac{l}{2\,r} - 1\right)$$

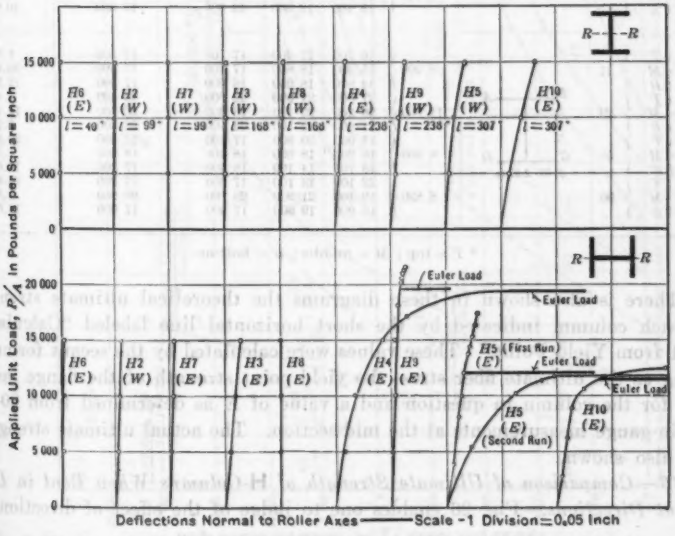

FIG. 23.—LOAD-DEFLECTION CURVES FOR 8-INCH, 32-POUND, H-COLUMNS, UNDER CENTER LOADINGS.

The value of $E$ used was that obtained from strain measurements on the center section, and $r$ was the measured value. Note the very close agreement

between observed and calculated deflections. Fig. 25 also shows the marked effect of the magnitude of the eccentricity of the load on the deflection of a long column like Column No. *H*4.

TABLE 16.—COMPARISON OF MAXIMUM FIBER STRESSES IN H-COLUMNS CALCULATED FROM STRAINS WITH STRESSES FROM LOAD AND DEFLECTION.

* *T* = top ; *M* = middle ; *B* = bottom.

There is also shown in these diagrams the theoretical ultimate strength of each column, indicated by the short horizontal line labeled "Calculated *P*/*A* from Yield Point." These values were calculated by the secant formula, using as the ultimate fiber stress the yield point strength of the flange material for the column in question and a value of *E* as determined from 20-in. strain-gauge measurements at the mid-section. The actual ultimate strengths are also shown.

*16.—Comparison of Ultimate Strength of* H*-Columns When Bent in Different Directions.*—Fig. 26 enables one to judge of the effect of direction of bending on the ultimate strength for equal values of $\frac{l}{r}$ and on the actual, as compared to the theoretical, strength. The full line represents the theoretical strength for a fiber stress equal to the average tensile yield point of the

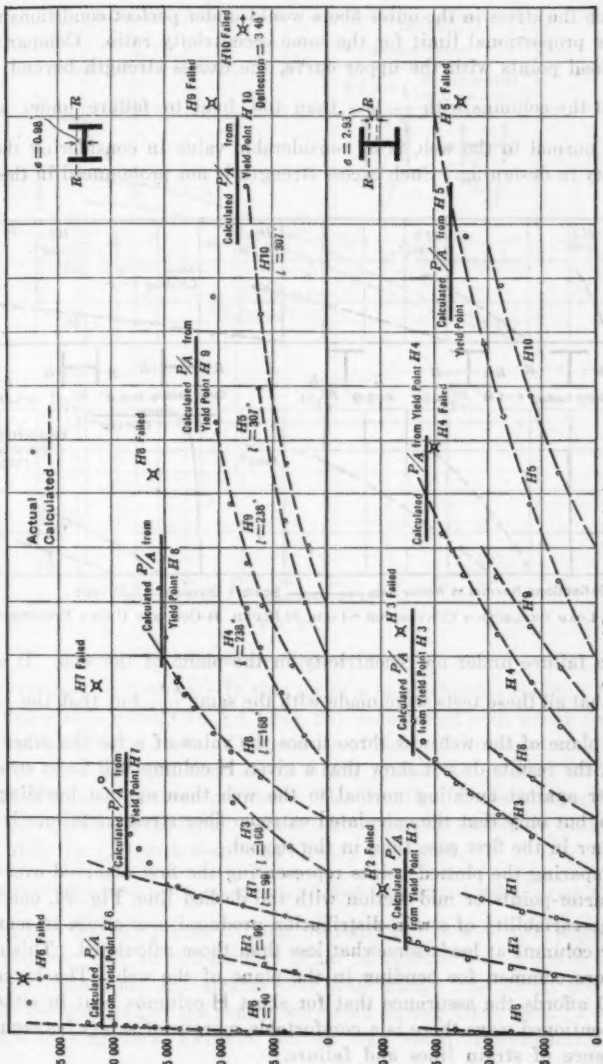

FIG. 21.—LOAD-DEFLECTION CURVES FOR 8-INCH, 32-POUND, H-COLUMNS UNDER ECCENTRIC LOADINGS. $\frac{ec}{r^2} = 1$.

material when $\frac{e\,c}{r^2} = 1$. The dashed line shows the theoretical unit load ($P/A$) at which the stress in the outer fibers would under perfect conditions reach the average proportional limit for the same eccentricity ratio. Comparing maximum load points with the upper curve, the excess strength beyond the yield point of the columns with $\frac{l}{r}$ less than 100, bent to failure under an eccentricity normal to the web, is of considerable value in considering the margin of safety in designing. Such excess strength is not pronounced in the columns

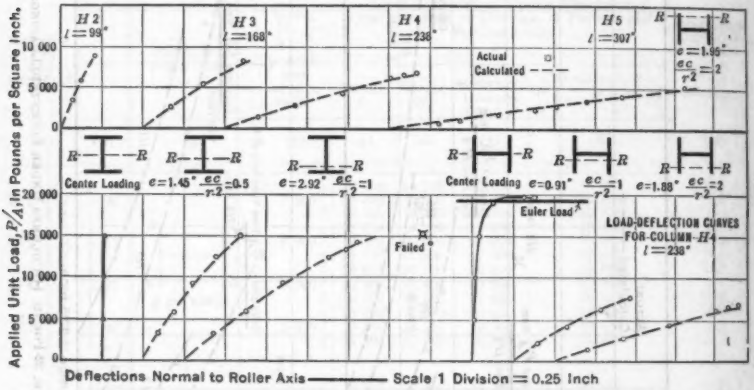

FIG 25.—LOAD DEFLECTION CURVES FOR 8-INCH, 32-POUND, H-COLUMNS UNDER ECCENTRIC LOADINGS.

bent to failure under an eccentricity in the plane of the web. It should be noted that all these tests were made with the same $\frac{e\,c}{r^2}$, but that the value of $e$ in the plane of the web was three times the value of $e$ for the other position. Hence, the results do not show that a given H-column will be as strong as, or stronger against buckling normal to the web than against buckling parallel thereto, but only that the calculated extreme fiber stress at failure is likely to be higher in the first case than in the second.

Comparing the plotted points representing the first observed over-strain at the quarter-points or mid-section with the dashed line, Fig. 26, one perceives that the variability of strain distribution produced over-strain in many of the shorter columns at loads somewhat less than those calculated. This condition was more common for bending in the plane of the web. The lower part of Fig. 26 affords the assurance that for short H-columns bent in either of the aforementioned ways there is a comfortable margin of safety between the first appearance of strain lines and failure.

These H-column tests furnish satisfactory confirmation of the reliability and accuracy of the secant formula when the conditions are known. There is need, however, of further tests of this character on sections of different form, to assist in answering the question of the effect of form in column design.

The arrangement of apparatus for the tests of Series (*B*) is shown in Fig. 27.

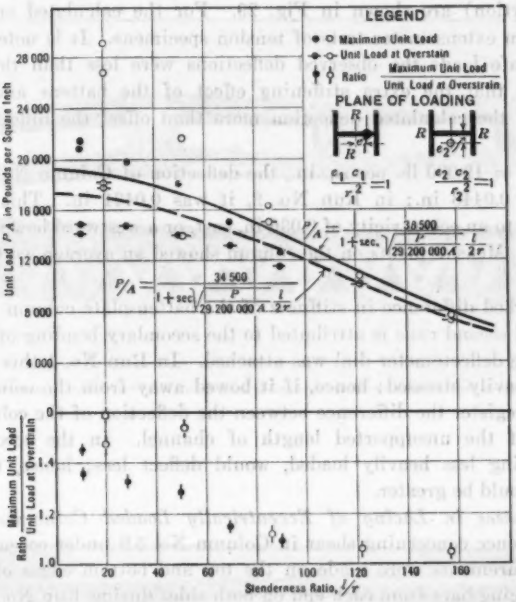

FIG. 26.

## TESTS OF SERIES (*C*)

*17.—Procedure in Testing.*—In this series a laced channel column, No. 5*B*, and a batten-plate column, No. 8*A* (Fig. 28) were tested both under eccentric loads and under oblique loads. The purpose of the eccentric load tests was to ascertain if there was sufficient shear strain present to increase materially the lateral deflection of these columns. The function of the oblique loading tests was to supplement the data on shear distortion and stresses in battens and channels of Series (*B*) with results as already presented.

In the eccentric load tests, each column was first tested with $\frac{e\,c}{r^2} = 0.4$ and bent normal to the web planes without over-strain. It was then shifted to a parallel position with an eccentricity equal in amount but opposite in sign. Both center deflections and strains over 8-in. gauge lengths on the corner fibers near the ends and at the center were read during these tests. Following the oblique loading tests, Column No. 5*B* was tested to destruction under eccentric loads with $\frac{e\,c}{r^2} = 0.6$, $e$ being normal to the webs; and Column No. 8*A* was crushed under eccentric loads with $\frac{e\,c}{r^2} = 1.0$, $e$ being parallel to the webs.

*18.—Deflection Data.*—The load-deflection curves for these eccentric load tests and the deflection curves calculated by the secant formula (which neglects shear distortion) are shown in Fig. 29. For the calculated curves, $E$ was derived from extensometer tests of tension specimens. It is noted that in all cases for safe loads the observed deflections were less than the calculated. This shows that the extra stiffening effect of the battens and lacing not included in the calculated deflection more than offset the influence of shear distortions.

At $P/A = 12\,000$ lb. per sq. in., the deflection of Column No. 5*B*, in Run No. 1, was 0.0448 in.; in Run No. 2, it was 0.0431 in. This discrepancy corresponds to an eccentricity of 0.036 in. east, or a westward bow at mid-length of 0.036 in. Measurements on the column showed an average westward bow of 0.023 in.

The marked difference in stiffness of the batten-plate column (No. 8*A*) in the first and second runs is attributed to the secondary bending of the channel to which the deflectometer dial was attached. In Run No. 1 this channel was the more heavily stressed; hence, if it bowed away from the column axis the dial would register the difference between the deflection of the column and the deflection of the unsupported length of channel. In the second run the channel, being less heavily loaded, would deflect less; hence, the recorded deflection would be greater.

*19.—Stresses in Lacing of Eccentrically Loaded Columns.*—To secure further evidence concerning shear in Column No. 5*B* under eccentric loading, strain measurements were made on the top and bottom edges of the second and third lacing-bars from each end on both sides during Run No. 6 to failure. From these strains the calculated average stress in the bars, at $P/A = 18\,000$ lb. per sq. in., was 1 140 lb. per sq. in. At this load stresses in the eight bars varied from 230 to 2 300 lb. per sq. in. These data, like the deflection-test evidence, indicate that the transverse shear in the eccentrically loaded column is very small. The maximum stress in the lacing-bars tested indicates a shear of $V = 0.011P$.

These general results as regards shear might have been predicted, as the theoretical shearing stress in a column with such a low slenderness ratio $\left(\frac{l}{r} = 22\right)$ is very small. In this case for $P/A = 18\,000$ lb. per sq. in., the theoretical end shear is only $0.0037P$, an amount too small to change the deflection sensibly. For more slender columns the effect would be greater. This question is discussed further in Part II.

*20.—Maximum Fiber Stresses at Failure.*—The failure of these columns was instructive. In the test of Column No. 5*B*, scaling was observed on the concave outer fibers just below the upper battens at $P/A = 16\,000$ lb. per sq. in., and failure occurred at $P/A = 19\,000$ lb. per sq. in., by bending normal to the rollers. Column No. 8*A* deflected normal to the rollers as a unit until the outer concave fibers were stressed well beyond the yield point; then the middle unsupported portions of channel suddenly buckled laterally as shown in Fig. 28. Scaling was not observed prior to the imposition of the maximum load.

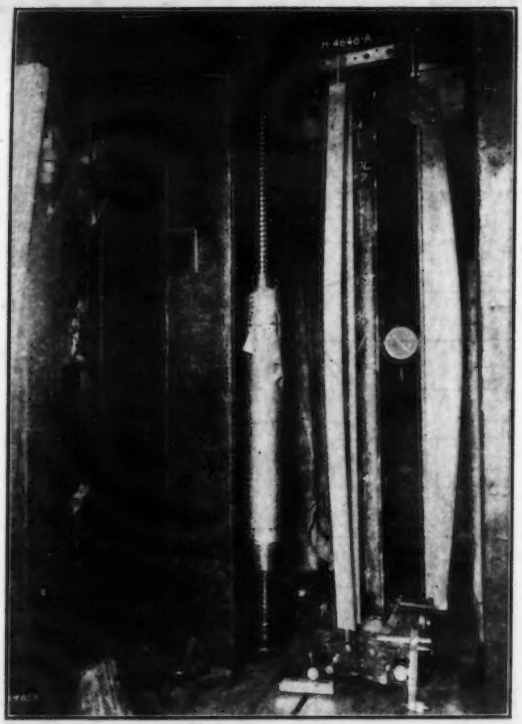

FIG. 27.—COLUMN NO. *H7* READY FOR AN ECCENTRIC LOAD TEST.

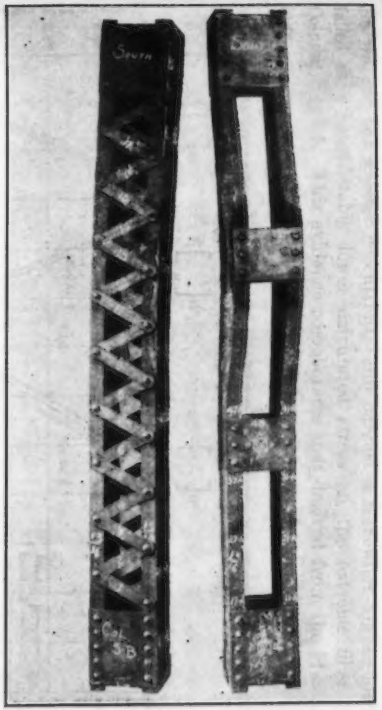

FIG. 28.—FAILURES OF COLUMNS NOS. *5B* AND *8A* TESTED UNDER ECCENTRIC LOADS.

Additional evidence of the influence of the form of cross-section on the maximum calculated fiber stress is afforded by the results of these two tests, which are summarized in Table 17. It will be seen that, although Column No. 5*B* had the greater eccentricity and carried a somewhat higher load, it failed at a considerably lower calculated stress on the extreme fiber than Column No. 8*A*. This evidence corroborates that derived from the H-column tests.

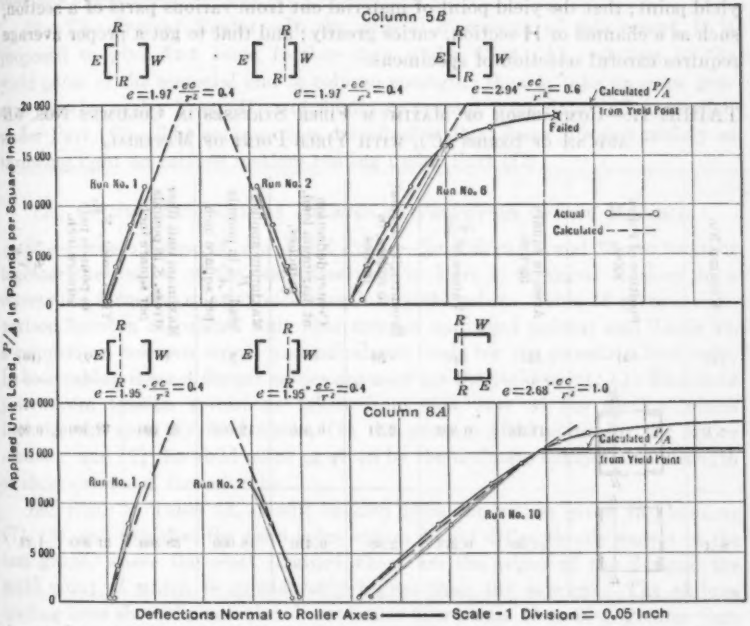

FIG. 29.—LOAD-DEFLECTION CURVES FOR COLUMNS NOS. 5*B* AND 8*A* OF SERIES (*C*).

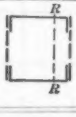
## PART II.—GENERAL REPORT



*21.—The Report of 1926.*—In the report of 1926,[8] the subject was divided into the following subdivisions:

(A) Strength as Related to Yield Point.—This topic was discussed with reference to results of tests on columns with slenderness ratios, $\frac{l}{r}$, not greater than 100 and with flat ends or flat-end behaviors. It was shown that for $\frac{l}{r} = 50$, the average ultimate strength was about 95% of the tensile yield point of the material composing the column, ranging in quality from nickel steel with a yield point of 56 000 lb. per sq. in. to low carbon steel with a

[8] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1485.

yield point of 25 000 lb. per sq. in. For $\frac{l}{r} = 100$, the average strength was about 88% of the yield point. The great majority of the results was larger than would be calculated by assuming an eccentric ratio, $\frac{e\,c}{r^2} = 0.1$, and by taking due account of the slenderness ratio, $\frac{l}{r}$. It was also shown that the tensile yield point of steel of various grades is closely equal to the compressive yield point; that the yield point of material cut from various parts of a section, such as a channel or H-section, varies greatly; and that to get a proper average requires careful selection of specimens.

TABLE 17.—COMPARISON OF MAXIMUM FIBER STRESSES IN COLUMNS NOS. 5*B* AND 8*A* OF SERIES (*C*), WITH YIELD POINT OF MATERIAL.

| Column No. (1) | Position of roller axes. (2) | Area, in square inches. (3) | Values of $\frac{c}{r^2}$. (4) | Eccentricity normal to rollers, in inches. (5) | Center deflection at maximum load, in inches. (6) | Maximum applied load, $\frac{P}{A}$, in pounds per square inch. (7) | Maximum unit fiber stress, $S$, in pounds per square inch. (8) | Yield point, $Y_F$, in pounds per square inch. (9) | $\frac{S}{Y_F}$ (10) |
|---|---|---|---|---|---|---|---|---|---|
| 5 *B* |  | 11.38 | 0.203 | 2.91 | 0.210 | 19 000 | 31 200 | 32 400 | 0.96 |
| 8 *A* |  | 11.30 | 0.373 | 2.68 | 0.410 | 18 000 | 38 800 | 31 800 | 1.22 |

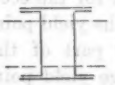
(B) Results of Tests on Columns of All Lengths Showing Integral Action.—All available tests were plotted and discussed. It was shown that tests on flat-end columns and those pin-end tests that showed flat-end behavior gave results fairly represented by a parabolic curve beginning at the yield point for $\frac{l}{r} = 0$, and tangent to the Euler curve, $P/A = \frac{4\,\pi^2\,E}{\left(\frac{1.12\,l}{r}\right)^2}$; and that tests on pin-end columns gave results fairly represented by a parabola beginning at the yield point and tangent to the Euler curve, $P/A = \frac{\pi^2\,E}{\left(\frac{0.78\,l}{r}\right)^2}$.

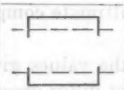
(C) Effect of Various Details on Strength of Columns.—Under this head was discussed the data relative to eccentricities, it being shown that few tests gave values greater than those represented by the eccentric ratio, $\frac{e\,c}{r^2} = 0.1$,

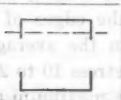
corresponding to a bending stress for short lengths of 10% of the direct stress. The unsupported lengths of column components were discussed as regards thickness of outside plates, and results were given to indicate that a ratio of rivet pitch to thickness equal to 20 was sufficiently low to develop the full strength of the column, and that current practice was conservative in this respect.

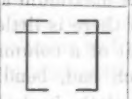
(D) Column Theories; The Column in a Truss; Working Formulas.—This proposed subdivision was left for a subsequent report.

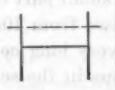
*22.—The Present Report.*—In the general discussion of this report, it is proposed to give first some further data under Part (A), relating to the yield point of the material and to column strength; then to take up some general theories under Part (D) and finally to present some data and discussion under Part (C). The column tests described in Part I are of value mainly as throwing light on various matters coming under Part (C).











## (A) Column Strength as Related to Properties of the Material

*23.—Column Strength and Yield Point.*—In Tables 18 and 19 are brought together the results of the tests described in Part I, arranged to show in a convenient form the relation of strength to yield point. Table 18 gives a comparison between calculated unit fiber stresses and yield points; and Table 19, a comparison between actual and calculated loads for the eccentric load tests. In both tables, three different values are used for the yield point: (1) The yield point from tension specimens taken from that part of the section which includes the most strained fibers; (2) the average yield point for the entire section; and (3) the yield point as given by the ultimate compressive strength of short prisms of the columns.

Referring to Table 18, it will be seen from the values given in Columns (7), (8), and (9), that the yield point values do not differ greatly except in the last group, where the most strained fibers are the edges of the flanges, the yield point of which is considerably higher than the average. The oblique loading tests showed a calculated maximum fiber stress 10 to 20% greater than the yield point. In these tests the fiber stress is a maximum at the end of the column, and diminishes toward the center so that there is little or no buckling action. The behavior is similar in nature to that of a column in a structure with heavy secondary bending moments at each end, bending the column into an S-shaped curve. All these columns were relatively short.

The eccentric load tests show two general results corresponding to the two conditions discussed in Part I, Section 16. Those tests where the deflection was in a direction such that a large part of the cross-section was stressed to the maximum, or nearly so, showed stresses from 96 to 115% of the yield point (Column (10), Table 18); those tests where but a small part of the section was stressed to the maximum, showed calculated stresses from 105 to 160% of the yield point, the small value of 105% being for a very long column. As stated in Part I, these excessive fiber stresses are fictitious in the sense that they are not actual stresses, but calculated values based on the elastic behavior of the material up to failure.

| | H 8 | | 86 | 1.05 | 60.2 | 43.0 | 39.6 | 38.8 | 1.40 | 1.52 | 1.55 |
| | H 9 | | 121 | 1.02 | 51.6 | 45.3 | 41.8 | 39.4 | 1.14 | 1.23 | 1.31 |
| | H10 | | 158 | 1.06 | 44.0 | 41.8 | 38.0 | 37.6 | 1.05 | 1.16 | 1.17 |

In Table 19 are given values of observed and calculated ultimate strengths of columns tested eccentrically, the calculated values being based on three different values of yield point as given in Columns (6), (7), and (8) of the table. Columns (9), (10), and (11) give ratios of observed to calculated stresses. The results are relatively about the same as given in Table 18, except that the ratios of observed to calculated loads of Table 19 are somewhat less than the ratios of fiber stresses to yield points of Table 18; that is, the ultimate loads do not show the same relative excess as the ultimate fiber stresses. This is due in part to the fact that in a column the fiber stress increases at a faster rate than the load.

*24.—Tests on Coupons.*—Two hundred and four tension tests and one hundred and eighty-two compression tests were made on specimens cut from the shapes used in the Wisconsin tests. Extra lengths of the stock from

which the columns were fabricated were furnished by the manufacturers with the columns. From these, test specimens were cut in accordance with the diagrams in Figs. 30 and 31. In these tests the proportional limit, yield point, ultimate strength, percentage elongation, percentage reduction in area, and modulus of elasticity were found. The speed of the movable head of the machine in the tension tests was 0.14 in. per min. as far as the yield point, and 0.023 to 0.068 per min. in the compression tests. From these tests on coupons only the strength data are presented herein.

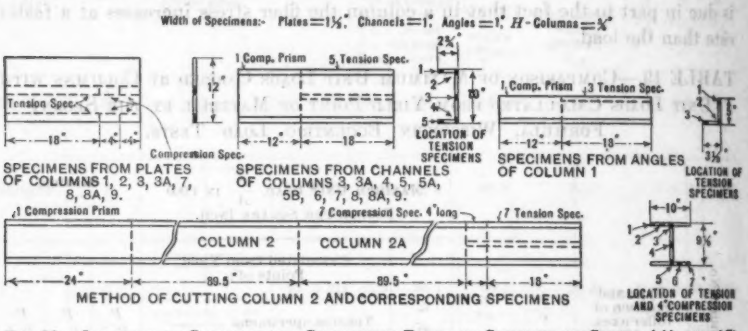

FIG. 30.—LOCATION OF SPECIMENS IN COMPONENT PARTS OF COLUMNS OF SERIES (*A*) AND (*C*).

Columns Nos. *H*1 to *H*5 (Fig. 31) were cut at the University Shops from lengths of 8-in., 32-lb., H-sections, Heat No. 52*E*465. Columns Nos. *H*6 to *H*10 were cut at the mill, in similar manner, from Heat No. 39*F*273. No 4-in. compression prisms were made corresponding to Columns Nos. *H*9 and *H*10. All tension and short compression specimens were ¾ in. wide. The ends of all compression members were milled.

* Heat test data. † Ultimate strength of a full-sized prism.

the averages for the different shapes, the results were weighted in proportion to the volume of the shape tributary to the specimen.

Study of the tabulated data obtained at Wisconsin shows that all shapes passed the specification requirements for yield point, but the average tensile strength for all the 10-in., 20-lb. channels was below requirements. The variations in the different properties are given in Table 22. Attention is called to the similarity in range for tensile and compressive yield point, also to the wide range of proportional limit values. It will also be noted that the thinner sections of a given shape exhibited higher yield points than the thicker sections.

* Heat test data.

Mill *vs.* Laboratory Tests.—Averaging the laboratory tests for a given shape and heat and comparing with mill tests, the maximum, average, and minimum ratios of

$$\frac{\text{Mill yield point}}{\text{Laboratory yield point}}$$

for the nine heats are found to be 1.16, 1.02, and 0.88, respectively. Proceeding in a similar manner, the corresponding ratios of

$$\frac{\text{Mill ultimate strength}}{\text{Laboratory ultimate strength}}$$

are, respectively, 1.07, 1.00, and 0.95.

Comparison of Yield Points in Tension and Compression.—Although the results in Table 22 indicate a considerable range in yield points of the material in the different shapes, the data of Table 23 shows that the ratio,

$$\frac{\text{Average yield point in tension}}{\text{Average yield point in compression}}$$

was nearly constant. For the nine heats represented, this ratio varied from 0.99 to 1.05, and averaged 1.01. These data supplement and confirm the statement previously advanced,[9] that, in general, the tensile yield point is a close indication of the compressive yield point, and, for the purpose in question, probably as satisfactory an indication of the column strength.

* No minimum specified—based on 30 000 lb. per sq. in.

*26.—Effect of Location on Strength of Specimens.*—Table 24 furnishes information regarding the effect of the position of the test piece in the shape on the yield point and ultimate strength. For the H-columns the specimens cut from the intermediate portions of the flanges[10] appear to represent best the entire shape. They also were the least variable. For the channels the web specimens were most representative. For the plates there was not much difference (2%) between specimens cut from the edge and from the center, although the former were consistently the stronger. The number of specimens from angles is too small to warrant definite conclusions. The root specimens were the best representatives for the angles tested. In most cases the specimens cut from the toes or edges of shapes exhibited higher yield points than other specimens cut from the same shapes.

*27.—The Uniformity of the Modulus of Elasticity of the Wisconsin Test Columns.*—By plotting the average strains for gauge lines which were symmetrically disposed about the axis of a given column, the modulus of elasticity was computed for the mid-segments of all Wisconsin test columns and in most cases for the segments at or near the quarter-points. Owing to the effect of

[9] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1524.

[10] See similar results in *Technologic Paper No. 328*, U. S. Bureau of Standards.

irregularities in milling of the ends of columns and in the bearing blocks, the average moduli for the gauge lines nearest the column ends are omitted from this discussion. The results of these calculations appear in Tables 25 and 26. In calculating $E$ for the segments of the built-up columns, the strains for the four corner gauge lines were averaged; but, in similar calculations for the H-columns, strains along the eight gauge lines shown in Fig. 8 were usually averaged. Values of mean $E$ for the column ("column-$E$") were obtained by averaging the values of $E$ for the segments.

* Full-sized prisms.

† Averages corresponding to those in Column (7).

It should be observed that practically all the columns were subjected to several trial loadings prior to the determination of the strains used in these calculations. This condition contributed to the obliteration of initial sets and to somewhat higher moduli of elasticity than would have been obtained had it been possible to have made all measurements during an initial loading.

The data in Tables 25 and 26 show that the average value of "column-$E$" for the 8-in. gauge lines of both the built-up and H-columns averaged 29 800 000 lb. per sq. in.; also, that "column-$E$" for the 20-in. gauge lines averaged 29 400 000 and 29 800 000 lb. per sq. in. for the respective types of columns. Considering 8-in. gauge lines, Column No. 1 had the lowest "column-$E$", 27 800 000 lb. per sq. in., and Columns Nos. 7 and $H5$ the highest, 30 900 000 lb. per sq. in. Hence, the range in "column-$E$" for the built-up columns is 10%; whereas, for the H-columns, it is 7 per cent.

Since marked variation in values of $E$ within a column materially affects its strength, the percentage range in $E$ for the three segments of each

column were inserted in Columns (8) of Tables 25 and 26 to secure some data covering this point. These values were calculated from,

$$\frac{\text{maximum } E\text{—minimum } E}{\text{"column-}E\text{"}}$$

The average range of $E$ for the built-up columns was 5.8% and for the H-columns the range was 3.9 per cent. The greatest range, 9.8%, occurred in batten-plate column (No. 9).

*Calculated by weighting specimens in proportion to tributary area.
† Mean of all specimens from the type of shape indicated in Column (1).
‡ Mean of specimens from the location indicated in Column (2).

If one assumes $E$ equal to 30 000 000 lb. per sq. in. for calculations in connection with these columns, the results entered in Columns (9) of Tables 25 and 26 show the average errors in percentage for the different segments and gauges of these columns. For the built-up columns the average percentage variation of $E$ from 30 000 000 lb. per sq. in. is only 3.2; for the H-columns, it is only 2.1. The maximum variation, 8.7%, is for Column No. 3*A*.

When one takes into account the nature of strain-gauge measurements and the variability of the cross-sectional area of such members, these data

furnish convincing proof of the uniformity of the modulus of elasticity of steel within a given shape and as between shapes.

Values of *E* from tests on the coupons cut out of these different shapes exhibit similar uniformity, but the average values of the tension and compression moduli from the H-column coupon tests, approximately 29 200 000 and 29 000 000 lb. per sq. in., respectively, are somewhat less than the values found in the column tests.

## (D) Column Theories: The Column in a Truss

It is not intended to give herein any considerable discussion of the various column formulas, but only a brief review of the various types and some points relative to their derivation and applicability.

*28.—The Euler Formula.*—This well-known formula for various end conditions has been shown by many tests conducted with carefully designed end conditions to be correct and reliable under the conditions assumed. It is based, as is well known, on the elastic modulus of the material and not on its strength. It is, therefore, applicable, if at all, only to lengths in which buckling can occur within the elastic limit of the material. It has proven very serviceable for such slender columns as airplane struts, but in the general field of structural engineering, it serves mainly as a guide for the limiting value, for the longer lengths, in the study of tests of columns and of column formulas, where conditions may approach those assumed in the Euler formula.

* Calculated by averaging the appropriate results in Column (9).

For pivoted ends, the formula is,

$$P/A = \frac{\pi^2 E}{\left(\frac{l}{r}\right)^2} \quad \ldots\ldots\ldots\

$c$ = distance from gravity axis to extreme fiber;

$\frac{e\,c}{r^2}$ = eccentric ratio;

$p_e = \frac{\pi^2 E}{\left(\frac{l}{r}\right)^2}$ = Euler load per square inch for centrally loaded pivoted-end columns;

$\phi = \frac{\pi}{2}\sqrt{\frac{p}{p_e}}$, a function of frequent occurrence;

$q = \sqrt{\frac{P}{E\,I}}$;

$f_b$ = intensity of bending stress on extreme fiber at center;

$f$ = total unit stress on extreme fiber at center on concave side.

Referring to Fig. 32, the equation of the elastic line is,

$$y = e\,(\tan\phi \sin q\,x + \cos q\,x - 1)$$

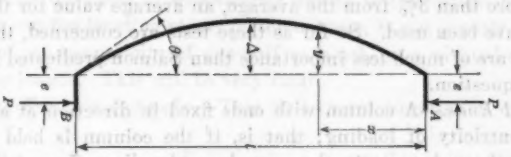

FIG. 32.

The inclination at the end is,

$$\frac{d\,y}{d\,x}(x = 0) = \theta = e\,q \tan\phi \qquad (9)$$

$$f_b = p\,\frac{e\,c}{r^2}\sec\phi$$

The total stress is,

$$f = p + f_b = p\left(1 + \frac{e\,c}{r^2}\sec\phi\right)$$

and,

$$p = \frac{f}{1 + \frac{e\,c}{r^2}\sec\phi} \qquad (10)$$

Placing $f$ = yield-point strength of the material, the value of $p$ will approximate the ultimate strength of the column.

If the loads are applied centrally, but the column is initially bent to an amount equal to $e$ at the center, the resulting stresses are somewhat less than for an eccentricity of loading of the same amount, but the difference is not great enough to warrant special treatment of this case. Where there is both eccentricity of load and crookedness of column, both eccentricities may be combined with little error.[12]

[12] For full discussion, see work on "Columns," by E. H. Salmon, Oxford Technical Publications, pp. 29, 42.

The foregoing formula, frequently known as the "secant" formula, is satisfactory from a theoretical standpoint, and for analytical purposes has many advantages over others; but for practical use, the eccentricity, $e$, must be assumed or determined by tests or observations, in much the same manner as the constants in other formulas, and when this is done, the formula is not readily solved for particular values of $\frac{l}{r}$, as the value of $p$ is included also in the quantity, $\phi$. This objection can be removed by the use of tables, but there is something to be said in favor of a formula that can be readily applied to any particular case. Various approximations to the secant formula have been proposed, the most elaborate study known to the Committee being that by Mr. R. W. Hawken,[13] in which he analyzes about seven different approximations and proposes one of his own.[14]

The accuracy of the secant formula when the eccentricity is known is well indicated by the results of the eccentric load tests of Series ($C$). The value of $E$ used in each case was that for the column in question, but as these values varied not more than 3% from the average, an average value for this quantity might well have been used. So far as these tests are concerned, therefore, the irregularities are of much less importance than Salmon predicated in his treatment of this question.

*31.—Fixed Ends.*—A column with ends fixed in direction at all loads can have no eccentricity of loading; that is, if the column is held securely in alignment by the end supports, there can be no bending effect at the ends due to eccentricity of loading. As a matter of fact, most columns rigidly connected in a framework are not really fixed-end columns, but are subjected to a certain amount of end moment and rotation of axis at the end, due to the action of the framework as a whole. This action will be discussed subsequently; but such a column is not a fixed-end column. The only kind of eccentricity which can exist in a fixed-end column is that (1) due to crookedness or curvature of the

[13] "Column Analysis and Design," Univ. of Queensland, Sydney, 1918; see, also, "A Simplified Column Formula of the Secant Type," by J. B. Hunley, *Bulletin No. 300*, Am. Ry. Eng. Assoc., 1927.

[14] The approximate formula proposed by Hawken is,

$$p = \frac{f}{1 + \frac{e\,c}{r^2} \cdot \frac{1 + 0.25\,\frac{p}{p_e}}{1 - \frac{p}{p_e}}}$$

in which, $\sec \frac{\pi}{2}\sqrt{\frac{p}{p_e}}$ of Equation (10) is replaced by the quantity, $\frac{1 + 0.25\,\frac{p}{p_e}}{1 - \frac{p}{p_e}}$. This is remarkably close to the true value, giving results for $p$ in error by less than 1% for values of $\frac{p}{p_e}$ as great as 0.9. This equation is readily solvable for $p_e$, giving,

$$p_e = p + \frac{\frac{f}{p} - \left(1 - 0.25\,\frac{e\,c}{r^2}\right)}{\frac{f}{p} - \left(1 + \frac{e\,c}{r^2}\right)}$$

and from the relation, $\left(\frac{l}{r}\right)^2 = \frac{\pi^2 E}{p_e}$, various values of $\frac{l}{r}$ can be directly calculated for various values of $p$, and curves or tables prepared for various values of $\frac{e\,c}{r^2}$.

axis of resistance; (2) due to actual crookedness of the section, or variation in the section; or (3) due to variation in the modulus of elasticity. The effect of a given amount of initial curvature can be determined by the same general process as applied to the eccentrically loaded, pivoted-end column. The mathematical process is somewhat complicated, and it will be sufficient to give here the general results as contained in Salmon's analysis. He shows that the bending stresses in such a case, assuming parabolic initial curvature, are, for small values of $\frac{p}{p_e}$ $\left(\text{low loads, or low values of } \frac{l}{r}\right)$, about twice as great at the end as at the center, like the bending stresses in an ordinary beam fixed at the ends. The sum of these end and center stresses is somewhat less than the center fiber stress in a pivoted end column of half the length, with the same initial eccentricity. For higher loads, the center and end stresses approach equality, and the sum of the two differs by an increasing amount from the fiber stress in a pivoted-end column of half length. Considering all the conditions, it may be concluded that the effect of eccentricity due to initial bends in a truly fixed-end column, on the bending stress in the column, is not greatly different from the effect of an eccentricity of one-half as much on a pivoted-end column of one-half the length. This will be very small.

*82.—The Rankine Formula.*—This well-known equation is of the form,

$$p = \frac{f}{1 + K\left(\frac{l}{r}\right)^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (11)$$

in which, $K$ is a constant depending on the end conditions and rests on experimental determination. For the ultimate strength, $f$ is approximately the yield point of the material.

A rather serious objection to this formula is that, in the nature of the case, $K$ can hardly be a constant, as may readily be shown. The formula can be written, $f = p + p\,K\left(\frac{l}{r}\right)^2$, in which the term, $p\,K\left(\frac{l}{r}\right)^2$, represents the bending fiber stress, $f_b$, at the center. Also, necessarily, $f_b = p\,\frac{\Delta\, c}{r^2}$, in which, $\Delta$ equals the total eccentricity at the center of the column. If this eccentricity is all due to bending, for any beam, $\Delta = \frac{K' f_b l^2}{c}$, in which, $K'$ is a constant depending on the manner of loading. $\left(\text{For a uniformly loaded beam, } \Delta = \frac{5}{48}\,\frac{f_b l^2}{c E}, \text{ and } K' = \frac{5}{48 E}\right)$. Then,

$$K\left(\frac{l}{r}\right)^2 = \frac{\Delta\, c}{r^2} = \frac{K' f_b l^2 c}{c\, r^2} = K' f_b \frac{l^2}{r^2}$$

or $K = K' f_b$. That is, the "constant", $K$, is proportional to $f_b$. If the eccentricity, $\Delta$, is due largely to initial bends and eccentricities, then $K$ is more nearly a constant, but, in any case, at failure, there will be a considerable degree

of bending and hence $K$ will not be a constant, but will increase with an increase in the bending stress, $f_b$. The fact that $K$ should increase with $f_b$, or with $\frac{l}{r}$, is indicated in the comparison of the formula with results of tests in the 1926 report of the Committee,[15] in which, the Rankine formula is seen to descend too rapidly from the horizontal for low values of $\frac{l}{r}$. An increasing value of $K$ with proper constants would give a flatter curvature near the origin and larger values of $p$.

While the Rankine formula, making $K$ a constant, is irrational, it has been widely used, and by selecting proper constants, it can be made to fit results of tests fairly well over the working range. A common method of adjustment is to use a relatively large value of $f$ so as to raise the curve near the $Y$-axis and then to slice off the top by adopting a maximum limit for $p$ somewhat less than $f$.

*33.—Empirical Formulas.*—Many straight-line formulas have been, and still are, in use. These are usually determined with reference to the yield point strength for low values of $\frac{l}{r}$; to the Euler formula for very high values; and to results of tests between these limits. The Johnson parabolic formula is perhaps the best of the empirical formulas so far as it goes. It is a parabola having its vertex on the $Y$-axis, and drawn tangent to a suitable Euler curve. It is not applicable beyond its point of tangency, which is at a point the $y$-ordinate of which equals one-half the ordinate for $x = 0$, or $p = \frac{1}{2} f$.

*34.—Shear in Columns.*—Two cases need to be considered:

(*a*) The shear in a column bent in single curvature: This will be a maximum at the ends. For the theoretical case of the pivoted-end column with eccentric loads, the shear is, from Equation (9),

$$V = P \tan \theta = P e q \tan \phi = P e \sqrt{\frac{P}{E I}} \tan \frac{l}{2} \sqrt{\frac{P}{E I}} \quad \ldots\ldots (12)$$

For practical calculations it may be assumed that the column at failure is bent in a parabolic curve with an inclination at the end of $\tan \theta = \frac{4 e'}{l}$, in which, $e'$ is the total central ordinate. The bending stress is, $f_b = \frac{p e' c}{r^2}$, or $e' = \frac{f_b r^2}{p c}$; hence, $\tan \theta = \frac{4 f_b r^2}{p c l}$, and the shear is,

$$V = P \frac{4 f_b r^2}{p c l} \quad \ldots\ldots (13)$$

At failure the bending stress, $f_b$, is the stress, $f - p$, from any rational column formula, $f$ being the yield point and $p$, the ultimate unit load on the column. Equation (13) gives the shear corresponding to the ultimate load, $P$.

(*b*) The shear in a column of a truss with rigid joints where the joint deformation or twisting is such as to cause the column to bend in an

[15] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1485.

S-shaped curve. The moments at the ends are the moments causing secondary stresses in the members. Columns subject to such loads are in effect acted on by direct forces applied eccentrically at each end, but of opposite direction, resulting in an obliquity of the applied load. If the eccentricity of each end equals $e$, the obliquity is $\frac{2\,e}{l}$, and the shear is,

$$V = P\,\frac{2\,e}{l} \qquad (14)$$

The quantity, $e$, may be expressed in terms of secondary stress or of ratio of secondary to axial stress. The secondary stress (bending fiber stress) due to an eccentricity, $e$, is $f_b = p\,\frac{e\,c}{r^2}$ and $\frac{f_b}{p} = \frac{e\,c}{r^2}$ = stress ratio = $\alpha$. Then, $e = \frac{\alpha\,r^2}{c}$, and,

$$V = P\,\frac{2\,\alpha\,r^2}{c\,l} \qquad (15)$$

This will be large only for small values of $\frac{l}{r}$. The values of $\alpha$ will vary greatly, being high for short members and for bending in the plane of the truss. In this plane the value of $\alpha$ may easily reach 0.40 or 0.50, but in a plane perpendicular to the truss, which is generally the plane of the lacing, the secondary stresses due to vertical loads will be small, and a value of 0.20 is probably a sufficiently high estimate. This value gives a shear of $V = P\,\frac{0.4\,r^2}{c\,l}$. Comparing this result with Equation (13) it will be seen that it gives higher values of $V$ whenever $\frac{f_b}{p}$ is less than 0.1; that is, for relatively short columns.

*55.—Factor of Safety Method in Column Design.*—Whatever formula may be used, the logical process in column design is to select a formula which will as nearly as practicable give values of ultimate strength, or some point which represents the practical ultimate value of the column; then to divide the resulting value of average stress, $P/A$, by the factor of safety corresponding to that used in other members, the object being to produce a structure in which all parts will be stressed to failure, or to their useful limits, simultaneously as the loads are increased.

Columns, unlike other members, are stressed by an amount (maximum fiber stress) which increases at a faster rate than the applied load, and hence if they should be designed so that under working loads the actual maximum fiber stress is, say, one-half the yield point of the material, an increase of load of 50% would produce more than a 50% increase in fiber stress, and the factor of safety for the column would be considerably less than 2.0. In most column formulas (where the load, $p$, is expressed as an explicit function of $f$), the working formula is obtained by applying the factor of safety to the entire expression for $p$ (the numerator in the Rankine formula), but in the case of the secant formula this cannot be done. If the factor of safety be applied to the numerator, $f$, the result will be a value of $p$ which will produce the assumed fiber stress, $f$. In

this case, ultimate values of $p$ must be tabulated, and the factor of safety applied to them. The same comments may be made with respect to shearing stresses. The logical method is to estimate shearing stresses at or near failure and apply a consistent factor of safety to such values for design purposes.

*36.—The Action of a Column in a Truss.*—The study of the strength of columns has necessarily been based almost wholly on results of tests in a testing machine, where the end conditions have been made as definite as possible, either flat-ended (corresponding generally to a fixed-end condition), or pin-ended, or some approximation to pivot ends. It has been difficult to arrange end conditions of any kind so as to meet precisely the corresponding theoretical conditions. In the case of flat-end tests much shimming has been required to adjust for inaccurately cut ends or non-parallel testing-machine plates. To simulate pivoted ends requires either knife-edge bearings, suitable for very small columns, or some other frictionless bearing. The pin bearing commonly used is far from frictionless, in fact, a pin-ended column in a testing machine acts at first like a fixed-end column, and if reasonably straight, continues so to act nearly or quite up to the maximum load. For pivoted ends, the roller device used in the tests described in Part I is probably the best practicable arrangement. On account of its very small frictional resistance, it gives a close approximation to the truly pivoted end; and because of its definiteness it would seem the most satisfactory arrangement to use in studies for the correlation of tests with theory and for the relative effects of the various elements of column construction. When this is all done, however, there remains the important task of relating the results of these tests and analyses on pivoted-end columns to the behavior of columns in a structure.

To arrive at some judgment in the matter, it is desirable first to consider the action of a compression member in a truss with riveted joints. Consider, first, the action in the plane of the truss. The effect of loading such a structure is to develop certain bending moments in all the members at a joint, giving rise to what are usually known as secondary stresses. These deformations and stresses are caused by the changes in the length of the various members, and are subject to reasonably close calculation. Some of the members will be bent in opposite directions at the two ends, giving rise to an S-shaped curvature; others will be bent in single curvature. The top chord members in a Pratt truss in all panels except the end ones are generally examples of single curvature. The verticals and end posts are likely to be bent in reversed curves. In any case, the angle of bend at each end is a fairly definite and calculable quantity, depending almost wholly on the axial strains in the various members. So far as this bending affects the strength of the compression member, it is obvious that the worst case is where the bending is of single curvature, thereby forcing the member into a form giving the maximum deflection near the center and thus reducing the strength of the member as a column. This bending action always occurs in a truss, but it is an effect not easily produced in a testing machine. This action may be investigated theoretically as follows.

Assume $A\,B$ (Fig. 33) to be a column in a truss, subjected to an axial load, $P$, and moments, $M$, at each end. These moments are due to the deforma-

tion of the truss as a whole and, within certain limits, are proportional to the load on the structure and the load, $P$.

The bending moment, $M$, at any point, $C$, a distance, $x$, from $A$, is,

$$M = M_1 + P\,y$$

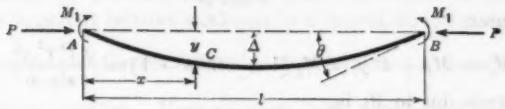

FIG. 33.

Then,

$$\frac{d^2\,y}{d\,x^2} = -\frac{M}{E\,I} = -\frac{M_1}{E\,I} - \frac{P\,y}{E\,I}$$

From this is derived, as in the secant formula:

$$y = \frac{M_1}{P}\,[\sec q\,x - 1] \qquad (16)$$

$$\tan\theta = \frac{q\,M_1}{P}\tan\phi \qquad (17)$$

and,

$$\text{Center deflection} = \Delta = \frac{M_1}{P}\,[\sec\phi - 1] \qquad (18)$$

Now, $\theta$ is the deflection angle fixed by the twist of the joints, $A$ and $B$, due to the distortion of the truss, and is, up to loads approaching the ultimate, closely proportional to the load or to the stress, $P$. These angles, $\theta$, are functions from which the secondary stresses may be calculated, and their magnitudes may be estimated by expressing them in terms of the corresponding bending or secondary stresses. For a member bent in single curvature with equal deflection angles, $\theta$, at each end, the corresponding secondary or bending stress at the end is,

$$f_s = \frac{2\,c\,E}{l}\tan\theta$$

Expressing the secondary stress as a fraction, $\alpha$, of the axial unit stress, $p$,

$$f_s = \alpha\,p = \frac{2\,c\,E\tan\theta}{l}$$

or,

$$\tan\theta = \frac{\alpha\,p\,l}{2\,c\,E} \qquad (19)$$

in which, $\alpha$ has a numerical value amounting ordinarily, in the cases considered, to 0.1 to 0.2; and in any particular case tan $\theta$ will increase directly with the the load or the value of $p$. This value of tan $\theta$ may then be used in Equation (17); then, solving,

$$M_1 = \frac{\alpha\,p\,l\,P}{2\,c\,E\,q\tan\phi} \qquad (20)$$

Substituting $p_e$ (Euler's value) for $\frac{\pi^2 E}{\left(\frac{l}{r}\right)^2}$, and $\phi$ for $\frac{\pi}{2}\sqrt{\frac{p}{p_e}}$,

$$M_1 = \frac{\alpha P r^2 \phi}{c \tan \phi} \quad \text{.....(21)}$$

and, at the center,

$$M_c = M_1 + P y = M_1 [1 + \sec \phi - 1] = \frac{\alpha P r^2 \phi}{c \sin \phi}$$

The bending stress due to $M_c$ is,

$$f_b = \frac{M_c c}{I} = \alpha p \frac{\phi}{\sin \phi} \quad \text{.....(22)}$$

This represents the bending stress at the center of the column the ends of which are gradually turned through an angle, $\theta$, proportional to the stress, $p$, but which are otherwise securely held. If $f$ = total fiber stress (yield point at failure) then, as before,

$$f = p\left(1 + \frac{\alpha \phi}{\sin \phi}\right)$$

and,

$$p = \frac{f}{1 + \frac{\alpha \phi}{\sin \phi}} \quad \text{.....(23)}$$

as the corresponding column formula.

Comparing this with the secant formula for pivoted ends, and assuming $\alpha = \frac{e c}{r^2}$, it will be noted that sec $\phi$ has been replaced by $\frac{\phi}{\sin \phi}$. In Fig. 34, Curve $A$ is the secant formula of Equation (10) and Curve $B$ is the formula of Equation (23). In these calculations, $f = 36\ 000$, $\frac{e c}{r^2} = \alpha = 0.25$, and $E = 29\ 000\ 000$. There is also a plotted curve, $C$, from Equation (10) for pivoted ends, but using in the formula the half length, corresponding to Euler's formula for fixed ends. This is,

$$p = \frac{f}{1 + \frac{e c}{r^2} \sec \frac{\phi}{2}}$$

It is noted that Curve $B$ lies only slightly below Curve $C$, showing that the end conditions assumed are not much different from fixed-end conditions with initial eccentricity due to curvature.

It may be concluded, therefore, that the strength of a column in a truss under the conditions assumed is not much less than that of a pivoted-end column of one-half the length.

In the case of columns bent in a reversed curve by the secondary stress moments, the bending stresses will be a maximum at the ends and small near the center, so that buckling action will be very small. The strength of such columns will be closely determined by the sum of the direct and bending stresses at the ends, as in the case of oblique loading tests given in Part I.

The strength of columns against buckling at right angles to the plane of the truss is not so readily estimated as in the case already considered. The

secondary stress moments and distortions in this direction are certainly quite small in top chord members of through bridges; but, on the other hand, the lateral members do not offer very great resistance to the lateral buckling of chord members in alternate directions in successive panels, giving a much nearer approach to pin-end conditions than the action in the plane of the truss. This apparent relative weakness in a lateral direction can be equalized by increasing the slenderness ratio, $\frac{l}{r}$, in this plane, a variation corresponding to common practice. Vertical posts with floor-beams and sway-bracing attached are thoroughly supported laterally, and act very definitely in the manner assumed in the foregoing analysis. The buckling tendency is small, and the maximum stress is likely to be at the top of the floor-beam. Compression web members in triangular trusses and the like are apt to be much less securely held against lateral bending than against bending in a vertical plane, although when riveted into heavy chord members they are quite well fixed. Here, again, equalization of buckling strength may be given by increasing the value of $\frac{l}{r}$ in a lateral direction.

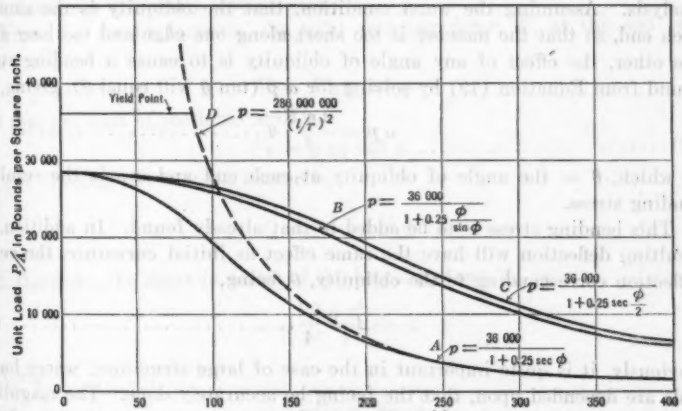

FIG. 34.

*37.—Effect of Dead Weight.*—The effect of the weight of the member on the center moment is of considerable interest. An exact analysis is quite complex, but an approximate estimate may be made by comparing the center deflection which may occur under the conditions already considered with the center deflection of the column due to its own weight, assuming fixed ends and the column to be horizontal.

The center deflection, not considering weight, is given by Equation (18). Substituting the value of $M_1$ from Equation (21),

$$\Delta = \frac{\alpha r^2 \phi}{c} \frac{(1 - \cos \phi)}{\sin \phi}$$

The deflection of a beam fixed at the ends is $D = \frac{w\,l^4}{384\,E\,I}$, in which, $w$ = the weight per unit length. This is approximately equal to $0.35\Delta$ lb. per in. of length, whenee,

$$D = \frac{0.35\,l^2}{384\,E}\left(\frac{l}{r}\right)^2$$

For purposes of comparison, consider, for example, a slender member with $\phi = \frac{\pi}{2}$; $\frac{l}{r}$ will equal about 108. Assume $l = 648$ in., $r = 6$ in., $c = 8$ in. For these values, $\Delta = 2.16$ in. and $D = 0.15$ in., or only 7% of $\Delta$. Again, take $\phi = \frac{\pi}{4}$, for which $\frac{l}{r}$ is about 75. With the same values of $r$ and $c$, the deflections will be, respectively, 0.42 in. and 0.032 in., the latter being 7.5% of the former. It appears, therefore, that the effect of weight is of little relative importance under the conditions assumed.

*38.—Effect of Obliquity of Flat Ends.*—Where dependence is placed mainly on butted ends, with relatively few rivets in splice-plates, the effect of variation from the true angle can readily be determined from the foregoing analysis. Assuming the worst condition, that the obliquity is the same at each end, so that the member is too short along one edge and too long along the other, the effect of any angle of obliquity is to cause a bending stress, found from Equation (19) by solving for $\alpha\,p$ ($\tan\theta$ will equal $\theta$), giving,

$$\alpha\,p = \frac{2\,c\,E}{l}\,\theta \qquad (24)$$

in which, $\theta$ = the angle of obliquity at each end and $\alpha\,p$ is the resulting bending stress.

This bending stress is to be added to that already found. In addition, the resulting deflection will have the same effect as initial curvature, the center deflection corresponding to the obliquity, $\theta$, being,

$$\Delta = \frac{\theta\,l}{4} \qquad (25)$$

Obviously, it is quite important in the case of large structures, where butted ends are depended upon, that the facing be accurately done. The magnitude of the allowable obliquity for any assumed value of stress, $\alpha\,p$, is, from Equation (24), $\theta = \frac{\alpha\,p}{2\,c\,E}$. For example, assume $\alpha\,p = 2\,500$ lb. per sq. in. = about 10% of the ultimate strength. Also, let, $\frac{l}{2\,c} = 15$. Then,

$$\theta = \frac{2\,500 \times 15}{30\,000\,000} = 0.00125$$

which is the permissible error in angle of the end face, or an error of 0.030 in. in a width of 24 in.

*39.—The Effect of Initial Bends.*—In the case here considered, this effect is of the same nature as in the fixed-end column, namely, less than the effect of one-half the same amount of deflection in a pivoted-end column of one-

half the length, and can be approximately allowed for by adding to $\alpha$ in the column formula one-half the quantity, $\frac{e' c}{r^2}$, in which, $e'$ = the deflection due to initial bends.

*40.—Effect of Deflection Due to Shear.*—In the tests of Part I, the relative rigidities of various columns in the plane of the web and at right angles thereto were determined, and it was shown that in the case of the laced channel columns the shearing distortion in the plane of the lacing was considerable under oblique loading. The relative deflections under cross-bending loads were also found, and in the case of the laced columns, the observed deflections in the plane of the lacing were nearly twice as great as the calculated deflections in which the effect of shearing strains was omitted. This raises the question of the effect of shearing distortion on the bending of columns in the plane of lacing as compared to bending in the plane of solid webs. To answer this in part, tests of Series (*C*) were made under eccentric loads, and so far as these tests were concerned, the effect of shearing strain on deflection in the plane of lacing was negligible (see Fig. 29). However, this question is worthy of further analysis.

It will be helpful to compare the shearing and bending stresses in a column with those in a uniformly loaded beam.

From the secant formula, the total shearing force, $V$, at the end of a column is,

$$V = P\, eq \tan \phi$$

and that per unit of sectional area is,

$$v = p\, eq \tan \phi \qquad (26)$$

The bending stress at the center is,

$$f_b = p \frac{e\ c}{r^2} \sec \phi$$

and, therefore, the shear in terms of the bending stress, $f_b$, is,

$$v = f_b \frac{q\, r^2}{c} \sin \phi$$

Writing

$$q = \sqrt{\frac{P}{E\, I}} = \frac{\pi}{l} \sqrt{\frac{p}{p_e}}$$

and taking $r = 0.8c$, approximately,

$$v = f_b \frac{2.52 \sqrt{\frac{p}{p_e}}}{\frac{l}{r}} \sin \phi \qquad (27)$$

For a beam uniformly loaded, the bending stress is,

$$f_b = \frac{w\, l^2\, c}{8\, A\, r^2}$$

The end shearing stress per square inch is,

$$v = \frac{w\,l}{2\,A}$$

and hence, with $r = 0.8c$,

$$v = \frac{3.2\,f_b}{\frac{l}{r}} \qquad (28)$$

Comparing Equations (27) and (28) for the same bending stress, $f_b$, the ratio,

$$\frac{v\ (\text{column})}{v\ (\text{beam})} = \frac{2.52\sqrt{\frac{p}{p_e}}}{3.2}\sin\phi = 0.79\sqrt{\frac{p}{p_e}}\sin\phi$$

Calculating this quantity, the values given in Table 27 are found, based on the secant formula for ultimate strength, $p = \frac{36\,000}{1 + 0.25\sec\phi}$. The ratio of shear in column to direct stress $\left(\frac{V}{P}\right)$ is also given.

TABLE 27.—Relation of Shears in Columns and Beams for Equal Bending Stresses.

| $p$. | $\frac{p}{p_e}$. | $\frac{l}{r}$. | $\frac{v\ (\text{column})}{v\ (\text{beam})}$, for equal bending stress. | $\frac{V}{P}$. |
|---|---|---|---|---|
| 28 500 | 0.047 | 22 | 0.058 | 0.0022 |
| 28 000 | 0.1 | 32 | 0.12 | 0.0034 |
| 27 100 | 0.2 | 45 | 0.23 | 0.0052 |
| 26 000 | 0.3 | 57 | 0.33 | 0.0072 |
| 24 700 | 0.4 | 69 | 0.41 | 0.0090 |
| 23 000 | 0.5 | 79 | 0.51 | 0.011 |
| 21 000 | 0.6 | 91 | 0.57 | 0.014 |
| 18 200 | 0.7 | 105 | 0.64 | 0.019 |
| 14 500 | 0.8 | 125 | 0.70 | 0.026 |
| 8 900 | 0.9 | 170 | 0.75 | 0.045 |

For ordinary values of $\frac{l}{r} = 50$ to 100, the ratio of shears for the same bending stress ranges from about 0.25 to 0.6.

In the cross-bending tests of Part I, the deflection due to shear in the laced channel columns averaged about 0.8 of that due to bending, and the value of $\frac{l}{r}$ was about 20. These bending tests were made with center loads. If they had been made with uniform loads, giving a shear distribution more nearly like that of a column, it can be shown that the average shearing stress for like deflection would have been 0.8 as much and hence the shearing distortions would have been less than those shown. Hence, $0.8 \times 0.8$, or about $\frac{2}{3}$ may be taken as representing the ratio of deflection due to shear if tested with uniform loads, to that due to bending under a central load. For the columns tested

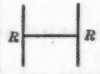
in Series (*C*), $\frac{l}{r} = 21.9$, for which the ratio of column shear to beam shear, as shown in Table 27, is about 0.06, and, hence, the relative shear distortion for this column, as a column, would be about $0.06 \times \frac{2}{3} = 0.04$ of that due to bending. Cross-bending tests of columns with $\frac{l}{r} = 50$, and with similar proportions to those tested, would, in accordance with Equation (28), have shown a relative shear deflection of about $\frac{2}{3} \times \frac{20}{50} = 0.26$; and for a column of $\frac{l}{r} = 50$, the shearing stress for a like bending stress (see Table 27) would be about 0.3 as much as in a beam, and hence the deflection due to shear would be expected to be about $0.3 \times 0.26 = 0.08$ of that due to pure bending as assumed in the column analysis. For $\frac{l}{r} = 100$, the result would be about the same.

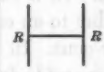
This gives an approximate measure of the relative rigidity in the plane of the lacing as compared to that in the plane of the webs. While other proportions of lacing and other tests would doubtless vary these results somewhat, this analysis is sufficient to indicate that shearing distortion is not of great relative effect upon the strength of columns. In this case, the actual effect upon the theoretical ultimate strength could be found by using a value of $E$ in the formula about 10% less than the value for direct stress, or, say, 26 000 000 lb. per sq. in. Any difference in strength in the two directions can be overcome by increasing the value of $r$, that is, by spreading the channels farther apart.

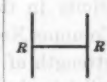
### (C) Strength of Columns as Affected by Various Details

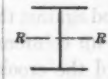
#### 1.—Eccentricities in the Wisconsin Test Columns

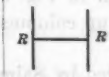
*41.—Method of Measuring Eccentricity and Crookedness.*—In order to secure data for determining the gravity axis of each H-column, micrometer measurements of both end cross-sections were made and recorded on separate carbon prints. From these data the location of the column axis with respect to the center of the web was calculated. This information was used in centering the columns on the bearing blocks for testing.

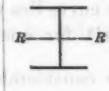


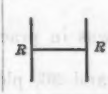












In order to secure some information concerning the straightness of these test columns, two methods of measurement were used. In the more accurate method, which was conveniently used on the short built-up columns, two transits were set up so that the lines of sight described north and south planes about 18 in. apart; and two other transits were arranged to describe similarly spaced east and west planes. Within these imaginary planes the column was set vertically on a base plate which was accurately leveled with a very sensitive spirit-level. By holding steel rules normal to the column it was possible to determine the distance from each of the four imaginary planes to the column. Twelve such measurements, three per plane, were made at each end, at the quarter-points, and at the middle. They were recorded on suitable sketches. Then the column was turned upside down to determine the obliquity of the upper end. From these observations, crookedness, obliquity of ends, and the amount of wind were calculated.

The straightness of an H-column was determined by supporting it in a horizontal position and making measurements from planes formed by four fine wires. These wires were spaced fixed distances apart and ran along the corners of the column.

The obliquity of the ends of the H-columns was determined by measuring the thickness of the shims required under the lower bearing block to produce parallelism between the top of the column and the upper bearing.

By averaging all measurements in either direction for each section of the column, and comparing these mean measurements with the end means, a measure of crookedness was obtained. Herein, only the crookedness as referred to the mid-section will be reported.

*42.—Eccentricities in H-Columns Due to Rolling.*—The results of the center of gravity determinations on the 8-in. columns are given in Columns (3) and (4) of Table 28. For these columns the values of $\frac{c}{r^2}$ for the central axis normal to the web is approximately 0.3, whereas for the other gravity axis it is about 1.0. Hence, in a short column, an eccentricity of 0.06 in. in the plane of the web causes a bending stress of only 2%, whereas in the plane normal to the web it amounts to 6 per cent. Such eccentricity normal to the web would correspond to a displacement of the web of about 0.09 in. In a long column with a slenderness ratio of 150, the reduction in strength due to an eccentricity of 0.06 in. normal to the web would amount to about 5 per cent. In most cases the tabulated eccentricities are well below 0.06 in. Hence, aside from inconvenience in making connections to adjoining members, the observed rolling eccentricities are not of importance in these columns.

*43.—Crookedness.*—The data in Column (5) of Table 28, show that crookedness is a far more important defect than rolling eccentricity in these small H-columns. The bowing in a plane normal to the web in Columns Nos. *H*9 and *H*10 would have caused an appreciable reduction in the strength of these columns had they been tested to destruction with rollers parallel to the webs. In Fig. 35 the crookedness in these H-columns has been plotted against the slenderness ratio. The crookedness at mid-section for the built-up columns has also been plotted against the slenderness ratio in Fig. 36, and the crookedness of both types has been plotted against the length of column in Fig. 37. These data show that, for columns of similar length, the built-up columns were the more crooked.

To enable comparisons to be made, the curves suggested by Salmon[16] have been incorporated in these diagrams. In Fig. 37 Salmon's curve lies well above the field of plotted points. Hence, the crookedness ($e'$) for one of these columns estimated by $e' = \frac{l}{750}$, would in most cases be considerably higher than the actual value. For these tests the crookedness was in practically all cases less than that given by $e' = \frac{l}{1\,500}$. In Figs. 35 and 36, plotted with

[16] "Columns," by E. H. Salmon, Oxford Technical Publications, p. 152.

respect to the slenderness ratio, Salmon's equation, $e' = 0.0023 \frac{l}{r}\left(\frac{l}{435\,r}\right)$, gives values too high for the H-columns and is more nearly a mean line than a limit for the built-up columns. For the H-columns practically all values lie below the boundary line representing $e' = \frac{l}{750\,r}$.

TABLE 29.—Obliquities in Wisconsin Test Columns.

| | Normal | 12 | 0.002 | 0.0002 |
| 5 *A* | Parallel | 10 | 0.003 | 0.0003 |
| | Normal | 12 | 0.036 | 0.0036 |
| 6 | Parallel | 10 | 0.028 | 0.0028 |
| | Normal | 12 | 0.004 | 0.0003 |
| 7 | Parallel | 10 | 0.006 | 0.0006 |
| | Normal | 12 | 0.002 | 0.0002 |
| 8 | Parallel | 10 | 0.013 | 0.0013 |
| | Normal | 12 | 0.020 | 0.0016 |
| 9 | Parallel | 10 | 0.019 | 0.0019 |
| | Normal | 1 | 0.007 | 0.0006 |

Considering all the results it would seem that the value of $e'$ is more nearly proportional to $l$ than to $\frac{l}{r}$, but the data are too meager to warrant any general conclusion. The relative influence of crookedness in these particular columns can be estimated to some advantage. Assume that $e' = \frac{l}{1\,200}$ and $\frac{c}{r} = 1.2$; then $\frac{e'\,c}{r^2} = \frac{\frac{l}{r}}{1\,000}$. For $\frac{l}{r} = 100$, $\frac{e'\,c}{r^2} = 0.1$, and for $\frac{l}{r} = 150$, $\frac{e'\,c}{r^2} = 0.15$. These values are considerably smaller than those usually assumed in the application of the theoretical formula for eccentric loads.

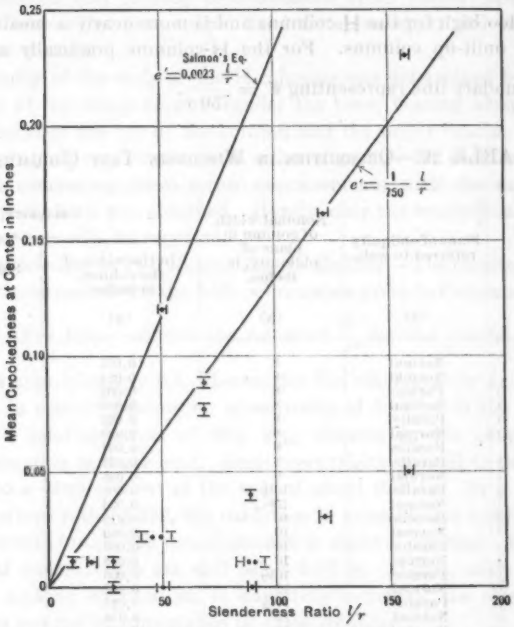

FIG. 35.—RELATION OF CROOKEDNESS TO SLENDERNESS RATIO, H-COLUMNS, UNIVERSITY OF WISCONSIN TESTS.

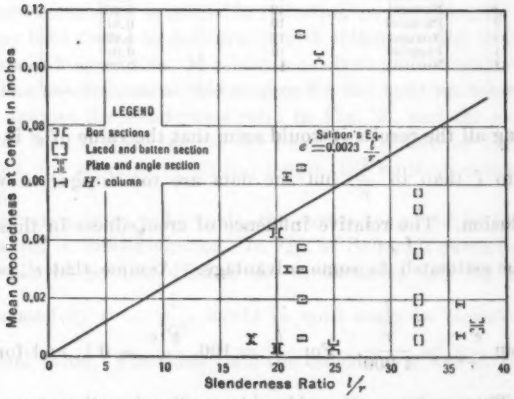

FIG. 36.—RELATION OF CROOKEDNESS TO SLENDERNESS RATIO, UNIVERSITY OF WISCONSIN TESTS.

*44.—Eccentricities in Center Loading Tests.*—In order to correlate rolling-eccentricity and crookedness measurements of H-columns with the position of the respective columns found by trial center loadings, the data in Columns (6), (7), and (8) of Table 28, have been prepared. If the correlation between measurements and trial centering was perfect, all the values in Column (8), Table 28, would be zero. However, most of the eccentricities at mid-section from measurement are small and the data indicate that eccentricity can be predicted with fair accuracy from shape and crookedness measurements.

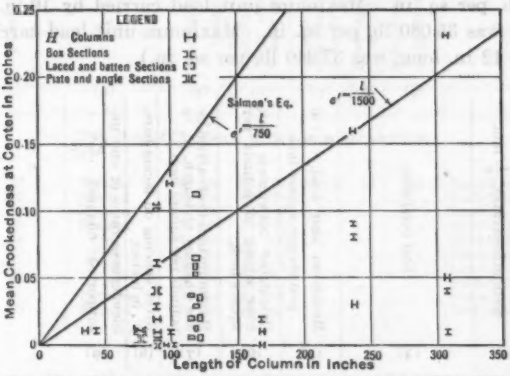

FIG. 37.—RELATION OF CROOKEDNESS TO LENGTH OF COLUMN, UNIVERSITY OF WISCONSIN TESTS.

Correlation between the measured eccentricities and strain measurements was also made by comparing the total eccentricities (measured eccentricities plus corresponding deflection) with the corresponding eccentricities computed by strain measurements.[17] In making this comparison the unit load ($P/A$) considered ranged from approximately 9 000 lb. per sq. in. for the column of maximum slenderness ratio to 20 000 lb. per sq. in. for some of the short H-columns. Considering both built-up and H-columns, the comparison of these two sets of eccentricities shows that the maximum discrepancy corresponded to a fiber stress difference of less than 11% and that, on the average, the fiber stress difference due to discrepancies in the values of $e$ would be less than 4 per cent. This close agreement furnishes further evidence of the value of shape and crookedness measurements of columns.

*45.—Obliquity of Ends.*—In these data, obliquity of ends means simply the difference in slope between two ends of a column. The calculated obliquities for the H-columns and the measured values for the built-up columns are given in Table 29. There seems to be no definite relation between the obliquities of the H-columns and slenderness ratios or lengths. The average obliquity of these columns is approximately 0.003. In the data for the built-up columns, the obliquity is somewhat greater in the longer columns than in those of shorter length. The data are insufficient, however, to establish definite conclusions regarding such relationship.

[17] For the method, see the 1926 report, *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1537.

TABLE 30.—The Effect of Unsupported Length of Channel on the Strength of Latticed Channel Columns. Single Lacing-Bars with Alternate Spacing of Rivets in the Flanges of a Single Channel.*

(Maximum unit load carried by 6-in. channel, 6 in. long, was 42 490 lb. per sq. in. Maximum unit load carried by 8-in. channel, 8 in. long, was 43 300 lb. per sq. in. Maximum unit load carried by 10-in. channel, 10 in. long, was 35 080 lb. per sq. in. Maximum unit load carried by 12-in. channel, 12 in. long, was 37 240 lb. per sq. in.)

Obliquities should be made as small as practicable, especially on short columns, for a difference in the slope of the ends amounting to 0.003 in a column 12 in. wide means a difference in length of the opposite sides of 0.036 in. If such a column, 10 ft. long, rests against rigid end bearings and carries a load sufficient to bring the bearings in full contact ($P/A = 4\,500$ lb. per sq. in., or more), it can readily be shown that the fiber stress caused by the resulting bending of the column will be 4 500 lb. per sq. in.

## 2.—Unsupported Length and Width of Column Components

*46.—Unsupported Length of Channels in Latticed Channel Columns.*—Table 30 shows data from tests of wrought-iron latticed channel columns reported in 1881.[18] The maximum fiber stresses in Column (6) Table 30, were calculated from the reported deflections on the assumption of fixed ends. Column (7) shows failure loads, $P/A$, for single flat-end channels having the same length as the unsupported channels in the corresponding fabricated columns. Column (9) shows the ratio of unsupported length of channel to least radius of gyration for a single channel. By comparing the results in Columns (9) and (10) it will be observed that the last set of 12-in. channel columns had the lowest ratio of $\frac{p'}{r_c}$ $(= 26)$ and that a buckling failure occurred in tests of all these columns. The maximum unit fiber stresses for these columns in Column (6), Table 30, were in every instance high and it is

[18] Report on Tests of Metals and Other Materials, Watertown Arsenal, 1881.

probable that the support from the lacing-bars was sufficient in all cases to develop the yield point of the channels before buckling took place.

Bouscaren's[19] latticed channel wrought-iron Columns Nos. 37 and 38 failed by buckling of the channels between the points of attachment of the lacing-bars (single lacing). The maximum unit loads were 29 600 and 32 300 lb. per sq. in., respectively. The ratio, $\frac{p'}{r_c}$, for these columns was 28. Bouscaren's Column No. 41, with $\frac{p'}{r_c} = 25$, approximately, and other dimensions similar to Column No. 37, failed by buckling and bending as a whole under a unit load of 32 400 lb. per sq. in.

Talbot and Moore[20] report failure of their steel Column No. 1 by buckling of the flanges between the lacing-bars at $P/A = 23\,450$ lb. per sq. in. The ratio, $\frac{p'}{r_c}$, for that column was 38.

The two large double latticed columns,[21] $LC_0LC_1$, made with four ribs, failed by buckling of the ribs between lattice-bars. For the column of carbon steel, $\frac{p'}{r_c}$ was about 27; for the Mayari steel column, $\frac{p'}{r_c}$ was approximately 23. Both these columns failed at unit loads below the yield point of the metal. These failures were undoubtedly influenced by the character and arrangement of the lattice.

Of the American Railway Engineering Association latticed channel columns, Types *A* to *E* (1915 Series) inclusive, none failed by buckling of the channels between lacing-bars. The slenderness ratios for these columns varied from 50 to 120, but the largest ratio, $\frac{p'}{r_c}$, for a single channel was only 16.

Whereas, from these fragmentary data no accurate conclusion can be drawn concerning the proper limiting value of $\frac{p'}{r_c}$ in latticed channel columns, the data indicate that no failures primarily due to buckling occurred for values of $\frac{p'}{r_c}$ less than 25. Furthermore, in none of the cases under consideration, where the ratio, $\frac{p'}{r_c}$, was greater than 26, is there any evidence of marked reduction in strength which can be directly attributed to local buckling of the channels.

*47.—Unsupported Length of Channels in Columns Tied with Batten-Plates.*—Table 31 shows the principal results of the American Railway Engineering Association tests of 1918 on channel columns tied with widely spaced battens. Unfortunately, this series of tests did not include columns with battens spaced closely enough to develop the full strength of the column. By plotting the ratio, $\frac{A}{B}$, in Column (7), Table 31, against the slenderness ratio

[19] *Transactions*, Am. Soc. C. E., Vol. IX (1880), p. 447.

[20] *Bulletin No. 44*, Univ. of Illinois Eng. Experiment Station; also, *Transactions*, Am. Soc. C. E., Vol. LXV (1909), p. 202.

[21] *Technologic Paper No. 101*, U. S. Bureau of Standards.

for a single channel (Column (3)), it appears that if the battens had been spaced so that the ratio of the unsupported length to least radius of gyration for a single channel $\left(\frac{p'}{r_c}\right)$ was 28, the full strength of the column would have been secured. However, since the unsupported channels of batten-plate columns are subjected to heavy bending stresses[22] when the load becomes slightly oblique to the channel webs, the proper ratio for $\frac{p'}{r_c}$ for such channels should be the objective of further tests.

TABLE 31.—EFFECT OF UNSUPPORTED LENGTH OF CHANNELS ON CENTRALLY LOADED COLUMNS OF AMERICAN RAILWAY ENGINEERING ASSOCIATION SERIES.

| Column No. | Slenderness Ratios. Whole column, $\frac{l}{r}$. | Single channel, $\frac{p'}{r_c}$. | Ratio, $\frac{\frac{l}{r}}{\frac{p'}{r_c}}$. | Average maximum unit load for three columns, in pounds per square inch, $A$. | Average maximum unit load of adequately laced columns of same length and sectional area, in pounds per square inch, $B$. | Ratio. $\frac{A}{B}$ |
|---|---|---|---|---|---|---|
| (1) | (2) | (3) | (4) | (5) | (6) | (7) |
| 1 *K* | 85 | 66 | 0.77 | 26 900 | 34 000 | 0.79 |
| 1 *I* | 85 | 84 | 0.99 | 25 400 | 34 000 | 0.75 |
| 1 *L* | 85 | 81 | 0.95 | 24 100 | 34 300 | 0.70 |
| 1 *M* | 120 | 121 | 1.01 | 15 100 | 30 800 | 0.49 |

*48.—Unsupported Length in Segmental Columns.*—In Bouscaren's tests on Keystone columns[23] failure occurred by bulging of the segments between the rivets when the unsupported length of the segment was 15 in. No bulging took place when the unsupported length was reduced to 12 in. For the latter length the ratio, $\frac{p'}{r_c}$, for the segment was 27.

Bouscaren's tests also indicate that the strengths of his Keystone columns (metal, ¼ to ⅜ in. thick) were improved by reducing the pitch of the rivets to 3 in. near the ends of the columns (see Columns Nos. 3, 8, 25, and 31).

*49.—Unsupported Width of Plates in Columns.*—Aside from the early work of Hodgkinson[24] and Fairbain,[25] and the tests of the U. S. Bureau of Standards made in connection with the building of the Delaware River Bridge,[26] there is little experimental data relating to the effect of width of unsupported plate on its resistance to axial compression.

In Column (10) of Table 10[27] of the Progress Report of 1926 is recorded the ratio,

$$\frac{\text{Unsupported width of plate between rivet lines}}{\text{Thickness of plate}}$$

[22] See "Stresses in Channels of Batten-Plate Columns," Table 12.

for the box-sections, consisting of two channels and two cover-plates reported in Tests of Metals and Other Materials (1884). From these data it will be noted that the short wrought-iron columns with 8-in. channels and 12½ by ⅝-in. plates, had ratios of unsupported width to thickness ranging from 35 to 40.4. The maximum unit loads, $P/A$, for these columns varied between 32 100 and 35 000 lb. per sq. in., the maximum fiber unit stress calculated from loads and deflections varied between 35 100 and 37 600 lb. per sq. in., and all columns save Column No. 379 failed by deflection. Column No. 379, having plates with a ratio of unsupported length to thickness equal to 23 and a ratio of unsupported width to thickness equal to 40.4, failed by buckling of plates at a unit load of 35 000 lb. per sq. in., which probably is fully as high as the yield point of the material.

The evidence from these column tests indicates that the ratios of unsupported width of plate to thickness of 40 or less caused no lessening of the axial resistance to compression of these wrought-iron plates.

In connection with the design of the towers for the Delaware River Suspension Bridge, tests were made by R. S. Johnston,[28] of the U. S. Bureau of Standards, on fourteen I-columns, 10 ft. long, consisting of web-plates, 35 in. wide, stiffened on the long edges by four 6 by 4 by ⅜-in. flange angles attached with 4-in. legs outstanding. The web-plate thickness ranged from ⅜ in. to 1½ in. in thickness. In four of the thicker webs two plates were stitch-riveted together. The ends of the columns were stiffened by 4 by 4 by ½-in. angles and filler-plates, and were carefully milled to afford true bearings for the load. Longitudinal deformations were taken on four gauge lines located on the flange angles. The lateral buckling of the web-plates was measured at nine points across each member (four points on the angles and five on the web-plate) on lines spaced 3 in. apart along the member.

Table 32 gives the principal results of these tests. Measurements of the initial contours of these plates show that there were pronounced initial waves or buckles in the web-plates, ⅜ in. and less in thickness. The largest waves were noted in Webs *G1A*-3, *G2*-4, and *G3A*-3. In Web *G3A*-3 waves having crests ⅛ in. on either side of the axial plane were observed. The contours of the thicker web-plates were more nearly plane. In the tests of these thin web members the presence of these initial waves (crookedness) contributed to premature buckling.

Another noteworthy influence which caused some variation in these tests was the edge restraint produced by the 4 by 6-in. angles. The load buckle curves indicate that this restraint was sufficient to hold the thin, but not the thick, plates in line. Therefore, in Table 32 the ratio of width to thickness of plate has been recorded both for a width of 26 in. between inner rivet lines (the usual specifications stipulation) and for a width of 35 in., which was the full width of these members.

In Fig. 38 the ratios,

$$\frac{\text{Proportional limit from the load buckle curve of the column}}{\text{Proportional limit of the web-plate material}}$$

[28] *Technologic Paper No. 327*, U. S. Bureau of Standards.

| $G7A$-1 | 2 by $\frac{3}{4}$ = 1$\frac{1}{2}$ | 41 000 | 38 000 | 1.08 | .... | .... |

found in Column (5) Table 32, have been plotted against the ratio,

$$\frac{\text{Width of the member } (w)}{\text{Thickness of the web-plate } (t)}$$

Fig. 38 shows that in most cases the proportional limit of members having webs $\frac{3}{4}$ in. or more in thickness, was reached prior to buckling. The record indicates that variability in material and crookedness were influential in creating the low buckling values of Webs $G6A$-1 and $G7$-1. Web $G3$-1, a fairly plane $\frac{5}{8}$-in. web-plate, carried 95% of the proportional limit of the material before buckling became pronounced.

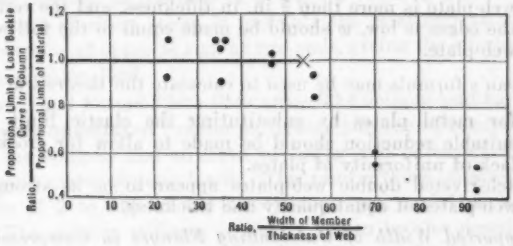

FIG. 38.

A formula for the calculation of the unit load, $p$, at which lateral buckling will occur in an axially loaded plate obtained from Bryan's discussion[29] on stability of ship plating under axial thrusts, is,

$$p = \frac{\pi^2 E t^2}{3 (1 - m^2) w^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

[29] *Proceedings*, Mathematical Soc., Vol. 22, p. 54, 1890.

If $m = 0.25$ and $E = 30\,000\,000$ lb. per sq. in., this may be changed to,

$$\frac{w}{t} = \frac{10\,300}{p^{\frac{1}{2}}} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

In the tests by Johnston the average proportional limit of the web-plate material was 37 700 lb. per sq. in. If that value be substituted in the equation for $p$, $\frac{w}{t}$ is found to be 53. This limiting value is indicated by the cross in Fig. 38. For this ratio, elastic failure would occur simultaneously due to compression and buckling. Considering $w$ equal to the full width of the member, this limiting ratio of $\frac{w}{t}$ based on a perfect plate and ideal supporting conditions is slightly less than $\frac{w}{t}$ for the $\frac{5}{8}$-in. plates and about 13% more than $\frac{w}{t}$ for the $\frac{3}{4}$-in. plates. From the existing data, it appears:

1.—If a plate is subjected to thrusts in the direction of its longitudinal axis and restrained along its long edges, it may fail in either of two ways: (*a*) If the width of the plate is not too great it will fail by direct compression, and failure will commence when the fiber stress reaches the elastic limit of the material; (*b*) if the width is large the plate will fail by lateral buckling before the unit load reaches the elastic limit of the material in compression.

2.—The maximum ratio of width to thickness, $\frac{w}{t}$, which a structural steel plate may have without reduction of its compression strength has been conservatively stated by Fairbain to be 30. The more recent tests indicate that for web-plates the limit of $\frac{w}{t}$ may tentatively be set at 50, if $w$ is taken as the full width of the member; and at 40, if $w$ is taken as the distance between rivet lines. If the stiffness of the edge supports is high, $w$ should be taken equal to the distance between the rivet lines. When the web-plate is more than $\frac{5}{8}$ in. in thickness, and the restraint along the edges is low, $w$ should be made equal to the full width of the web-plate.

3.—Bryan's formula may be used to calculate the theoretical limit of $\frac{w}{t}$, for metal plates by substituting the elastic limit for $p$, but suitable reduction should be made to allow for crookedness and lack of uniformity of plates.

4.—Stitch-riveted double web-plates appear to be as strong as single web-plates of equal quality and thickness.

*50.—Unsupported Width of Outstanding Flanges in Compression.*—From analysis supplemented by tests, Roark[30] has shown that if a flange of uniform thickness, $t$, and perfectly restrained along one edge, is subjected to uniform compressive fiber stress, the unsupported edge will buckle laterally when the unit load, $p$, exceeds,

$$p = 0.6\,E\left(\frac{t}{w'}\right)^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (31)$$

[30] *Engineering Record*, Vol. 68, p. 722; Vol. 74, p. 592.

in which, $w'$ is the unsupported width of the outstanding flange. If $p$ be made the proportional limit of the material, the ratio, $\frac{w'}{t}$, at which failure due to direct compression and lateral buckling would simultaneously occur, may be found. Using a proportional limit of 30 000 lb. per sq. in. for structural steel, $\frac{w'}{t} = 24$. Hence, allowing for imperfections in such material, if the unsupported width of the outstanding flange is less than about 20, the flange should develop full compressive strength before buckling.

### 3.—Strength and Stiffness of Lateral Connections

*51.—Lateral Connections.*—The efficiency of lateral connections between the longitudinal components of a column is one of the most important elements of column design, and one of the most difficult to determine either from analysis or experimentation. Assuming integral action, the tests and analysis heretofore given indicate that the strength of a column can be closely calculated if the end conditions and the yield point of the material are known. Integral action of built-up columns depends, however, on the effectiveness of lateral connections, and this is a function not only of the strength of such connections, but also of their stiffness or rigidity. The theoretical analysis given in Section (D) shows that there are two quite different conditions under which the shearing stress to be carried by lateral connections may be large: (*a*) Relatively long columns bending in single curvature; and (*b*) relatively short columns which are subjected to heavy shears by the bending moments developed at the joints, either from the general distortion of the structure, or by unequal or oblique bearings. Columns with truly centrally applied loads are subjected to only small shears, even when the initial bending may be considerable, but a truly central load is a condition hardly to be realized in the case of a column forming a member of a truss. The worst case of shear stress is probably the relatively short column subjected to moments of opposite sign at two ends, giving the effect of an obliquely applied compression load.

*52.—Laced and Batten-Plate Columns.*—The oblique loading tests described in Part I were undertaken for the particular purpose of securing information regarding the stiffness and strength of lacing and batten-plates of relatively short columns under oblique loads. The results there obtained under shearing stresses of 2 to 5% of the direct stress are useful as bearing on this problem. The relative stiffness is clearly shown by the shearing distortions. The batten-plate columns were naturally the most flexible and the weakest, but the shearing stress of 5% is very high, and is not likely to occur except in the case of very short columns or under abnormal conditions. For more normal values, such as would occur in the ordinary case, the batten-plate column may be a satisfactory and economical design. More study and experimentation are needed on this subject.

The laced channel columns under oblique loading showed no unexpected behavior. The very thin lacing failed at a value corresponding to its strength

separately determined. Otherwise, the full strength of the channels was developed.

*53.—Strain Measurements in Lacing-Bars.*—Careful strain measurements were made on the lacing-bars of the columns described in Part I under both central and oblique loading, and similar measurements have also been made by other investigators. Such measurements give valuable information regarding stresses due to eccentricities and other causes not subject to calculation, and which have a bearing on practical design.

Although there is no shear stress in an ideal column axially loaded, various defects in the column and method of loading cause such stress in the centrally loaded column of practice. Information regarding the importance of such stresses in laced channel columns is afforded from the tests of Talbot and Moore,[21] from the American Railway Engineering Association series,[22] and from the tests at the University of Wisconsin.

All the columns herein considered had single lacing save the Talbot and Moore Column No. 2(*a*), which had double lacing riveted at mid-length. The columns tested by Talbot and Moore had pin ends with pin axes parallel to the lacing; those of the American Railway Engineering Association series had square ends; and those tested at the University of Wisconsin were loaded through roller bearings with the axes of the rollers normal to the lacing. Additional data on the properties of the Wisconsin columns may be found in Table 1 and Fig. 4. From the strain measurements, considering $E$ to be 29 000 000 lb. per sq. in., the unit stress, $S_b$, in the most stressed bar of each of thirty different columns, has been calculated and recorded in Column (8) of Table 33. The corresponding excess shears, $V'$, found in Column (9), Table 33, were obtained from the relation,

$$V' = S_b A_b \sin \theta_b \qquad (32)$$

in which, $A_b$ is the cross-sectional area of the lacing-bars in a given panel, or a column, and $\theta_b$ is the inclination of the bar to the column axis. The ratios of these calculated shears to the load on the column, $\frac{V'}{P}$, are shown in Column (10).

Fig. 39, compiled from the data of Table 33, indicates that the lacing-bars of short columns are likely to be more severely stressed than the bars of long columns. This is undoubtedly due to inequalities in end bearings as heretofore mentioned, which would cause greater shear stresses in short, than in long, columns.

Further evidence of shear stresses in excess of the nominal amount is afforded by the results of Table 34. These data were obtained from the oblique loading tests made at Wisconsin. In a similar manner, the shears, $V_1$, corresponding to the most stressed bar in each column, were calculated and recorded in Column (7), Table 34. Then the excess shears, $V'$, and the ratios, $\frac{V'}{P}$, were entered in Columns (10) and (11), Table 34.

* Calculated from strain measurements made only on the outer faces of the bars except in the Illinois tests where they were made on opposite faces. Tension, +; compression, −.

† Bar had an initial bow at middle of 0.01 in. outward.

From a consideration of the $\frac{V'}{P}$ ratios (Table 33), for loads less than the maximum, it will be observed that only 5 columns out of 30 tested exhibited strains corresponding to values of $V'$, larger than $0.02P$. For loads less than the maximum, only 2 of the 335 bars under observation exhibited strains corresponding to values of $V'$ in excess of $0.03P$. The high value, $V' = 0.105P$, for Column No. 17, at a unit load of 15 000 lb. per sq. in., appears abnormal. This conclusion is substantiated by the fact that the strain in the corresponding bar diminished considerably when the column was subjected to higher loads. In one bar of Column No. 58 and one of Column No. 66, high strains were measured at loads near the maximum, but there is no evidence recorded that weakness in these bars caused failure.

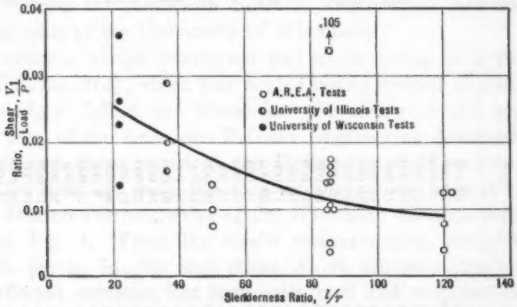

FIG. 39.—RATIO OF SHEAR TO LOAD CALCULATED FROM MOST STRAINED LACING-BAR IN CENTRALLY LOADED COLUMNS.

Only one failure, that reported by Talbot and Moore of their Column No. 1, when equipped with 1 by ¼-in. lacing-bars under a "slightly" oblique load of 150 000 lb. (8 060 lb. per sq. in.), is attributed solely to weakness in the lacing-bars. Since these flimsy bars when separately tested failed under compressive loads of 2 100 lb., Talbot and Moore calculated the equivalent shear in the column at bar failure to have been $V' = 0.025P$.

The data in Columns (6) and (11) of Table 34 show that in most cases where the calculated stresses and excess shears were high, the bars had initial bends which would contribute an increase to the strain measurements. Since no measurements of crookedness in the lacing were reported in the University of Illinois or American Railway Engineering Association tests, no estimate of the effect on measured strains can be made. It appears likely, however, from the results of Table 34, that the high values recorded in Table 33 for certain American Railway Engineering Association columns were enlarged by crookedness of the bars.

Referring again to the results of the Wisconsin tests on obliquely loaded laced columns, it will be recalled that the maximum stresses in excess of the calculated ones were found in tension bars (Table 9). Furthermore, it will be recalled that in only the abnormally thick bars of Column No. 6, carrying small strains which were difficult to measure accurately, did the compression bars exhibit stresses much in excess of the load stresses.

§ " " " " " " " " 0.07 in. "

‖ " " " " " " " " 0.01 in. outward.

These results indicate that under large definitely known shears the stresses in the lacing-bars tend to approach the calculated values under the higher loads, but in design the excess stresses shown in Table 34, Column (11), indicate that the obliquity should be liberally estimated. Under nominally central loads the stresses in the lacing-bars will be considerable and larger for the shorter columns. The data of Table 33, Column (10), indicate a shearing stress generally of $V' = 0.015P$ to $0.02P$, with larger values for the shorter lengths.

In order to secure a rough estimate of the magnitude of the stress differences in channels of centrally loaded laced columns, and thus determine the stress transfer which must be made by the lacing, the average fiber stresses near the stay-plates of Columns Nos. 4, 5, 5*A*, and 6 were calculated from strain measurements over the adjoining gauges. They show, for unit loads, $P/A$, of approximately 15 000 lb. per sq. in., that this stress difference was usually less than 10%; in Column No. 6, the worst case, it reached 20 per cent.

*54.—Strain Measurements in Lattice Systems of Large Bridge Columns.*— In the tests of large bridge columns reported in *Technologic Paper No. 101*, U. S. Bureau of Standards, strain measurements were made on the lattice members of several of the columns. The results of some of these measurements are given in Table 35, in terms of the stress per square inch. All the columns listed had longitudinal diaphragms except the last two. All had transverse diaphragms. The columns of the first three types were provided with double lacing set at 45° with the column axis. Columns of the first type had no transverse bars. Columns of the second and third types had transverse angles at each panel point which restrained the lateral spreading of the outer ribs. Column $US_2MS_1$ (carbon steel) had four ribs and was provided with a cover-plate on one side. On the opposite side the outer flanges were tied with a single system of lacing-bars. These had independent ends, and served to connect each outer rib with the adjacent inner rib. Bars were set at an angle of 60° with the column axis. The inner ribs were connected by the tie-plates placed at each intersection of the lattice-bars. Column $LC_0LC_1$ (carbon steel) had four ribs which were tied on both flanges in a manner similar to Column $US_2MS_1$.

Considering the first type, without transverse bars, there is little resistance, except near the batten-plates, to the outward bending of the flanges which results from the pantograph action of the latticing when the column is under compressive stress. The result is that the lattice-bars show very little stress (1 500 to 2 000 lb. per sq. in. as a maximum), except in the panel next to the batten-plate where the maximum stress observed is 18 400 lb. per sq. in., or about 30% of the column stress. Even at the transverse diaphragm the stresses in the lattice-bars were very small, showing the same outward bulging as at other points.

The columns of the next two types, having transverse bars, show considerable compressive stresses in all lattice-bars and tensile stresses in all transverse bars. The tensile stresses in the batten-plates (in a transverse direction) are relatively large. These results show the general tendency of transverse bars to maintain the main ribs in line better than latticing without transverse bars

and thus to prevent some of the bending stresses which occur in the latter type near the batten-plates. Neither the longitudinal diaphragm nor the transverse diaphragm appear to have had much effect on this action.

The strain-gauge measurements on the lattice system of Column $US_2MS_1$ and Column $LC_0LC_1$ were not sufficient to afford a detailed study of the stresses. From the measurements made on Column $US_2MS_1$, it is apparent that the lattice-bars suffered considerable flexure in their own plane, also that the average unit stress in these bars was small. The manner of failure of Column $LC_0LC_1$ (carbon) and Column $LC_0LC_1$ (Mayari) suggests that the lattice system was insufficient to develop integral action between the several ribs, and that there was considerable secondary bending stress caused at the ends of the lattice-bars by the rigidity of the riveted connections. The ratio of ultimate strength to yield point, as shown in Column (4) of Table 35, is a maximum for Type 1, and nearly uniform for the various columns of Types 2 and 3. The last type was relatively weak, due apparently to the weakness of the lattice system, no longitudinal web being present to assist in carrying the shear.

Additional information concerning the lateral bulging of column ribs under the pantograph action of a double lattice system and the constrictions produced by tie-plates at the ends is afforded by measurements on Columns $TC4_2$, $TC5_2$, and $TC6_2$, which were tested in 1912 for the New Quebec Bridge.[32] Columns $TC4_2$ and $TC5_2$ consisted of two built-up channel sections with transverse diaphragms at the pin-plates and double lattice without transverse bars. Column $TC5_2$ had some intermediate diaphragms also. Each rib in these columns consisted of two 4 by 4-in. by $\frac{5}{8}$-in. angles turned outward and a 22-in. by $\frac{1}{4}$-in. web-plate. The lattice for Column $TC4_2$ consisted of 2½-in. by $\frac{7}{16}$-in. bars; for Column $TC5_2$ it was made of 4-in. by $\frac{7}{16}$-in. bars.

Column $TC6_2$ had two I-shaped ribs each made of four 4 by 4-in. by $\frac{5}{8}$-in. angles united by a 24-in. by $\frac{3}{8}$-in. web-plate. The ribs were connected along their axes by a longitudinal diaphragm, 16 in. by $\frac{3}{8}$ in. in section, which was attached to the ribs by four 4 by 3-in. by $\frac{5}{8}$-in. angles. A double-lattice system made of 3-in. by ¼-in. bars was used to tie each pair of flanges. Transverse diaphragms were also supplied at intervals along the column.

By means of the strain measurements taken on transverse gauge lines separated about 1 ft. along the axis of the columns, it was found that spreading at the edge of the tie-plate for Columns $TC4_2$ and $TC5_2$ amounted to about 0.003 in., and at 1½ ft. from the plates, it was about 0.01 in. In Column $TC6_2$, equipped with the longitudinal diaphragm, the strains were about one-fourth of these values. The measurements showed that the ribs were bent concave outward at the tie-plates and convex outward for the length of the first panel of lattice. Calculations of stress showed that the bending stress at the tie-plate augmented the direct compression in the ribs of Columns $TC4$ and $TC5$ by about 20 per cent.

*55.—The Effect of Diaphragms on Column Strength.—*

Longitudinal Diaphragms.—A good example of the value of a longitudinal diaphragm is afforded by a comparison of Columns $TC4$, $TC5$, and $TC6$ of the

[32] See The Quebec Bridge Report, Vol. 1, p. 207.

Quebec Bridge tests. The general make-up of these columns has already been described in discussing stresses in lattice. The lengths of these columns were the same; all were equipped with double lattice and transverse bars; but only Column *TC*6 had a longitudinal diaphragm. The principal results of these tests are summarized in Table 36. Each result represents two tests.

TABLE 36.—COMPARISON OF COLUMNS, QUEBEC BRIDGE.

| Column No. | Ratio, unsupported width of web-plate to thickness (estimated). | Relative ratio, weight to cross-sectional area. | Ratio, ultimate strength of column to yield point of metal. | Relative strengths in proportion to weight. |
|---|---|---|---|---|
| *TC*4 | 23 | 1.00 | 0.566 | 1.00 |
| *TC*5 | 23 | 1.05 | 0.559 | 0.94 |
| *TC*6 | 21 | 1.09 | 0.669 | 1.08 |

Mention has already been made of the effect which the longitudinal diaphragm exerted to lessen the lateral bulging of the flanges at the end batten-plates in Column *TC*6.

Attention is also called to the comparisons in Table 37. Although there are many variables other than the effect of the longitudinal diaphram, which affect these comparisons, yet it seems probable that the influence of the diaphragm was the most important factor in raising the efficiency of the column in which it was used.

In test of Column 31*HC*1 (*Technologic Paper No. 101*, U. S. Bureau of Standards), measurements were made of the axial and transverse strains in the longitudinal diaphragm at the middle of a panel where the transverse tension in the diaphragm would be expected to be greatest. At $P/A = 30\,000$ lb. per sq. in., the unit axial compression was 0.00111, and the unit lateral extension was 0.000375. If Poisson's ratio was 0.30 and $E = 29\,000\,000$ lb. per sq. in. for this column, then the axial compression was 31 600 lb. per sq. in. and the transverse tension, 2 340 lb. per sq. in. These results show that the diaphragm was participating in carrying the load and also sustaining a small amount of transverse tension. The ribs were spaced 16½ in. on centers, the diaphragm was ⅜ in. thick, and a double lattice of 3 by ¼-in. bars, with 4 by 3-in. by ⅜-in. angle transverse ties, was used. Assuming the tensile stress uniform over a length of diaphragm equal to the rib-spacing, the total transverse pull in that portion was $16.5 \times \frac{3}{8} \times 2\,340 = 16\,900$ lb., or about 0.73% of the column load

Stresses at Transverse Diaphragms.—The ratio of the spacing of transverse diaphragms to the unsupported widths of the adjoining web-plates, and the position of these diaphragms with respect to the lattice intersections, are factors which probably greatly affect the stresses near the diaphragms. Data containing a systematic arrangement of these variables are wanting, but strain measurements made during the Quebec Bridge tests are of importance in this connection.

Columns *TC*4 and *TC*5 were equipped with transverse diaphragms which intersected the ribs at panel points of the lattice. Readings of strain in the

outer fibers of the rib flanges showed that the compressive stresses on these fibers for gauges spanning the diaphragm were from 7 to 14% higher than the stresses in adjoining gauges on the same fibers. These data show that the diaphragm offered restraint against the outward thrust of the lattice-bars. Consequently, the rib flanges were thus bowed concave outward at the diaphragm in much the same way as at the end battens. Measurements on Column *TC6* which had I-shaped ribs and a longitudinal diaphragm, failed to show any marked discrepancy between strains across the transverse diaphragms and elsewhere.

In Column $U_2U_3$ (*Technologic Paper No. 101*, U. S. Bureau of Standards), the diaphragms were placed at the intersection of the lattice (mid-points of panels) at intervals of two panel lengths. In Column $U_8U_9$, the end diaphragms were similarly placed, but the center diaphragm was attached at panel points of the lattice. Measurements of strain along the edges of the center diaphragm in the plane of the lattice gave the results shown in Table 38. It will be noted that the stresses are somewhat greater in the $\frac{5}{8}$-in. diaphragm of Column $U_8U_9$ than in the $\frac{1}{4}$-in. diaphragm of Column $U_2U_3$. This discrepancy is probably due to the difference in the positions of the diaphragms with respect to the lattices.

## SUMMARY OF RESULTS

The results of tests and the theoretical studies contained in this report may be summarized briefly, as follows:

(1) When correctly interpreted, the average tensile yield point of the material is a satisfactory measure of the ultimate strength of columns, except for columns having high values of the slenderness ratio, in which buckling takes place at stresses below the yield point.

(2) The shearing rigidity of columns varies greatly as between columns with solid webs, columns with lacing, and columns with batten-plate connections.

(3) The strength of single lacing-bars in resisting column shear can be determined approximately by tests on single bars, in the manner set forth in the report.

(4) Columns the component parts of which are connected by batten-plates are relatively weak in shear, and under loads involving heavy shearing stress, will be subjected to relatively high stress in the extreme fibers of the individual segments. Under loads producing small shearing stresses, the tests are not conclusive as to the economy of batten-plate columns.

(5) Under loads the eccentricities of which are known, the results of tests check very closely with theoretical results.

(6) Eccentric load tests on H-columns showed a very considerable excess of ultimate strength over that determined on the basis of yield point in the case where the eccentricity was in a direction perpendicular to the web, so that the most stressed fibers were on the edges parallel to the web. This excess strength was, in general, greater the smaller the slenderness ratio, $\frac{l}{r}$.

(7) On a theoretical basis, the flexibility of a column in the plane of the lacing due to shearing distortion is not of great influence on the ultimate

strength of columns under eccentric loads. Such reduction of strength as may be caused by this increased flexibility can be overcome by an increase in the corresponding radius of gyration.

(8) The results shown in the Progress Report of 1926 to the effect that the tensile and compressive yield points are very nearly equal, are confirmed by the tests herein described.

(9) The yield point of the material varies considerably according to the location of the specimens in the section. For H-columns, the specimens cut from the intermediate portions of the flanges appear to represent the section best. For channels, the web specimens were most representative. For thin plates, not much difference was found between specimens cut from the edges and those cut from the center.

(10) The value of the modulus of elasticity of the column as a whole is nearly constant, ranging only about 5% more or less than 29 500 000 lb. per sq. in.

(11) The theoretical analysis of a column forming a part of a riveted truss indicates that the strength of the column as regards bending in the plane of the truss is much greater than that of a pivoted end column, and approaches rather closely the strength of a pivoted end column of one-half the length under eccentric load, with eccentricity corresponding to the secondary bending moments assumed in the analysis.

(12) In the case of columns forming compression members of riveted structures, the effect of eccentricity due to crookedness and the effect of weight as regards bending in the plane of the truss are relatively small, the effect of crookedness being less than one-half that due to the same amount of crookedness in a pivoted end column of one-half the length.

(13) The crookedness of the columns tested was, in most cases, less than 1/1500 of the length. All columns were fabricated under standard American Railway Engineering Association specifications.

(14) The obliquity of the ends of columns designed to transmit largely by end-bearing is a matter of importance. As measured by the slope of one end with respect to the other, the average obliquity of the H-columns tested was found to be about 0.003.

(15) A study of the existing data relative to the failure of individual column components shows that in laced channel columns, no failures occurred where the ratio, $\frac{p_1}{r_e}$, was less than 25. The tests studied were, however, too limited in number to be at all conclusive.

(16) The tests made by the U. S. Bureau of Standards for the Delaware River Bridge Commission indicate that a safe ratio of plate width to thickness for structural steel is about 40, provided the width is measured between rivet lines and the plates are well restrained at the edges.

(17) Under perfect conditions of support at one edge, outstanding structural steel plates or flanges may be expected to carry the full proportional limit stress of about 30 000 lb. per sq. in. without buckling, provided the ratio of outstanding width to thickness is not greater than 20.

(18) The stresses in lacing are likely to be considerably greater than those due to calculations from shear; in centrally loaded columns (shear = 0) generally they are greater by an amount from 0.015 to 0.02 $P$, and in obliquely loaded columns, by 0.015 to 0.03 $P$. For loads approaching the maximum, the stresses in the lacing-bars approach more nearly the calculated values.

(19) The action of double lacing without transverse bars forces the ribs of a column apart, and introduces considerable bending stresses near the stay-plates. With transverse bars and double lacing, this action can be reduced, but the lacing will then receive considerable compressive stress, and this arrangement involves details which are undesirable in some respects.

(20) Tests on large bridge members indicate difficulty in securing integral action of the several ribs of a large member by means of lattice-bars only. Longitudinal diaphragms or cover-plates are more effective.

## Suggestions Relative to Future Work

From the studies made thus far, it seems evident that further investigation of columns may well be considered in two parts: (1) The strength and effectiveness of lacing, batten-plates, and diaphragms; effect of form of section, outstanding flanges, etc.; unsupported length of component parts; and other details affecting integrity of action; and (2) the conditions of the column as a part of a structure, its end conditions, crookedness, and the effect of other members thereon.

The first group of studies can best be made with end conditions definitely known, as by the use of roller-bearing blocks; the second group can only be made by studies and observations of actual columns and trusses. If details are designed to secure with certainty integrity of action, and then if the conditions of the column in the truss are known, it would seem that the application of theoretical principles is the rational process of design and is quite as well warranted as in the design of beams. The attempt to study the entire problem by the customary flat-end test is a slow process, and does not yield results that are readily analyzed and applied.

Further needed information can be secured regarding the first group of problems by a moderate expenditure for test specimens and laboratory work; the second part of the problem is more difficult, and will probably require a considerable amount of field work.

Respectfully submitted,

May 7, 1928.

# DISCUSSION

HENRY S. PRICHARD,[34] M. AM. SOC. C. E. (by letter).—A consideration of the progress reports, made in January, 1926,[35] and January, 1929, by the Special Committee on Steel Column Research, excites admiration for extensive, painstaking, able analyses, and gives ground for hope that much of practical value will result from the research after the contemplated further investigations have been completed. The final report will be awaited with much interest.

The theory of flexure is based on the proportionality of stress to strain and on the modulus of elasticity being constant for the material to which the theory is applied. When it is applied to a body as a whole, it is assumed that the details are properly proportioned. In general, the theory is applied as if friction between the bodies or parts to which it is applied and other bodies or parts is negligible. It is gratifying to find so much verification of theory in the physical investigations within these qualifications. It is also gratifying that the modulus of elasticity for steel proved to be so nearly uniform for all cases observed, and that the mathematical analyses based on proportionality of stress to strain agree with experimental determinations, as far as the general behavior of columns is concerned, over such a considerable range of stress.

Engineers and architects, for many years, have based their practice with regard to beams on the ordinary theory of flexure, and during the same period have based their practice as regards columns on arbitrary formulas, some being little more than rule-of-thumb methods modified more or less by experiments and experience, some being the result of mistakes in theory, and some being based on pseudo theories or mere notions. Yet the ordinary theory of flexure applies more closely to columns than to beams and, intelligently applied, finds better confirmation in the case of columns than in that of beams. This is due in part to the facts that the ordinary theory of flexure neglects the influence of shear on deformation and shear is more of a factor in beams than in columns. The permanent sets under transverse loads indicated in Column (6) of Table 5 may have been due to the transverse load at the center being almost concentrated on a line. The ordinary theory of flexure, which neglects the influence of shear on deformation, gives no indication, in the cases tabulated, of stresses intense enough to produce permanent sets. When the influence of shear is considered, however, it indicates that very high stresses, much higher than those indicated by the ordinary theory, may occur if the transverse load is too highly concentrated.[36]

Under ideal conditions a centrally loaded column with frictionless hinged ends would be subjected to no shear; but in order that the various fibers constituting the column shall act together, it must have potential resistance to shear. This potential resistance has been neglected in Euler's formula, in consequence of which that formula gives a result which is, theoretically,

[34] Pittsburgh, Pa.

[35] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1485.

[36] *Loc. cit.*, p. 1257, Equation (22); see, also, Vol. LXXV (1912), pp. 932–953, for effect of shear on deformation of beams.

slightly too great, but only very slightly so for a column with a reasonable cross-section.[37]

Section 35, advocating "Factor of Safety Method in Column Design", is highly commendable and should receive special consideration. If rational methods of computing the relation between loads and stresses and shears are used, then, actually to obtain, in a column, the factor of safety desired, it must be applied to the critical load and not to the critical stress or shear, the critical load being the load which would produce the critical stress or shear; that is, the stress or shear at or near failure.

Quoting from Section 35:

"* * * the logical process in column design is to select a formula which will as nearly as practicable give values of ultimate strength, or some point which represents the practical ultimate value of the column; then to divide the resulting value of average stress, $P/A$, by the factor of safety corresponding to that used in other members* * *".

This leaves an open question as to just what point in loading should be considered the critical point to which the factor of safety should be applied. In its First Progress Report the Committee stated[38] that:

"The Society's Special Committee on Steel Columns and Struts made use of what was named by it the 'Useful Limit Point' (U. L. P.)[39] as being of more significance in some respects than the ultimate strength of the column or the yield point of the material. Although there is good ground for adopting this point in the stress-deformation diagram, as the best measure of column strength, it is not practicable to adhere to this method in a study of all available data. Information does not exist to determine the U. L. P. in a great many of the tests that have been made; but, nevertheless, it is believed that the results of such tests are valuable and cannot be neglected."

The Committee further stated:[40]

"It is possible that some such point as the U. L. P. used by the Society's Special Committee on Steel Columns and Struts would be a more accurate reference point than the yield point, but as no other tests give this information,[41] it seemed best to use the yield point instead, and it is believed that the diagrams represent fairly the relations indicated.

"The difficulty of securing correct information regarding the elastic properties of the material actually used is well known. The values of yield point as determined by the usual 'drop of the beam' method depend largely on the details of testing; the mill tests vary largely from laboratory tests; and the material varies greatly in thin and thick sections, and at different points in the same section."

The writer's opinion of the critical value of a structural steel member in direct compression or tension, in the formation of which he gave great weight to the report of the Special Committee on Steel Columns and Struts, has been published.[42]

[37] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1423; see, also, *Engineering News*, February 25, 1909, p. 206.

[38] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1487.

[39] *Loc. cit.*, Vol. LXXXIII (1919–20), p. 1618.

[40] *Loc. cit.*, Vol. 89 (1926), p. 1522.

[41] In numerous tests contained in various Watertown Arsenal reports the strains near the U. L. P. were recorded at short intervals of stress. In each of such cases, the U. L. P. can be closely approximated.

[42] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), pp. 1236 and 1239.

In ordinary cases the only criteria which an engineer or architect has of the strength of the steel in the structure he has designed, are the specimen tests, furnished by the mill, of the tensile yield point, as determined by "drop of beam", and the ultimate tensile strength. The "yield point" as furnished by the mill is often much higher than that found in laboratories, such as that of the U. S. Bureau of Standards, and is usually much higher for specimens than for full-sized structural members.

The U. L. P., the yield point, and the ultimate strength of different rolled sections, as found in properly conducted tests in reliable laboratories, differ greatly for steel nominally of the same quality, even from the same heat. For instance, in the careful tests by Marshall, the "elastic limit", as he terms it, taken by "drop of beam", of a specimen from a 4-in. by ½-in. flat, was 50% greater than that of a specimen from a 3 in. by 1¾-in. flat, although they were from the same blow of Bessemer steel.[43] The extremes in the characteristic U. L. P.'s of the columns made of 60 000 lb. (desired) steel, tested for the Society's Special Committee on Steel Columns and Struts, were 19 000 and 35 000 lb. per sq. in., respectively.[44]

The great differences in utilizable strength due to the thermal and mechanical conditions encountered in the normal processes of manufacture, as distinguished from differences in chemical composition, overshadow the differences due to length, radius of gyration, and form of cross-section, in cases where the conditions are such that the capacity of the column can be gauged more by its resistance to stress than by its degree of stiffness. In long columns, the intensity of elastic stress which steel will resist is not so much of a factor.[45]

The members of framed structures, even pin-connected ones, have secondary stresses, in addition to direct stresses. The direct stresses are generally computed as if the structure were perfectly articulated and the differences between the combined stresses and the direct stresses are considered secondary stresses. The determination of the secondary stresses is a complicated matter. It requires for each member a consideration of all the members, including their section and make-up, and, from a practical point of view, is only approximate, on account of the complication due to connections at the ends of the members. Apart from these considerations, as the determination of secondary stresses is based on the proportionality of stress to strain, it can only be correct within the limits to proportionality. If carried beyond these limits it is liable to be very faulty.

In view of the uncertainties as to the intensity of stress to which steel structures are liable in many of their details and of uncertainties as to the elastic resistance to stress possessed by the numerous pieces of steel used, it is fortunate that steel possesses capacity to recover elasticity—albeit with permanent set—after it has been subjected to plastic deformation in service. This phase of the subject should and probably will form part of the research of the Committee before it has concluded its labors.

[43] *Transactions*, Am. Soc. C. E., Vol. XVII (1887), Table 1, p. 68(a).
[44] *Loc. cit.*, Vol. 89 (1926), p. 1268.
[45] *Loc. cit.*, p. 1292, Fig. 6.

The many phases involved in column research should be kept in mind in judging the reports of the Committee; otherwise, too much will be expected. Many uncertainties are inevitable under the conditions of manufacture, testing, and use which now exist.

E. H. SALMON,[46] ESQ. (by letter).—The Committee is to be congratulated on its second Progress Report, which contains much information worthy of the closest study. The writer is convinced that important progress will develop from a detailed investigation of the behavior of columns, particularly those forming part of a truss. In the ordinary structural column, length-strength considerations do not have the preponderating importance which has been attached to them in the past.

The Committee refers to some estimates by the writer of the imperfections, initial curvature, etc., likely to occur in practical columns, and the statement is made that the measured imperfections in specimens used for the report were considerably less. It is freely admitted that there is nothing sacrosanct about the writer's estimates, which were based on the data available in 1915. Nevertheless, what the Committee's observations really prove is that its specimens were very well straightened. Although the columns were required to conform to the General Specification for Railway Bridges of the American Railway Engineering Association, it would, perhaps, be rather natural if a little extra care were taken with members intended for such a special purpose. However this may be, it is of interest to compare the Committee's suggested formula, $e' = \frac{l}{1\,500}$, with earlier observations. The writer has reached the conclusion that there is no evidence to show that the initial deflection is a function of $\frac{l}{r}$ rather than of $l$, with which the Committee seems to agree. The larger diagram in Fig. 40 is the original from which the rule, $e' = \frac{l}{750}$, was deduced; a line representing the Committee's suggestion, $e' = \frac{l}{1\,500}$, has been added. It is found by counting that of the 185 plotted points, 7 lie outside the line, $e' = \frac{l}{750}$, and 78 (42%) lie outside the line, $\frac{l}{1\,500}$. It is submitted that this number is much too large to be fortuitous, and that, in practice, it would not be feasible to rely on securing a crookedness as slight as $\frac{l}{1\,500}$. Examining Fig. 37 in the same way: Of the 39 plotted points, 5 of them, or 13%, are outside the line, $e' = \frac{l}{1\,500}$. It is to be observed that most of these specimens were about 100 in. long, and that in the fewer long specimens, the initial deflection was small, whereas in Fig. 40 the percentage in which $\frac{l}{1\,500}$ is exceeded, is greater for the greater lengths.

[46] Clark & Standfield, London, England.

Taking Fig. 37 in conjunction with Fig. 40, it appears to the writer that, with the data available, the estimate, $e' = \frac{l}{750}$, is not unreasonable. Nevertheless, what he would like to see would be the measurement (as suggested in the Committee's previous report[47]) of a large number of actual members (not test specimens) as fabricated ready for erection, made at different yards, and classified as to size and shape; that is, small single bars differentiated from large built-up members. The cost should not be excessive, and if from these data, the Committee could fix a standard which might pass inspection in the shops, he conceives that one debated point in column design would have been settled. This is a matter in which the large steel fabricating companies might co-operate usefully to a common advantage.

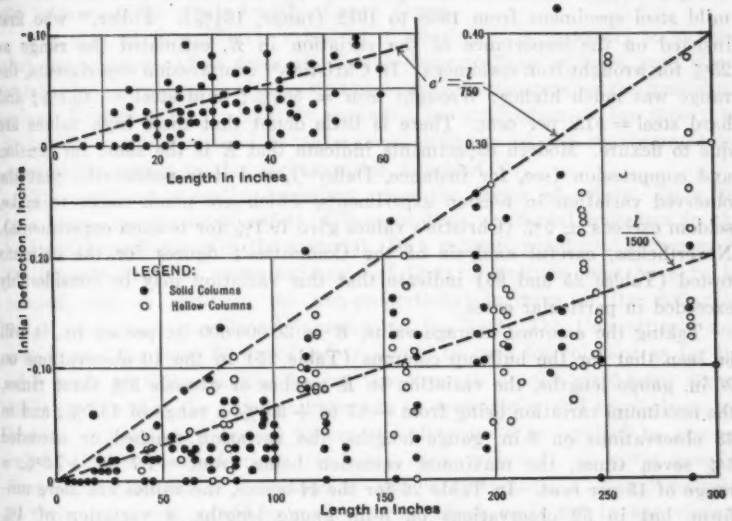

FIG. 40.—TESTS TO DETERMINE VALUE OF $e'$.

The Committee finds that the variations in $E$ and its effects are of much less importance than predicated by the writer. This remark appears to have reference primarily to the average value of $E$ for the column as a whole; that is, as used in the secant formula. Perhaps a little misunderstanding has arisen here, for the writer fully agrees with this conclusion; in fact, he has shown[48] that a $\pm 10\%$ variation in $E$ made no practical difference in the value of $EI$, provided the average value was used for $E$. It is of importance, however, to recognize the effect of a difference in the value of $E$ for the two flanges of a built-up member, for example, in shifting the center of resistance away from the geometrical center of the cross-section. It is easy to prove

[47] *Transactions*, Am. Soc. C. E., Vol. 89 (1926), p. 1537.
[48] "Columns," by E. H. Salmon, Oxford Technical Publications, p. 34.

that a $\pm$ 10% variation in $E$ shifts the center of resistance, $\frac{h}{20}$, from the geometrical center, where $h$ is the distance between the centroids of the two flanges.

With the data available prior to 1915, the writer estimated the probable variation in $E$ as $\pm$ 10 per cent. The Committee finds for the built-up columns a range of 10% (— 6.6 to + 3.8%). It is quite probable that the previous estimates for the values of $E$ in compression are inaccurate. The determination of $E$ in compression experiments is not easy. Strain-gauge measurements are really not very suitable, and the effect of flexure is probably always present. The writer based his estimate chiefly on Bauschinger's[49] experiments on wrought-iron specimens, which were very carefully made (range, 22½%), and on fifteen experiments made at Watertown Arsenal[50] on mild steel specimens from 1908 to 1912 (range, 16½%). Fidler,[51] who first insisted on the importance of the variation in $E$, estimated the range as 23% for wrought-iron specimens. In Christie's[52] compression experiments, the range was much higher: Wrought iron = 56½%; mild steel = 45.7%; and hard steel = 51.2 per cent. There is little doubt that these high values are due to flexure. Modern experiments indicate that $E$ is the same for tension and compression (see, for instance, Dalby[53]), and it is noteworthy that the observed variation in tension experiments, which are much easier to make, seldom exceeds $\pm$ 5% (Christie's values give 19.1% for tension experiments). Nevertheless, careful analysis of the Committee's figures for the columns tested (Tables 25 and 26) indicate that this variation may be considerably exceeded in particular cases.

Taking the assumed average value, $E$ = 30 000 000 lb. per sq. in., it will be seen that for the built-up columns (Table 25) in the 10 observations on 20-in. gauge lengths, the variation in $E$ reaches or exceeds 5% three times, the maximum variation being from —8.7 to + 5.0%, a range of 13.7%; and in 33 observations on 8-in. gauge lengths, the variation reached or exceeded 5% seven times, the maximum variation being from —7.7 to +7.3%, a range of 15 per cent. In Table 26 for the H-beams, the values are more uniform, but in 52 observations on 8-in. gauge lengths, a variation of 4% was reached or exceeded on nine occasions, the maximum variation being from —5.7 to +7.7%, a range of 13.4 per cent. In 12 observations on 20-in. gauge lengths, however, the maximum variation was only from —3.3 to +1.0%, a range of 4.3 per cent.

When it is remembered that these observations are already averages of four, six, or eight gauge-length readings, it seems fair to inquire, if in as few as thirteen built-up specimens, a 10% range in the average value of $E$ for the whole column is observed, and a 15% range on individual gauge

lengths, whether it is very extravagant to suppose that a possible 20% difference in $E$ might occur between the two flanges of a built-up column in practice. Presuming that the ends of such a member were fixed in direction, and the writer's suggestion (that one-half the shift of the center of resistance be regarded as initial curvature, and one-half as eccentricity) is adopted, the eccentricity would not affect the strength, and the proposal would be equivalent to taking the 10% range found by the Committee entirely as initial curvature. Even so, if such a member were short, the effect of the difference in modulus would be the larger part of the initial curvature. In this connection it may be recalled that Fidler took the variation in the modulus as the sole imperfection.

It would be of much interest if the Committee would give the actual difference in $E$ between the two flanges of these thirteen columns, averaging the value over the whole length of each flange.

The question immediately arises as to whether it is necessary to assume that the member suffers from all possible imperfections at once, and, if so, whether it is necessary to assume that each imperfection reaches the maximum value. Professor R. H. Smith[54] suggested an application of the theory of probabilities, and proposed to take seven-elevenths of the maximum total eccentricity, acting in the worst possible direction.

The question is really dependent upon the factor of safety. In a tie or a beam, one factor of safety will cover both accidental increases in the load and imperfections in the material. In a column, accidental increases in the imperfections, or under-estimates of their magnitude, also have to be covered, and, in addition, the non-proportional increase in the deflection which accompanies accidental increases in the load. The Committee's suggestion that the same factor of safety should be used for columns as for the other parts of the structure, basing the strength on the yield-point stress, really implies that the true conditions as to eccentricity and crookedness are known; and unless a special factor of safety is to be applied to average values of these imperfections (as some have proposed), to cover possible exceptional material or exceptionally bad straightening, a liberal estimate of their magnitude should be made—such, indeed, as is not in any circumstances likely to be exceeded in practice. It might be urged further that, since in the ordinary short structural column the stress due to bending is small, an over-estimate is not a serious consideration.

Much the same arguments appear to apply in connection with one of the most significant results of the Committee's research, in which it confirms the large variation in the yield point which occurs in ordinary structural mild steel. In discussing the later Watertown Arsenal experiments, Howard repeatedly calls attention to similar variations, and their effect in bringing about local failure in built-up members.

While the Committee may fairly be said to have established that, for practical purposes the tensile yield point may be taken as the failure stress, either a low minimum value should be taken as the yield stress, or if the

[54] "The Strength of Struts," *Proceedings*, Edinburgh and Leith Eng. Soc., 1878, Vol. IV, p. 42.

average value is taken, a reduction of 15 to 20% should be allowed to cover the possible variations. In other words, the Committee's results lend support to the rather usual practice of adopting a lower working stress in compression than in tension.

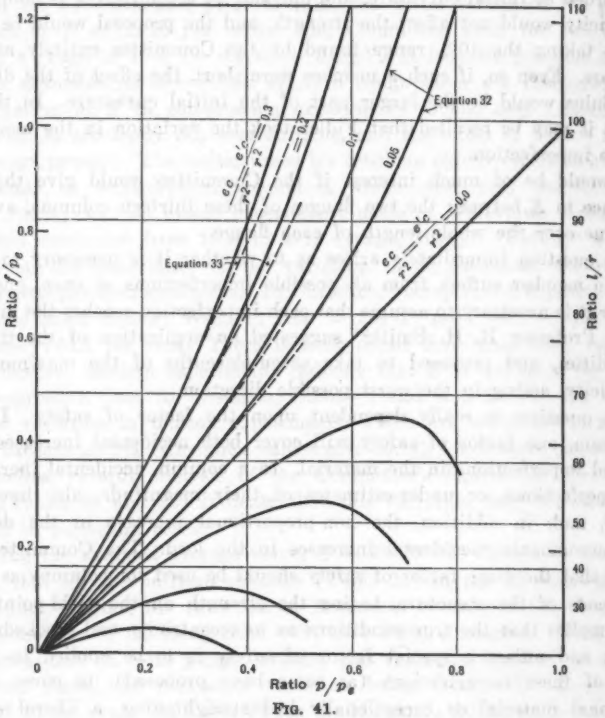

FIG. 41.

Assuming then that a suitable value had been taken for $e$, and that the column has position-fixed ends, the Committee's use of the secant formula to calculate the stress at yield in the column—as indeed is proved by the experiments—is perfectly sound. The method is probably sufficiently accurate in the case of a direction-fixed column provided that a suitable value is taken for the "free length". In seeking an approximation to replace the secant, the writer believes that it is justifiable to take into consideration the fact that, due to the relative shortness of ordinary structural columns, only a small part of the secant curve has any relevance, and that part is very flat. A simple formula can then be used to determine the stress in the column. Fig. 41 has been plotted to illustrate this point. The abscissas represent the ratios of $\frac{p}{p_e}$, and the ordinates, $\frac{f}{p_e}$. Thus, the abscissas

represent to some scale the load per square inch on the column, and the ordinates the maximum stress in the extreme fibers. If the column remained absolutely straight up to Euler's crippling load, $p$ would be equal to $f$, and the maximum stress would be represented by the straight line, $OE$, at 45 degrees. If the column bends, the stress will increase on the concave side and decrease on the convex. This is shown in the heavy curved lines, which are plotted from the formula:[55]

$$\frac{f}{p_e} = \frac{p}{p_e}\left[1 \pm \frac{c}{r^2}\left\{e \sec \frac{\pi}{2}\sqrt{\frac{p}{p_e}} + \frac{8\,p_e\,e'}{\pi^2\,p}\left(\sec \frac{\pi}{2}\sqrt{\frac{p}{p_e}} - 1\right)\right\}\right] \quad \ldots(33)$$

The first half of Equation (33) will be recognized as the secant formula for eccentric loading, the second half is the corresponding expression for initial curvature. Four cases are shown corresponding to $\frac{e\,c}{r^2} = \frac{e'\,c}{r^2} = 0.05$, 0.1, 0.2 and 0.3, respectively. It is assumed for this purpose that, of the total deviation from axial loading, one-half is due to eccentricity and one-half to initial curvature. The last case is approximately equivalent to $\frac{e\,c}{r^2} = 0.6$ representing, according to Moncrieff,[56] the worst experimental columns, and taken by him as a suitable value for a practical column. On the same diagram is plotted the formula:[57]

$$\frac{f}{p_e} = \frac{p}{p_e}\left[1 + \left(1 + \frac{3\,p}{2\,p_e}\right)\frac{c}{r^2}\,(e + e')\right] \quad \ldots\ldots\ldots\ldots(34)$$

which is represented by the light broken lines. It will be seen that up to the value, $\frac{p}{p_e} = 0.3$, the agreement is excellent; up to $\frac{p}{p_e} = 0.4$, the agreement is good; and even at $\frac{p}{p_e} = 0.5$, for the greatest value of $\frac{e\,c}{r^2} = \frac{e'\,c}{r^2}$, the error is only 10.3 per cent. The ratio, $\frac{p}{p_e}$, is the factor of safety in Euler's formula, that is, against instability, and for ordinary structural columns this is not likely to be less than 5, or $\frac{p}{p_e} = 0.2$; for the shorter columns, it will be much greater. A series of horizontal lines has been drawn on Fig. 41 representing the value of $\frac{l}{r}$, for which, $f = 30\,000$ lb. per sq. in., the minimum value for the yield point of the steel used in the Committee's experiments, plotted from the formula:

$$\frac{f}{p_e} = \frac{f}{\pi^2\,E}\left(\frac{l}{r}\right)^2 \quad \ldots\ldots\ldots\ldots(35)$$

[55] "Columns," Equation (86), p. 42.

[56] "The Practical Column Under Central or Eccentric Loads," *Transactions*, Am. Soc. C. E., Vol. XLV (1901), p. 334.

[57] "Columns," Equation (93A), p. 44.

It will be seen that for the worst case, $\frac{e\,c}{r^2} = \frac{e'\,c}{r^2} = 0.3$, when $f = 30\,000$ lb. per sq. in.; that is, at the failure point, if $\frac{l}{r} = 100$, the value, $\frac{p}{p_e}$, is only equal to 0.46, and if $\frac{l}{r} = 50$, the value, $\frac{p}{p_e}$, is only equal to 0.15.

These values of $\frac{p}{p_e}$ are sufficiently small to justify the use of Equation (34) practically up to the failure point of such columns; and at working stresses the corresponding values of $\frac{p}{p_e}$ will be less than one-half.

Equation (34) is very much simpler than the secant formula, or any of the algebraic substitutes which have been proposed, ingenious as they are, and in view of the fact that a possible variation in $f$ of 33% must be considered and that, at best, $e$ and $e'$ must be probable assumptions, it seems to the writer that the much simpler equation is all-sufficient for practical work provided always the ratio, $\frac{p}{p_e}$, never exceeds 0.5. If it is preferred to treat the deviation entirely as an eccentricity, $e$, and arrange so that the stress shall be entirely covered by the approximate formula when $\frac{e\,c}{r^2} = 0.6$ and $\frac{p}{p_e} = 0.5$, the constant, $\frac{3}{2}$, may be changed to suit the circumstances, and Equation (34) modified to,

$$\frac{f}{p_e} = \frac{p}{p_e}\left[1 + \left(1 + \frac{5}{2}\,\frac{p}{p_e}\right)\frac{e\,c}{r^2}\right]$$

but for the majority of practical columns Equation (34) can be used with safety.

For columns direction-fixed at their ends (and most practical columns approximate this condition), the curves representing the increase of stress with increasing values of $\frac{p}{p_e}$ are even flatter (see Fig. 42), and a similar device can be applied with even greater justification.

Fig. 42 is plotted differently; the base line represents the ratio, $\frac{p}{p_e}$, as before except that, in this case, $p_e$ is $\frac{4\,\pi^2\,E}{\left(\frac{l}{r}\right)^2}$; but the ordinates represent, to a particular scale, the ratio, $\frac{f_b}{p_e}$, in which $f_b$ = stress due to bending. The curves show that for values of $\frac{p}{p_e}$ from 0 to 0.5 at least, the bending stress in a fixed-ended column increases slowly relative to the increasing load. Incidently, the writer's

diagrams illustrate the fact that for small values of $\frac{p}{p_e}$, that is, under working conditions, the stress due to bending at the ends is double that at the middle, approaching equality when $p = p_e$.

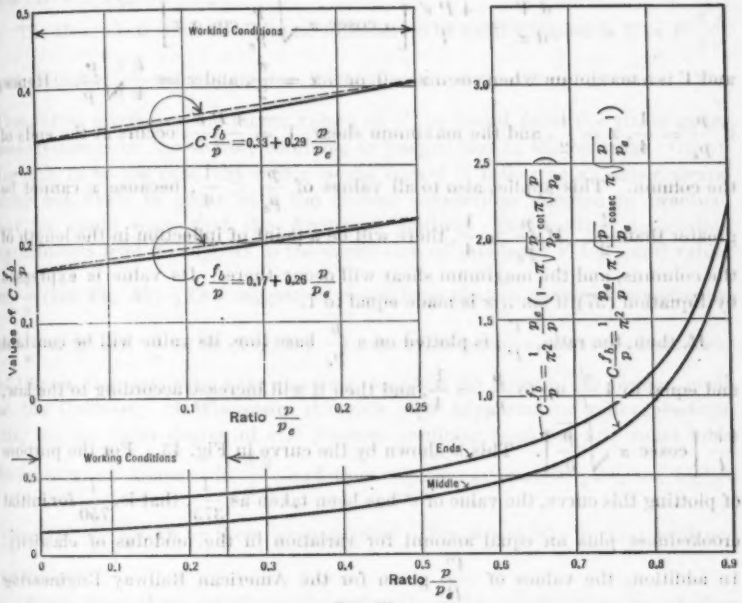

FIG. 42.

If use is made of the suggested algebraic equivalents for the unwieldy trigonometrical expressions, there seems no real reason why the fixed-ended column should not be designed rationally instead of by pivoted-end formulas (which at best are rough approximations), particularly if adjustment were made for possible imperfection in the direction-fixing.

Turning to the Committee's observations on shear for axially loaded columns, the writer considers that this is one of the points in which the "free-length" method of treating fixed-ended columns is apt to be misleading. In a fixed-ended column with parabolic initial curvature, if the origin is taken at its midpoint, the equation[58] for the shear force is:

$$V = \frac{d\,M}{d\,x} = \frac{8\,P\,e'}{\alpha^2\,l^2}\left(\alpha\,k\,\frac{\alpha\,l}{2}\operatorname{cosec}\frac{\alpha\,l}{2}\sin\alpha\,x\right) \ldots\ldots\ldots\ldots (36)$$

in which, $\alpha = \frac{2\,\pi}{l}\sqrt{\frac{p}{p_e}}$; $p_e = \frac{4\,\pi^2\,E}{\left(\frac{l}{r}\right)^2}$; and for a column with perfectly direction-

[58] "Columns," Equation (446), p. 193.

fixed ends, $k = 1$. This reduces to:

$$V = \frac{4\,P\,e'}{l}\left[\operatorname{cosec}\,\pi\sqrt{\frac{p}{p_e}}\sin\alpha\,x\right] \quad \ldots\ldots\ldots\ldots\ldots\ldots (37)$$

so that,

$$\frac{d\,V}{d\,x} = \frac{4\,P\,e'}{l}\left[\alpha\,\operatorname{cosec}\,\pi\sqrt{\frac{p}{p_e}}\cos\alpha\,x\right]$$

and $V$ is a maximum when $\cos\alpha\,x = 0$, or $\alpha\,x = \frac{\pi}{2}$, and $x = \frac{l}{4}\sqrt{\frac{p_e}{p}}$. Hence, if $\frac{p}{p_e} = \frac{1}{4}$, $x = \frac{l}{2}$, and the maximum shear, $V = \frac{4\,P\,e'}{l}$, occurs at the ends of the column. This applies also to all values of $\frac{p}{p_e} < \frac{1}{4}$, because $x$ cannot be greater than $\frac{l}{2}$. If $\frac{p}{p_e} > \frac{1}{4}$, there will be a point of inflection in the length of the columns, and the maximum shear will occur there. Its value is expressed by Equation (37) if $\sin\alpha\,x$ is made equal to 1.

If, then, the ratio, $\frac{V}{P}$, is plotted on a $\frac{p}{p_e}$ base line, its value will be constant and equal to $4\,\frac{e'}{l}$ up to $\frac{p}{p_e} = \frac{1}{4}$, and then it will increase according to the law, $\frac{4\,e'}{l}\left[\operatorname{cosec}\,\pi\sqrt{\frac{p}{p_e}}\right]$. This is shown by the curve in Fig. 43. For the purpose of plotting this curve, the value of $e'$ has been taken as $\frac{l}{375}$, that is, $\frac{l}{750}$ for initial crookedness plus an equal amount for variation in the modulus of elasticity. In addition, the values of $\frac{V'}{P}$ given for the American Railway Engineering

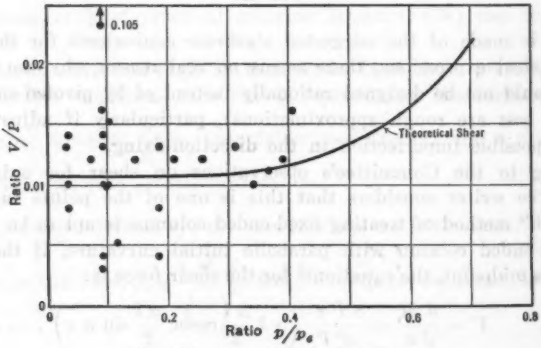

FIG. 43.—FIXED-ENDED COLUMNS.

Association experiments on columns with square ends have been plotted on the same diagram. For this purpose the specimens have been considered direction-fixed at their ends. Although the points lie grouped about the curve, too much importance should not be attached to the fact, because the value of

$e'$ will be different for each, but with the data at his disposal the writer is unable to make a better estimate. It is difficult to believe, however, that in a practical column the ratio of $\frac{V}{P}$ can increase as $\frac{l}{r}$ diminishes, as suggested by the curve in Fig. 39.

The theoretical shear in a column intended to be axially loaded is $V = P\frac{dy}{dx}$, and certainly $\frac{dy}{dx}$ will be greater in long columns than in short ones. The Committee attributes the larger values of $V$, as found from the strain-gauge measurements on the shorter columns, to inequalities in the bearings. Granting this to be the case, the writer would regard it rather as an experimental error not likely to occur with the riveted connections adopted in practice; but he would urge that the American Railway Engineering Association experiments lend no support to the suggestion of increased $V$ for small values of $\frac{l}{r}$ (see Fig. 43). This suggestion comes from the two groups of experiments at $\frac{l}{r} = 22$ and $\frac{l}{r} = 38$ (Fig. 39). In the latter group, made at the University of Illinois, the specimens were abnormal, and had pin ends; in the former, made at the University of Wisconsin, the ends were supported on roller bearings. May not the extra degree of end freedom resulting from pin and roller ends have led to an increase in $\frac{dy}{dx}$, and thus explain, at least in part, the higher values of $\frac{V}{P}$ shown by these experiments? One would like further evidence on this point.

Apart from these questions the writer is rather doubtful as to whether strain-gauge measurements on lattice-bars really give an accurate indication of the shear force in columns. The results obtained are quite variable, and are undoubtedly influenced by the flexure of these thin bars. Nevertheless, they are of service in that they confirm the evidence that the shear is small, and that for axial loading the usual assumption of from 2 to 2½% of the longitudinal load is approximately correct.

The writer is in thorough agreement with the Committee's proposals relative to future work. He conceives that the proposed investigations under both Part (1) and Part (2) will lead to just the kind of information that is lacking, and, in particular, is most pleased that it is proposed to investigate the action of actual columns in trusses. Such observations, he is confident, will lead to the establishment of a really rational basis for the design of columns.

J. H. GRIFFITH,[59] M. AM. SOC. C. E. (by letter).—This report presents the data of a carefully conducted series of tests which clarify many points not fully understood in steel column behavior. Among the more important subjects considered, may be mentioned: The effects of the end conditions and eccentric placements of columns in the testing machine; the weights of

[59] Prof. of Experimental Eng., Iowa State Coll., Ames, Iowa.

influence to be attached to irregular deportments of lattice-bars, such as the pantograph action; the proper strengths of lattice and batten-plates; cross-sectional variations; and unintentional cambering of columns. Supplementing its tests, the Committee gives an extended review of important column tests made in the past. This aids much in crystallizing thought as to what constitutes the highest efficiency in column design and fabrication.

Among the various devices discussed, the frictionless end-bearing will commend itself to testing experts. It calls to mind the earlier forms of bearings used by Bauschinger, von Tetmajer, and Considére,[60] with which the more modern bearing permits favorable comparison. The new bearing seems very substantial and quite adequate for the heavier column loadings of present-day practice in testing. Although no provision is made for the possibility of some torsion in the columns, which is taken into account in the higher analysis, actual bridge columns in service are largely constrained to displacements in the plane of the truss without twist. A review of the test data shows that these bearings fulfilled the intents of the experimenters and were sensitive enough to respond to very small variations in the intentional eccentricities used in the tests. The determinations of the frictions at the column ends to an order of magnitude of a single percentage seem to be amply sufficient. These findings help to remove one of the chief uncertainties present in column investigations—the indetermination existing at the terminals.

The apparatus used for the oblique loading tests is unique and quite simple in construction. Tests of the kind submitted should be appreciated by architectural and mill engineers who, of necessity, must load small columns with extreme eccentricities, as for example, the columns used to support the light crane runways of machine shops. The specimens tested in oblique loadings showed the irregular and discontinuous kind of failures expected in the case of batten-plate and lattice-bar constructions in some instances; in others, they showed the familiar reverse curves for elastic lines as described in various treatises.

Some discrepancy arises between the theoretical derivations and the actual results experienced when latticed columns are tested transversely. This shows one type of inefficiency, among the many others, which occurs in lattice-bar constructions. The method of using bubble levels commends itself in measuring the slopes of the elastic lines for columns in service that are tested in conformity with Manderla's analysis for secondary stresses. This method has been used in Germany to some extent and should be accorded a wider usage because it gives a direct measurement of the variation in curvature which is the cause of the strain usually determined by extensometers or strain-gauges.

The apparatus used for obtaining the stresses in lattice-bars, which are treated as small columns individually, appears to secure results that simulate in behavior (although in a magnified form) the type of strain which will actually take place in the column. It is easily constructed and applied to the ordinary testing-machine platens. Until engineers design a more efficient form

[60] Discussed by the late J. B. Johnson, M. Am. Soc. C. E., in the earlier editions of his book, "The Materials of Construction".

of transverse bracing than the lattice-bar type with its many anomalies and enigmas of deportment, it seems desirable to make as many investigations as possible, so that the material supplied for the purpose may be ample. If once a device is used, however unsatisfactory, it tends to persist by a kind of inertia and is very difficult to displace however conscious most engineers may be of the numerous defects, such as those in lattice construction.

The analyses submitted and the remarks pertaining to the integral behaviors of columns exposed to strain are usually of most interest to engineers. The question naturally arises, in the light of what has been reported by the Committee, as to what is the most approved form of column equation? Furthermore, does the formula actually check with the test results? Is the formula completely determinate and what details best realize integral behavior? The Committee is apparently inclined to the opinion that the well-known secant formula is the most useful and determinate when the necessary data are obtainable. This was shown quite clearly in the H-sections, the agreement between calculations and tests being all that could be expected, considering the numerous variables that are really under consideration.

A fair confirmation between theory and tests was found in the case of some large bridge columns of alloy steel reported by the U. S. Bureau of Standards.[61] When the results were interpreted according to methods suggested by Henry S. Prichard, M. Am. Soc. C. E., and Dr. O. H. Basquin, some very interesting agreements were found relative to predicted and actual results. The large columns tested followed the secant law until the pin-plates slipped or until the end plane of the column ceased to rotate about its peripheral edge of contact with the upper testing machine platen so that the joint closed. Then, because the eccentricity became practically constant, the stress was relatively constant. This phenomenon was occasioned by the difficulty of getting a uniform contact with the platen and would undoubtedly have disappeared if a roller bearing of the type used by the Committee had then been available. The reason that the stress-strain diagrams in such cases are slightly curved instead of being straight lines is because the assumed mathematical rotation about the outer edge is, in fact, a rocking which is probably caused by the line contact becoming blunted under the column pressure resulting in a slight changing of the eccentricity taking place under stress.

The secant column formula is, in the writer's opinion, the logical consummation of the Bernouilli-Euler or elastic line analysis as applied to compression members. When the equation is developed in the series form by expanding the secant expression, it shows, by a term-to-term comparison (neglecting appropriate terms of higher order), the degree of rationality that attaches to the various short formulas that have been suggested, namely, the short-column formula, the Johnson "straight-line" formula, the parabolic formula, and, as a limiting case, the well-known Euler expression for very slender columns. While the Rankine formula cannot be thus included it is an easy matter to

[61] *Technologic Paper No. 101*, U. S. Bureau of Standards.

show the type of discrepancy that occurs. The writer believes that if the secant formula were developed in elliptical or Weierstrass sigma functions as was once suggested by Dr. George R. Olshausen in correspondence at the time of tests of the large bridge columns previously mentioned, such an extension would represent the Bernouilli-Euler elastic line analysis to perfection. It would include all the other shorter formulas based on the elastic line analysis to the extent in which these short formulas are admissible as logical derivations according to the law of expressing the bending moment as a function of the curvature. It would serve as the norm of comparison for elastic line column analyses as fast as careful analyses were presented.

In its summary the Committee re-affirms the opinion, advanced from time to time in earlier papers, that the tensile elastic limits of test specimens give the criteria for determining the compression strengths for columns of moderate slenderness ratios. This rule was followed with satisfactory results by most of the consulting engineers, who observed the Bureau of Standards tests, in their estimates of the strengths. Not merely the elastic limits and yield stresses, but the maximum and ultimate stresses, are really conditioned by the rates of loading; therefore, the time factor should enter column analyses as a parameter. In making calculations of the stresses and strains in test pieces, the speed of the straining heads on the testing machine (from 0.05 in. to 12 in. per min.) should be taken into account. The strength of a column under test is likewise affected by the speed of the straining head. The apparent strength may be augmented by increasing the speed.

Items 19 and 20 of the Committee's "Summary of Results" call attention to the difficulties of securing integral action in the column and an appropriate distribution of stresses as the result of the presence of lattice-bars. As the bar systems shorten under pressure caused by pantograph action, they force the column ribs to deflect laterally, which is a behavior not contemplated in efficient design. To be sure the intermediate bars introduced by the late C. H. Cartlidge, M. Am. Soc. C. E., on the test columns for the Metropolis Bridge,[62] eliminated this entirely and did much to insure integral action. Nevertheless, there are compressions introduced in the lattice-bars, as mentioned by the Committee, together with unsatisfactory secondary stresses and alternating actions under stress, that cannot very well be avoided. Since the writer believes that lattice-bars appear to have more disadvantages than advantages, it is pertinent to ask why they should be retained in column construction. Mr. James E. Howard once showed[63] that, under normal conditions, they serve no function in taking stress.

It would seem to the writer that lattice-bars and their attendant evils may be easily omitted altogether: (1) By the use of transverse diaphragms or cross-braces spaced at intervals equal to about twice the depth of the member; and (2) by a suitable reinforcement of the rib flanges in the plane of the truss, not only to maintain a properly balanced section about the column centroid but also to carry any shear normal to this plane. On the side of the column where the lattice-bars are to be replaced there should be a trans-

[62] *Technologic Paper No. 101*, U. S. Bureau of Standards.
[63] *Transactions*, Am. Soc. C. E., Vol. LXXIII (1911), p. 492.

verse strut of the type used by Mr. Cartlidge[62] between lattice panels in maintaining the integral behavior of the column. Such transverse diaphragms and struts would effectively stiffen the column and reinforce it against the possibilities of twisting. It would insure unity of action in the manner evidently intended by the late Mr. Cartlidge, thoroughly holding the open face flanges in line. The construction would be freer of access for inspection and painting and the diaphragms could be made ample to carry any normal shear, such as that due to heavy wind pressure. There would be none of the anomalous behaviors that are now encountered in the case of lattice-bars. Extra longitudinal ribs or diaphragms could be added if desirable. While the diaphragms would introduce a greater efficiency of behavior, the writer believes the cost of construction would be less.

The two suggestions under the paragraph "Suggestions Relative to Future Work" are very pertinent. It is very important to insure a continuity of action within the steel as well as in the components and details. Since, on the large alloy-steel columns previously mentioned, all the pin plates slipped and there was evidence of considerable mechanical hysteresis, it might be well to consider the possibility of welding the pin plates and other component parts in addition to the riveting of columns. In the best class of work, the present riveting and reaming practice should be continued to insure continuity and unity of behavior. The costs and labor saved by the omission of lattice-bars, etc., could be applied to the extra expense incurred by electro-welding. Moreover, it is a maxim in the science of dynamics, first enunciated by Kelvin[64] and later re-affirmed by Lamb,[64] that the irrotational motion of a liquid, within a region having a single boundary, is accompanied by the storing of less energy consistent with the same normal motion of the boundary. The late George F. Swain, Past-President, Am. Soc. C. E., and Mr. Frank Cilley long ago stated[65] the closely analogous proposition that structures with the fewest statically indeterminate component parts are not only the most efficient carriers of stress, but that they are the most economical to construct. This fact is recognized in most conservative specifications.

The writer believes that the time has come when the elastic line analysis for bridge columns may be very favorably superseded by so-called "field methods". When structures are composed of members that are "trunk-line" carriers of stress, without a multiplicity of small statically indeterminate members, it is easy to determine the types of fields by means of the method much used and well illustrated by Bach.[66] He divided a number of his specimen faces into fields of small squares or rectangles which, by their distortions under strain, showed the types of strain occurring in the pieces. In like manner the faces of the column ribs and diaphragms may be similarly divided into small squares or rectangles. In fact, this was done to some extent on the alloy-steel columns tested by the U. S. Bureau of Standards, but the relative inelastic displacements under stress largely rendered the efforts in-

[65] *Massachusetts Institute Technology Quarterly*, Vol. 10, 1897, No. 2, p. 267.
[66] "Elasticität und Festigkeit."

operative, causing large sets and hysteresis. Love[67] proves the theorem that, when the surface displacements of the surface tractions are measurable, the problem is uniquely determinate.

The proposed method is one which readily adapts itself to the strain-gauge measurements used extensively by A. H. Fuller, H. C. Berry, George E. Beggs, Members, Am. Soc. C. E., and Professor H. L. Whittemore. The displacement functions, the components of which (measured in the direction of the coordinate axes, say, $x$, $y$, and $z$), are usually designated as $u$, $v$, and $w$, may be found by summing the respective elongations of the small squares, for example, of sides 8 or 10 in. long. The strains, expressed as the partial derivatives, $\frac{d\,u}{d\,x}$, $\frac{d\,v}{d\,y}$, and $\frac{d\,w}{d\,z}$, etc., are found by differentiating the surfaces: $u = u\,(x, y, z)$; $v = v\,(x, y, z)$; and $w = w\,(x, y, z)$. Having found the strains or displacements, it is a simple matter of differentiation to obtain the stresses expressed as functions of the position variables, $x$, $y$, and $z$, referred to a suitable origin on the column faces. Numerous examples of procedure are given by Love[67] and by Prescott[68] in a manner more suitable for the use of engineers. Attention is called to interesting plats of the surfaces obtained by similar methods herein proposed on a celluloid model of the Stevenson Creek Dam by Professor Beggs[69] and by W. A. Slater, M. Am. Soc. C. E.[70] and to the type of analysis to be used by H. M. Westergaard, M. Am. Soc. C. E., in his analyses of the same arch dam.[71]

The column analyses may be simplified if the stress equations are suggested by the secant type of formula, or by Manderla's extension of the elastic line theory as applied to trusses, the latter affording the cue to the class of functions desired. The writer has applied these methods with excellent results to complicated problems in earth resistance, in which large strains and hysteresis phenomena are present. The problems of the column are simplified by eliminating strain hysteresis in the manner already discussed. Moreover, one need only consider the first-order strains of the theory of elasticity in deriving the surfaces.[72] The addition of many small members will, of course, render such methods practically prohibitive by complication of the processes.

# SEWAGE WORKS OPERATION AND CONTROL

## FINAL REPORT OF THE COMMITTEE OF THE SANITARY ENGINEERING DIVISION[1]

This Committee was appointed in 1926 by the Executive Committee of the Sanitary Engineering Division, to deal with the underlying principles the adoption of which seem to insure the satisfactory operation and control of sewage works. A brief progress report was made by the Committee and presented to the Division at the Annual Meeting of the Society on January 19, 1928.[2] Since that time the Committee has been studying such questions as the best manner of obtaining funds to operate sewage works, the qualifications and adequate compensation of the personnel employed in such works, the establishment of schools for sewage works operators, the question of control analyses at sewage works, etc.

The Final Report of the Committee was presented to the Executive Committee of the Sanitary Engineering Division on April 9, 1929. After thorough discussion, it was adopted by the Division at its meeting in Cleveland, Ohio, on July 10, 1930. In the light of this action and after further review, the report is herewith presented in its final form.

C. E. KEEFER, *Chairman*,

*Committee.*

June 17, 1931.

### THE OPERATION AND CONTROL OF SEWAGE WORKS

The art of designing and constructing sewage works has advanced to the stage where municipal sewage can be treated adequately in order to produce an effluent of any reasonable degree of purity. The operation of such works, however, has not kept pace with the advances made in their

[1] Presented at the meeting of the Sanitary Engineering Division, Cleveland, Ohio, July 10, 1930.

[2] *Proceedings*, Am. Soc. C. E., March, 1928, Society Affairs, p. 153.

design. A survey of these works has indicated that many of them are poorly operated, with the result that the welfare and health of many communities are imperiled. The outstanding reasons for the unsatisfactory operation of sewage treatment plants are the lack of sufficient operating funds and the need of well-trained and efficient personnel. The purpose of this report is to outline the underlying principles which it seems necessary to follow to insure the satisfactory operation of sewage works.

## State Supervision of Sewage Works

Each State department of health or other similar State board through adequate legal statutes should have approval of the design and control of operation of the sewage works in its own State. The State board should also have sufficient appropriations and adequate personnel to keep in touch with all sewage treatment works in the State. In case a sewage plant is not operated and maintained in a satisfactory manner the board should have the legal right to require the owner to employ a competent person or persons to operate the plant and make such repairs and improvements as may be necessary. The necessary legislation to accomplish this purpose is typified by the Ohio law given in Appendix I. Where adequate laws do not exist, legislation should be passed conferring such powers upon the State board of health.

## Financing Sewage Works Operation

One of the most important matters affecting the successful operation of sewage works relates to the securing of sufficient funds for this purpose. Most sewage works owned and operated by municipalities, or other political sub-divisions, are financed out of the general tax levies. It is frequently the aim of those public officials who decide the amount of money to be appropriated for annual operating budgets to keep the tax rate as low as possible. The result is that funds for the efficient operation of sewage plants are generally inadequate. Such have been the findings from a survey made by the Committee. In order to correct such a condition attempts have been made to find some other practicable method of financing sewage works operation.

The Legislature of the State of Ohio has passed a law (see Appendix II) which permits the council of any city or village in that State to establish by ordinance equitable rates or charges for sewerage service. It is provided in the Ohio law that these rates are to be paid only by those persons who are served by the sewerage system. In Ohio a number of the smaller cities, including Delaware, Oxford, and Salem, and the large city of Dayton, have passed the necessary ordinances as a result of this law. The ordinances providing for sewer rentals for Delaware, Dayton, and Oxford, are given in Appendix III.

The Committee believes that as far as practicable the maintenance and operation of all sewage works as well as the tributary sewerage systems should be financed by funds collected from the persons or property owners

who are benefited. These funds should be levied in the form of rents, payable at stated intervals, and should be used only for the maintenance and operation of the sewage works and the sewerage system. The financing of the cost of construction of sewerage works should be borne by the entire communities benefited.

### Qualifications for Sewage Works Superintendents

The operation of sewage works should be in the hands of competent men. The number of the personnel and their training depends upon the size and the type of the treatment plant. The responsibility for the satisfactory operation of the plant rests largely with the superintendent. For that reason he should have the necessary training and experience to qualify him properly for the responsibilities of his position.

The qualifications for superintendents of sewage works of different types and sizes have been classified roughly, as follows:

A Grade A Superintendent should be a graduate of an engineering or technical school of recognized standing, and should have had experience for not less than five years in problems relating to sewage treatment. He should also be able to supervise and direct the work of others.

A Grade B Superintendent should be at least a high school graduate with additional training in chemistry and engineering, and should have had experience for not less than five years in problems relating to sewage treatment. He should be able to supervise and direct the work of others.

A Grade C Superintendent should have had at least an elementary school education with the training equivalent to that of a skilled mechanic or skilled laborer. He should be able to supervise and direct the work of others.

*Grades of Superintendents Required.*—All sewage treatment plants should be operated under technical control or supervision.

In the case of large plants, serving approximately 100 000 or more people and involving such treatment as by Imhoff tanks, sedimentation and separate sludge digestion, trickling filters, or the activated sludge process, Grade A Superintendents should be employed.

For moderate-sized plants, serving from approximately 50 000 to 100 000 people, Grade B Superintendents may be satisfactory; but for the more complicated plants it is desirable to have the operation supervised by a sanitary engineer or chemist who has the qualifications of a Grade A Superintendent.

In the case of less complicated plants, such as fine screening, serving less than about 50 000 persons, Grade C Superintendents may be satisfactory, provided there is adequate supervision by a sanitary engineer or chemist with the qualifications of a Grade B or a Grade A Superintendent. For small plants of a complicated type, or for dealing with difficult conditions, a Grade B or Grade A Superintendent may be required.

*Compensation for Sewage Works Superintendents.*—In order to attract and secure properly qualified men to act as superintendents their compensation should be commensurate with their responsibilities. The Committee suggests

the following relative salaries, based on common labor receiving a wage equivalent to 1.0:

| | |
|---|---|
| Grade C Superintendent | 1.0 to 2.0 |
| Grade B Superintendent | 2.0 to 3.0 |
| Grade A Superintendent | 3.0 to 5.0 |

This method of rating has been adopted because the scale of wages is not uniform in all places, and varies from time to time in the same locality.

The practice followed by some communities of having a competent sanitary engineer to advise the officials regarding problems of sewage works operation is a good one. This plan is especially desirable for a period immediately following the opening of a new sewage works. Where a community cannot afford to pay for the services of a full-time technically trained superintendent, it may be possible to unite with near-by communities in employing an experienced chemist or sanitary engineer for the supervision of operation, or it may be possible for a small municipality to secure the part-time services of a technically trained superintendent of some large sewage plant to supervise the operation.

### Schools for Sewage Works Operators

Many of the operators and other assistants at sewage works, particularly at the small plants, lack the basic training which is necessary to understand the fundamentals of sewage treatment and to supervise and operate in a satisfactory manner the plants they control. A number of State departments of health are awake to this condition, and as a corrective measure there have been established in some States short-time schools, where instruction in the general principles of sewage treatment is given.

The need for this type of training is so great that additional schools should be provided. It would be desirable to have at least one school for each State, except where the number of sewage works is small, in which case it may be feasible to organize one school for two or more adjacent States. The various factors involved in conducting these schools will depend upon local conditions. The most important points to consider are the organizing and financing of the school, the character of instruction to be given, and the paying of the students' expenses.

State departments of health and sewage works associations are the logical organizations to establish and promote schools for sewage works operators. Where there is a suitable State educational institution conducting extension work, this is the most desirable place to conduct the school. As such institutions are financed by public funds only nominal fees would be charged. Students would thus have no great difficulty in paying for their instruction.

The general purpose of the course should be to train students in the fundamentals of sewage treatment and in making laboratory tests. The instruction should include lectures, laboratory work, and inspection trips. The lectures should deal with elementary sewage plant design, and the fundamentals of hydraulics, chemistry, and bacteriology. The scope of the laboratory work should vary with the length of the course and the previous

training of the student. The most elementary course should include the keeping of records, the collection of samples, the measuring of settleable solids with Imhoff cones, the relative stability test, the determination of the pH of sewage and sludge, and the operation of chlorine apparatus. These studies may be supplemented, if time is available, or if an advanced course is given, by practice in the use of the chemical balance, the determination of suspended solids, dissolved oxygen, bio-chemical oxygen demand, and the numbers of bacteria and *B. coli*. The length of the course would have to be limited to a short period—preferably not less than one week. A two-week session would possibly be the maximum length of time that could be devoted to this work.

The method of financing the students' tuition and expenses will depend upon local conditions. In those municipalities where the officials are convinced of the importance of such schools it is possible that the major part, or perhaps all, of the expense will be borne by the municipality. Legal limitations governing the expenditure of municipal funds may be a controlling factor. In any event, the training received by the operator should increase his capabilities and add to the value of his services. The Committee recommends that the necessary expenses of sewage works operators for attending schools or conferences be paid by the municipalities.

## Sewage Works Associations

Membership in sewage works associations affords another means of acquiring valuable knowledge relative to the operation of sewage treatment plants. Several of these associations have been formed in a number of States or groups of States. These associations usually meet at least once a year for a two or three-day convention when papers are presented, practical problems are discussed, and inspections are made of plants of interest.

A Federation of Sewage Works Associations has been formed, which publishes a *Sewage Works Journal*. This publication affords the sewage works operator an additional opportunity of familiarizing himself with problems relating to sewage treatment.

Some State departments of health are responsible for calling conferences of sewage works operators for the purpose of promoting an exchange of ideas regarding sewage treatment problems and for improvement in economy and efficiency of the operation of sewage works within the State.

## Analytical Determinations and Tests Required at Sewage Works

There are three main objects of making analyses and tests at sewage treatment works: (1) For control of operation; (2) for record of accomplishment; and (3) for research investigations.

The number and kind of analytical determinations and tests to be made will vary with the size and type of works. For small plants the routine tests may be confined to those required for the control of operation. For larger plants, especially where litigation may ensue, it is important to do more laboratory work than is required for the control of operation alone. Data

should be obtained, not only for studying the efficiency of the plant, but also for comparison with similar data from other plants. At large sewage works, particularly where there are problems involving improvements or enlargements to the plant, or the recovery of by-products, research work should be carried on.

Research in the treatment of sewage and industrial wastes is greatly needed, not only to promote economy and efficiency of treatment, but also to determine ways of recovering valuable by-products. The analytical determinations and tests involved in research investigations are too varied to designate in this report, but will depend upon the problem being studied.

The analytical determinations and tests required for the control of operation and for a record of accomplishment may be classified according to the treatment provided. It is impracticable in this report to cover all kinds of sewage treatment, but some of the more widely used methods will serve for illustrative purposes.

*Sewage Flow and Population Served.*—It is very important that a continuous record of the sewage flow be kept. Where Venturi meters have not been installed, the use of weirs, or some other means, should be resorted to, in order to determine the sewage flow. The quantity and time of by-passing sewage around all or any part of the sewage works, should be noted. During storms, the volume of storm-water, which does not receive treatment, should be recorded. Where an appreciable quantity of industrial wastes is treated, the volume, character, and equivalent population load should be determined.

*Screening.*—For the control of the operation of screens, the quantity of sewage screened and the volume of screenings obtained should be determined. The time that the screens are in service, the work required on them, and their power consumption should be noted.

For a record of accomplishment the screenings, where possible, should be weighed, and the water content determined. The amount of solids removed from the sewage can then be computed. The efficiency of screening in removing suspended solids is accurately determined by adding to the weight of suspended solids determined in the screen effluent the weight of dry solids in the screenings from a corresponding volume of sewage, and computing the percentage of solids removed by the screens. By determining the loss on ignition of the suspended solids in the effluent and of the solids in the screenings, the percentage removal of organic matter can be estimated in a similar manner.

*Sedimentation.*—A minimum requirement for the control of treatment by sedimentation should be the conical measuring glass test for the volume of settleable solids in the influent and effluent. The quantity of sewage and the volume of accumulated sludge are also important factors in the control of the treatment.

For a record of accomplishment the removal of suspended solids, by weight, should be ascertained by gravimetric determination of suspended solids in the influent and in the effluent. It is also important to determine the removal of organic matter. This may be done by determining the organic nitrogen or albuminoid nitrogen and oxygen consumed in the influent and the

effluent. The reduction in bio-chemical oxygen demand has come to be considered an important index of the purification accomplished. Tests for dissolved oxygen in the influent and the effluent should be made with sufficient frequency to show whether the sewage has become septic.

*Trickling Filter Treatment.*—Relative stability tests of the effluent are desirable for the control of operation of trickling filters. The volumetric determination of settleable solids in the sewage applied and in the effluent is an index of the extent of the storage or unloading of solids in the filters. The volume of sewage treated by the filters and the condition of the filters with respect to clogging are also important factors in the control of operation.

For a record of accomplishment the reduction in organic matter can be ascertained by determining the organic nitrogen or albuminoid nitrogen and oxygen consumed, or of bio-chemical oxygen demand in the influent and in the effluent. The extent of oxidation is further shown by reduction in free ammonia nitrogen and increase in nitrogen as nitrites and nitrates.

Where trickling filter effluents are passed through sedimentation tanks, the same determinations should be made of the tank effluent as have been recommended for the filter effluent. The suspended solids in the trickling filter effluent and the tank effluent should be determined gravimetrically. The dissolved oxygen in the effluent before and after sedimentation will indicate, not only the degree of oxidation, but also the effect of the sludge in the sedimentation tank.

*Activated Sludge Treatment.*—For the control of activated sludge treatment, the flow of sewage, the proportion of activated sludge returned to the sewage, the volume of air applied, and the amount of power used, are important factors. The proportion of activated sludge present can be determined by sedimentation tests or more quickly by the centrifuge. A knowledge of the amount of solids in the sludge by weight is also important in the control of treatment. Tests for turbidity, suspended matter, and relative stability should be made on the effluent after sedimentation. The sludge level in the sedimentation tanks should be kept under control by measuring the depth of sludge in the tanks and by observing the character of the sludge withdrawn.

For a record of accomplishment, in addition to these tests, determinations of total nitrogen or albuminoid nitrogen and oxygen consumed, or of bio-chemical oxygen demand, should be made on the sewage and the effluent. The extent of oxidation is indicated by determinations of free ammonia nitrogen and nitrogen as nitrates, and dissolved oxygen in the effluent.

*Disinfection.*—Tests for the control of disinfection should be made for residual chlorine after an adequate period of contact. For a record of accomplishment bacteria counts and *B. coli* tests should be made before and after disinfection. In some cases, it will be desirable to determine the reduction in bio-chemical oxygen demand accomplished by disinfection. The quantity of chlorine applied should be noted. For reasons of economy it may be desirable to vary the dosage of chlorine to correspond with the chlorine demand of the sewage.

*Sludge Digestion.*—For the control of sludge digestion the appearance and odor of the sludge and the reaction, or pH index, during digestion are important. Temperature is also important especially where control is exercised over it. For a record of accomplishment the total solids and organic matter by loss on ignition should be determined of the raw and the digested sludge in order to ascertain the proper volume to withdraw. Where gas is collected, it is desirable to obtain its volume and composition. A record should be kept of the volume and character of the sludge liquor discharged from separate sludge digestion tanks.

*Dewatering of Sludge on Sludge Beds.*—When sludge is dewatered on sludge beds, the volume of sludge applied, depth of application, time of drying, number of applications per year, weather conditions, and volume of dewatered sludge should be determined. Records of sludge-bed operation should include the percentage of solids in the sludge as applied and as removed.

*Mechanical Dewatering of Sludge.*—Where sludge is dewatered by mechanical means, it is important to make tests of sludge density, or solid content, and reaction, or pH value, checked by rate-of-filtration tests in connection with the conditioning of the sludge for dewatering. The rate of dewatering by filtration of the sludge and the yield of cake are important. Determinations of the water and the solids in the dewatered sludge should also be made.

When sludge is dried and prepared for fertilizer, the determination of its mechanical composition, percentage of moisture, and of the total and available nitrogen and other fertilizing constituents, is important.

*Treatment of Sewage Containing Industrial Wastes.*—Where industrial wastes or sewage containing abnormal quantities of industrial wastes are treated, analytical determinations and tests, in addition to those previously mentioned, may be required such as color, fats, alkalinity or acidity, iron, copper, lead, zinc, aluminum, calcium, magnesium, sulfates, and sulfides, depending on the kinds of industrial wastes present.

*Effect of Discharge of Sewage or Effluent on the Receiving Waters.*—In many cases, especially where there is a possibility of litigation, tests should be made to determine the effect of the discharge of sewage or sewage effluent at different points on the receiving waters. These tests should ordinarily include color, suspended solids, dissolved oxygen, and relative stability or biochemical oxygen demand. The presence of sludge banks should be noted. Periodic determinations of the number and kinds of plankton in the receiving waters may be desirable. In cases where the receiving waters are used for water supply, bathing, or shell fish culture, bacteria counts and *B. coli* tests should be made. The time, extent, and frequency of such tests will depend upon local conditions. In certain instances, particularly in tidal waters and lakes, studies should be made of the currents where sewage effluents are discharged. A knowledge is desirable of the dilution afforded by the receiving waters, particularly during the summer when temperatures are high and stream flows are at a minimum.

*Importance of Sampling.*—For comparative and analytical determinations and tests it is of the utmost importance that the samples be truly representative. In order to obtain representative composite samples individual samples should be taken at frequent intervals and in proportion to the sewage flow. Determinations of chlorine in the form of chlorides are of assistance in indicating to what extent samples are comparable.

*Laboratories.*—In order to perform the necessary analytical determinations and tests, it is essential that suitably equipped laboratories should be provided. The larger plants will require complete equipment for making analytical determinations and tests needed for research investigations, as well as for a record of accomplishment. In the case of small plants, it may be sufficient to provide equipment only for the tests required to control the operation. Where local laboratories are not available, control samples should be collected at regular intervals and analyzed by the technical supervisor.

*Influence of Local Conditions.*—It is impossible to stipulate just what analytical determinations and tests should be made at every sewage treatment plant. Local conditions will often govern. The analytical determinations and tests suggested in this report may be considered generally applicable. Other determinations and tests will be required in special cases. In all instances it is desirable to record the temperatures of the sewage, effluents, and sludges, in order to compare the results in different localities. Sufficiently complete analyses of the sewage should be made to determine its general character and composition.

It is unnecessary in this report to describe the methods of analysis which should be used. Technically trained men, having the control or supervision of the treatment plants, will know the methods of analysis and how to interpret the results.

## Operation and Maintenance Cost Data

In addition to complete records of operating and analytical data, operation and maintenance costs should be kept at sewage treatment works. These costs should be segregated into labor and materials. Moreover, it is desirable to keep operation and maintenance costs separate, with a further record of the cost of all new additions or improvements. Should any money be collected from the sale of screenings, sludge, or other materials, the amounts should be recorded. At the large plants it is desirable to make a further segregation by keeping separate accounts of the cost of screening, sedimentation, sludge treatment, etc. A record should be made of the sewage flow and the population served so that costs of treatment per unit volume of sewage and per capita can be calculated.

As improvements are made to the works from time to time and as old units are abandoned, the cost of these should be added to or deducted from the first cost of the plant so that the fixed cost, comprising the interest on the investment and depreciation can be determined.

### Reports Covering Sewage Works Operation

In spite of the large number of sewage works of considerable size in the United States, the number of these is remarkably small, at which printed reports giving operating data are prepared. These reports are of much interest and value to all those engaged in the design, construction, or operation of sewage works. It is mutually helpful for sewage works superintendents to exchange reports. It is, therefore, highly desirable that printed reports be prepared, preferably annually, giving the operating and cost data of sewage treatment works, particularly in the case of works of any magnitude. The yearly budget, which provides for the cost of operation, should include an item covering the printing of an annual report. It is also very desirable that articles relating to sewage works operation be published in engineering magazines or journals.

## APPENDIX I

### Ohio State Department of Health Law[3]

Sec. 1255. (Order for improvement of water purification or sewage treatment works.) When the commissioner of health finds upon investigation, that any water purification or sewage treatment works, on account of incompetent supervision or inefficient operation is not producing an effluent of such quality as might be reasonably obtained from such water purification or sewage treatment works, and by reason of such neglect the public water supply has become impure and dangerous to health, or that a stream, water-course, canal, lake, pond or body of water has become offensively polluted or has become a public nuisance or that a public water supply taken from such stream, water-course, canal, lake, pond or body of water has been rendered impure and dangerous to health, the commissioner of health shall issue an order to the mayor or managing officer or officers of the city, village, public institution, or corporation, partnership or person having charge of or owning such water purification or sewage treatment works, to secure an effluent of such quality as might be reasonably expected from such works and satisfactory to the commissioner of health. (108 Pt. I, 297.)

Sec. 1256. (Order to appoint and pay competent person; approval by commissioner.) If the managing officer or officers of such city, village, public institutions or corporation, partnership or person fails, for a period of five days after receiving such order, to secure an effluent satisfactory to the commissioner of health, the commissioner of health shall report the fact to the public health council and upon its approval may order such managing officer or officers or person owning such works to appoint within ten days, and pay the salary of a competent person to be approved by the commissioner of health, to take charge of and operate such works as to secure the results demanded by the commissioner of health. (108 Pt. I, 297.)

[3] The Ohio law has been sustained on several occasions by the Supreme Court of Ohio.

Sec. 1257. (Right of appeal; procedure.) If the findings or order of the commissioner of health, when approved by the public health council and made in pursuance of the provisions of this chapter relating to stream pollution and public water supply, are not acceptable to any city, village, public institution, corporation or owner affected thereby, such city, village, public institution, corporation or owner shall have the right of appeal as follows: Two reputable and experienced sanitary engineers shall be chosen, one by the city, village, public institution, corporation or owner and the other by the commissioner of health, who shall not be a regular employee of the State department of health. Such persons shall act as referees. If the referees so chosen are unable to agree, they shall choose a third engineer of like standing and the vote of the majority shall be final. As soon as such referees are chosen, the commissioners (commissioner) of health shall file with them a certified copy of the complaint and the findings, and order of the State department of health, and it shall be the duty of such referees to investigate the conditions complained of and to determine if such findings are correct and if the order provides a proper remedy for such conditions. The appeal provided for in this section shall be made within thirty days from the date of service of the order upon the mayor or managing officer or officers of the city, village, public institution or corporation or owner, and notice thereof in writing, shall be served upon the commissioner of health by personal service for which there shall be acknowledgment, or sent by registered letter.

Sec. 1258. (Powers of referees; fees and expenses, how paid.) Such referees may affirm or reject the findings or order of the commissioner of health or may modify such order as to the time within which improvements or changes shall be made, and their decision, which must be in writing and be made within a reasonable time, shall be reported to the commissioner of health and to the city, village, public institution, corporation or owner and shall be final except as hereinafter provided. If said findings and order shall be approved or modified by said referees, the order shall be enforced by the commissioner of health in the manner provided for in this chapter. The fees and expenses of the referee appointed by the commissioner of health shall be paid from funds appropriated to the State department of health for such purpose. The fees and expenses of the referee appointed by the city, village, public institution, corporation or owner shall be paid by the city, village, public institution, corporation or owner making such appeal. The fees and expenses of the third referee shall be equally divided between the State department of health and the city, village, public institution, corporation or owner making appeal. (108 Pt. I, 297.)

Sec. 1258-2. (Vacating or modifying order.) An order as made by the commissioner of health or as approved or modified by the referees as herein provided, shall be reversed, vacated or modified by the Supreme Court on a petition of error, if upon consideration of the record such Court is of the opinion that such order was unlawful and unreasonable. (108 Pt. I, 297.)

Sec. 1258-6. (Supreme Court only has power to suspend order.) No Court other than the Supreme Court shall have the power to review, suspend or delay any order of the commissioner of health, or enjoin, restrain or interfere with the commissioner of health or public health council in the performance of official duties required or power exercised under the provisions of this act. (108 Pt. I, 297.)

Sec. 1260. (Forfeiture for failure to obey orders.) If a council, department or officer of a municipality, or person, partnership or private corporation fails or refuses for a period of thirty days, after notice given him or them by the commissioner of health of his findings and order, and the approval thereof by the public health council, to perform any act or acts required of him or them by this chapter relating to stream pollution and public water supply, the members of such council or department, or such officer or officers, person, partnership or private corporation shall be personally liable for such default, and shall forfeit and pay to the State of Ohio five hundred dollars to be paid into the State treasury to the credit of the general revenue fund. (108 Pt. I, 297.)

Sec. 1261. (Action for recovery.) An action may be begun for the recovery of such penalty by the prosecuting attorney of a county in the name of the State in the Court of Common Pleas of such county having jurisdiction of any such party or parties, or it may be begun by the attorney general in such county or the County of Franklin, as provided by law. The Court of Common Pleas, upon good cause shown, may, at its discretion, remit such penalty or any part thereof. (108 Pt. I, 297.)

## APPENDIX II

### Ohio Sewer Rental Law[4]

Council may by ordinances establish rates or charges of rent to be paid city or village.

Section 3891-1. The council of any city or village which has installed or is installing sewerage, a system of sewerage, sewage pumping works, or sewage treatment or disposal works for public use, may by ordinance establish just and equitable rates or charges of rents to be paid to such city or village for the use of such sewerage, a system of sewerage, sewage pumping works or sewage treatment or disposal works by every person, firm or corporation whose premises are served by a connection to such sewerage, system of sewerage, sewage pumping works or sewage treatment or disposal works. Such charges shall constitute a lien upon the property served by such connection and if not paid when due shall be collected in the same manner as other city and village taxes. The council may change such rates or charges from time to time as may be deemed advisable. Provided, however, that in a municipality operating under a muni-

[4] Passed April 5, 1923.

cipal charter the council or other legislative body may establish the schedule of rates herein authorized and provide for its administration by designating the department or officer of the municipality to be charged with the enforcement of the provisions of this act.

Director of public service, general duties.

Section 3891-2. In a city the director of public service shall manage, conduct and control the sewerage system and sewage pumping, treatment and disposal works, and when the council has established a schedule of rates or charges of rents for their use shall collect sewer rentals, and he shall appoint the necessary officers and agents for such purposes.

Board of trustees of public affairs shall manage and control sewerage system, etc.

Section 3891-3. When the council of a village has established a schedule of rates or charges of rents for the use of the sewerage system and sewerage pumping, treatment and disposal works, the board of trustees of public affairs shall manage, conduct and control such sewerage system and sewage pumping, treatment and disposal works and shall collect sewer rentals and shall appoint necessary officers and agents for such purposes; and shall assume all duties, in relation to sewers, imposed upon the street commissioner by Section 4364 of the General Code, whereupon the street commissioner shall be relieved of such duties.

By-laws and regulations.

Section 3891-4. The director of public service and the board of trustees of public affairs may make such by-laws and regulations as may be deemed necessary for the safe, economical and efficient management and protection of the sewerage system and sewage pumping, treatment and disposal works; and for the construction and use of house sewers and connections to the sewerage system. Such by-laws and regulations shall have the same force and effect as ordinances when not repugnant thereto or to the constitution or laws of the State.

Reception and distribution of funds derived from sewer rentals.

Section 3891-5. The funds received from the collection of sewer rentals shall be deposited weekly with the treasurer of the corporation. Money so deposited shall be kept as a separate and distinct fund and shall be known as the sewer fund. When appropriated by council, it shall be subject to the order of the director of public service of a city or board of trustees of public affairs of a village. Such director or board shall sign all orders drawn on the treasurer of the corporation against such fund. This fund shall be used for the payment of the cost of the management, maintenance, operation and repair of the sewerage system and sewage pumping, treatment and disposal works and any surplus in such fund may be used for the enlargement or replacement of the same and for the payment of the interest on any debt incurred for the construction of such sewerage system and sewage pumping, treatment and disposal works, and

for the creation of a sinking fund for the payment of such debt, but shall not be used for the extension of a sewerage system to serve unsewered areas or for any other purpose whatsoever.

Section 3891-6. That Section 4357 of the General Code shall be amended to read as follows:

When board shall be established.

Section 4357. In each village in which water works, an electric light plant, artificial or natural gas plant, or other similar public utility is situated, or when council orders water works, an electric light plant, natural or artificial gas plant, or other similar public utility, to be constructed, or to be leased or purchased from any individual, company or corporation, or when the council shall have determined to establish a schedule of rates or charges of rents for use of the sewerage system and sewage pumping, treatment and disposal works of the village, council shall establish at such time a board of trustees of public affairs for the village, which shall consist of three members, residents of the village, who shall be each elected for a term of two years.

## APPENDIX III

### Sewer Rental Ordinance No. 1125, Delaware, Ohio[5]

To Provide Funds for the Maintenance, Operation and Control of the Sewerage System and Sewage Treatment Works of the City of Delaware, Ohio:

Whereas, The City of Delaware, Ohio has installed a Sewerage System and Sewage Treatment Works, and

Whereas, It is necessary for the preservation of the public health and for compliance with orders of the State Department of Health, that the said sewerage system and sewage treatment works be properly maintained, operated and controlled, and

Whereas, Funds for the maintenance, operation and control of said sewerage system and sewage treatment works will not be available from the current operating revenue of the City, and

Whereas, The General Assembly of the State of Ohio has enacted a law, amending Section 4357 of the General Code, to permit municipalities to assess and collect for the use of sewers, said charges to provide for the proper maintenance, operation and control of sewerage systems and sewage treatment or disposal works,

Now, Therefore, Be it Ordained by the Council of the City of Delaware, State of Ohio:

[5] Estimated 1929 population about 9 000 for city, and 2 500 for Ohio Wesleyan University. Passed August 1, 1927.

Section 1. That the Director of Public Service be and he is hereby authorized and directed to manage and control the sewerage system and sewage treatment works in a safe, economical and efficient manner.

Section 2. That the Director of Public Service be and he is hereby authorized and directed to make such by-laws and regulations as may be deemed necessary for the safe, economical and efficient management and protection of the sewerage system and sewage treatment works, and for the construction and use of house sewers and connections to the sewerage system; that such by-laws and regulations shall have the same force and effect as ordinances when not repugnant thereto nor to the constitution or laws of the State of Ohio.

Section 3. That the terms and conditions upon which the owners of lots and lands within the corporate limits of the City of Delaware, may connect to the sewerage system either directly or indirectly, shall be as follows:

Article 1. Charges shall be paid at the office of the Director of Public Service, and for each calendar year or part thereof they shall be in accordance with the following schedule of rates:

Dwellings and Apartments:

One-Family (one connection), $4.00 per annum.
Two-Family (one connection), $7.50 per annum.
Two-Family (two connections), $8.00 per annum.
Four-Family (two connections), $15.00 per annum.
Others (for each family), $4.00 per annum.
For each additional family on the same connection, $3.75 per annum.

Hotels:

For each room with bath, $1.75 per annum.
For each room without bath, $1.00 per annum.

Rooming Houses and Fraternities:

Four Dollars ($4.00) per annum plus One Dollar ($1.00) per annum for each person renting a room therein.

Stores, Restaurants, Offices and Mercantile Establishments:

Private toilets, each $4.00 per annum.
Public toilets, each $8.00 per annum.
Kitchen sinks, each $4.00 per annum.
Slop sinks, each $2.00 per annum.

Factories and Shops:

For each and every person employed or engaged in service on the premises, in accordance with the following schedule:

Ten persons or less, each $1.00 per annum.
More than 10 and not over 25, 90 cents per annum.
More than 25 and not over 50, 80 cents per annum.
More than 50 and not over 100, 70 cents per annum.
All over 100, 60 cents per annum.

Churches.

For each toilet, $2.00 per annum.

Colleges:

All college buildings and dormitories not subject to taxation shall be grouped and the sewer rental fixed on per capita student population:

For each registered student, 75 cents per annum.

Hospitals and Sanitariums:

Delaware Spring Sanitarium, $100.00 per annum.
Jane M. Case Hospital, $60.00 per annum.

Miscellaneous:

For special cases which are not clearly defined in the above schedule, rates shall be established by Council upon the recommendation of the Director of Public Service.

Article 2. Charges shall become due and payable in advance on the first day of January, April, July and October. All bills not paid by the fifteenth of the month in which same becomes due shall be subject to a 10 per cent. penalty.

Article 3. Charges shall constitute a lien upon the property served by such connections, and if not paid within ninety days, shall be collected in the same manner as other city taxes.

Article 4. Charges for discharging industrial wastes into the sewerage system shall be fixed by the Director of Public Service and approved by Council.

Section 4. That the funds received from the use of sewers shall be deposited with the Treasurer of the City, and money so deposited shall be kept in a separate and distinct fund and shall be known as the Sewer Rental Fund. When appropriated by Council it shall be subject to the order of the Director of Public Service and said Director shall sign all orders drawn on the Treasurer of the City against said fund.

Section 5. Funds received from the use of sewers shall be used for the payment of the costs and expenses of the management, maintenance, operation and repair of the sewerage system and sewage treatment works and any surplus in such fund shall be used for the enlargement or replacement of the same or for the payment of the interest on any debt incurred for the construction of such sewerage system and sewage treatment works, or for the creation of a sinking fund for the payment of such debt, but shall not be used for the extension of the sewerage system to serve unsewered areas nor for any purpose whatsoever.

Section 6. That this ordinance constitute a part of an emergency measure and shall take effect and be in force from and after its passage.

### Sewer Rental Ordinance No. 13448, Dayton, Ohio[6]

Whereas, The City of Dayton has built and has in operation a sanitary sewerage system for the purpose of collecting sanitary sewage and conveying the same away from the premises where produced to a place of disposal, and is constructing intercepting sewers, pumping stations, force mains and a disposal works for the treatment of such sewage; and

[6] Estimated 1929 population about 180 000. Passed by the Commission, December 28, 1927.

WHEREAS, The City Commissioner finds, in order to promote the public health, safety, welfare and convenience, that a system of sanitary sewerage, including intercepting sewers, and force mains, sewage pumping works and a sewage treatment works, are necessary, and that in order to pay the cost of the management, maintenance, operation and repair, or for the enlargement and replacement of the sanitary sewerage system and the sewage pumping, treatment and disposal works and to pay the interest upon the bonds issued and outstanding and to be issued to provide funds for the construction thereof and to retire said bonds as they mature, it is necessary to levy and collect a charge of rental upon the lots, lands and premises served by sewerage connection with the sanitary sewer system of said City; therefore,

BE IT ORDAINED by the Commission of the City of Dayton:

Section 1. It is hereby determined and declared to be necessary and conducive to the protection of the public health, safety, welfare and convenience of the City of Dayton, Ohio, to levy and collect charges or rentals upon all lots, lands and premises served by having connections with the sanitary sewerage system and by the sewage, pumping, treatment and disposal works of said city, the proceeds of such charges or rentals so derived to be for the use of the sanitary sewerage system and the pumping, treatment and disposal works of said city, as hereinafter provided.

Section 2. For the purposes of this ordinance the terms, "Sanitary Sewage" and "Industrial Wastes", are defined as follows:

(a) "Sanitary Sewage" is hereby defined as the waste from water closets, urinals, lavatories, sinks, bath tubs, showers, household laundries, cellar floor drains, garage floor drains, bars, soda fountains, cuspidors, refrigerator drips, drinking fountains and stable floor drains.

(b) "Industrial Wastes" are hereby defined as being the liquid waste resulting from any commercial, manufacturing or industrial operations or processes.

Section 3. For the purposes as provided in Section 1 and 8 hereof there is hereby levied and assessed upon each lot, parcel of land, building or premises having any sewer connection with the sanitary sewerage system of said city or otherwise discharging sewerage, industrial wastes, water or other liquids, either directly or indirectly into the City sanitary sewerage system, a sewerage service charge or rental payable as hereinafter provided, and in amount determinable as follows:

(a) For any lot, parcel of land, building or premises, situated within the corporate limits of the City of Dayton, Ohio, and having any connection with the city sanitary sewerage system or otherwise discharging sanitary sewerage, industrial wastes, water or other liquids, either directly or indirectly, into the City sanitary sewerage system, said charge or rental shall be based upon the quantity of water used thereon or therein as the same is measured by the City water meter there in use, and there shall be charged for the first 3 000 cubic feet of water, or part thereof, so used per quarter year, the sum of One Dollar ($1.00); for each thousand cubic feet of water used in excess of 3 000 cubic feet and not exceeding 10 000 cubic feet, per quarter year, at the rate of Thirty Cents (30¢) per 1 000 cubic feet; for each thousand cubic feet of water in excess of 10 000 cubic feet and not in excess of 20 000

cubic feet, per quarter year, at the rate of Twenty-five Cents (25¢) per 1 000 cubic feet; for each thousand cubic feet of water in excess of 20 000 cubic feet and not in excess of 100 000 cubic feet, per quarter year, at the rate of Twenty Cents (20¢) per 1 000 cubic feet; for each thousand cubic feet in excess of 100 000 cubic feet and not in excess of 500 000 cubic feet per quarter, at the rate of Fifteen Cents (15¢) per one thousand cubic feet; for each thousand cubic feet in excess of 500 000 cubic feet per quarter at the rate of Ten Cents (10¢) per 1 000 cubic feet; provided, that the minimum charge shall be One Dollar ($1.00) per quarter year or part thereof.

(b) For any lot, parcel of land, building or premises situated outside of the corporate limits of the City of Dayton, Ohio, and having any connection with the City sanitary sewerage system or otherwise discharging sanitary sewage, industrial wastes, water, or other liquids, either directly or indirectly, into the City sanitary sewerage system, said charge shall be based upon the quantity of water used thereon or therein as the same is measured by a water meter there in use which meter shall be to the approval of the Director of Water, and there shall be charged for the first 3 000 cubic feet of water, or part thereof, so used per quarter year, the sum of One Dollar and Twenty-five Cents ($1.25); for each thousand cubic feet of water used in excess of 3 000 cubic feet and not exceeding 10 000 cubic feet, per quarter year, at the rate of Thirty-eight Cents (38¢) per thousand cubic feet; for each thousand cubic feet of water in excess of 10 000 cubic feet and not exceeding 20 000 cubic feet per quarter year at the rate of Thirty-one Cents (31¢) per thousand cubic feet; for each thousand cubic feet of water in excess of 20 000 cubic feet and not exceeding 100 000 cubic feet per quarter at the rate of Twenty-five Cents (25¢) per thousand cubic feet; for each thousand cubic feet in excess of 100 000 cubic feet and not in excess of 500 000 cubic feet per quarter, at the rate of Nineteen Cents (19¢) per thousand cubic feet; for each thousand cubic feet in excess of 500 000 cubic feet per quarter at the rate of Thirteen Cents (13¢) per thousand cubic feet; provided that the minimum charge shall be One Dollar and Twenty-five Cents ($1.25) per quarter year or part thereof.

(c) In the event a lot, parcel of land, building or premises discharging sanitary sewage, industrial waste, water or other liquids into the City sanitary sewerage system, either directly or indirectly, is not a user of water supplied by the Department of Water of said City and the water used thereon or therein is not measured by a city water meter, or by a meter acceptable to the Director of Water, then, in each such case, the amount of water so used shall be otherwise measured or determined by the Director of Water in order to determine the sewer service charge or rental provided in this ordinance, or the owner or other interested party at his expense may install and maintain a meter acceptable to the Director of Water for said purpose.

(d) In the case a lot, parcel of land, building or premises discharges industrial wastes, either directly or indirectly, into the City sanitary sewerage system, and the Director of Water finds that it is not practical to attempt to measure such wastes by meter, he shall measure such wastes in such manner and by such method as he may find practicable in the light of the conditions and attendant circumstances of the case, in order to determine the sewer service charge or rental, according to the corresponding rates per thousand feet provided in this ordinance.

(e) A discount of five (5) per cent. shall be allowed for prompt payment.

In addition to the charge or rental determined according to the rates specified herein further charge of five (5) per cent. of such amount so determined shall be added thereto in each case of failure to make prompt payment, and the total thus obtained shall be the sewerage service or rental in each such case.

The period within which payment shall be made in order to be classified as a "prompt payment" shall be determined by the Director of Water and shall be expressed through the rules or regulations which he is authorized by this ordinance to make for the purposes hereof:

(f) The sewer service charge or rental provided in this ordinance shall be payable quarterly at the office of the Department of Water, and, at the option of the Director of Water may be made payable at the same time as water bills in the district in which the property is located are payable.

(g) All lots, lands, buildings and premises located within the corporate limits of the City of Dayton, Ohio, and owned and used by the City School District for school purposes, all lots, lands, buildings and premises located within the corporate limits of the City of Dayton and owned and used by Montgomery County, by the State of Ohio and by the Federal Government for public purposes, together with all lots, lands, buildings and premises owned by the City of Dayton, are hereby exempted from said sewer service charge or rental, provided that nothing therein shall be construed as exempting the Dayton State Hospital for the Insane, The National Military Home for Disabled Soldiers of the United States, or The Wright Field, an aviation field maintained by the United States Government near said City from paying said sewer service, charge or rental.

Section 4. For any lot, land, building or premises from which connection is made with the City sanitary sewerage system or which begins to discharge sewage, any industrial waste, water or liquids into the City sanitary sewerage system, either directly or indirectly, after this ordinance becomes effective, a charge shall be made pursuant to this ordinance, the same to be a per diem pro rata amount based upon the minimum rate per quarter from the time such sewer connection is made, or such discharge into the City Sewerage system, either directly or indirectly, is begun, until the next following quarter period, except should the measured service exceed the minimum charge the corresponding measured rate or rates shall be charged.

Section 5. The charge or rental levied and assessed by this ordinance shall be payable in four quarterly payments in each year, as provided in Section 3, paragraph (f), hereof, provided that the amount of the rental payable for any lot or premises at the first payment period after this ordinance becomes effective shall be determined on the basis of a per diem pro-ratement of the minimum charge herein established beginning with the date this ordinance becomes effective, except that in those cases in which the metered or measured charge will exceed the minimum charge, the metered or measured charge shall be the basis.

Section 6. Each charge or rental levied by or pursuant to this ordinance is hereby made a lien upon the corresponding lot, land or premises served

by a connection to the sanitary sewerage system of the city of Dayton, Ohio, and if the same is not paid within thirty (30) days after it shall be due and payable it shall be certified to the Auditor of Montgomery County, Ohio, who shall place the same on the tax duplicate of said county with the interest and penalties allowed by law and be collected as other taxes are collected.

Section 7. The charges or rentals levied pursuant to this ordinance shall be collected by the Department of Water, and the Director of said Department shall make and enforce such by-laws and regulations as may be deemed necessary for the safe, economical and efficient management and protection of the City Sewerage system and the sewerage pumping, treatment and disposal works. for the construction and use of house sewers and connections to the sewerage system, and for the regulation, collection, rebating and refunding such charges or rentals.

Section 8. The funds received from the collection of the charges or rentals authorized by this ordinance shall be deposited daily with the City Treasury and shall be accounted for and be known as the Sanitary Sewer Fund, and when appropriated by the City Commission, shall be available for the payment of the cost and expenses of the management, maintenance and repair of the City sanitary sewerage system and the sewage pumping, treatment and disposal works, and any surplus in such fund shall be used for the payment of the interest on bonds issued and outstanding or which may be issued to provide funds with which to pay the City's portion of the cost of constructing such sanitary sewerage system, or part thereof, and such sewage pumping, treatment and disposal works and to retire such bonds when they mature, and or for the enlargement or replacement of said sanitary sewerage system, pumping, treatment and disposal works, except that no part thereof shall be used for the extension of such sewerage system into unsewered areas.

### Sewer Rental Ordinance No. 23, Oxford, Ohio[7]

An ordinance establishing the rates or rents to be paid to the Village of Oxford, Ohio, for the use of the sewerage system and the sewage treatment and disposal works by every person, firm, corporation or institution whose premises are concerned in connection with such system of sewerage and sewage treatment and disposal works.

Be It Ordained by the Council of the Village of Oxford, Ohio:

Section 1. That there be and is hereby established the rents or charges to be paid the Village of Oxford, Ohio, for the use of the sewerage system and the sewage treatment and disposal works by every person, firm, corporation or institution whose premises are served by a connection to such sewerage system and sewage treatment and disposal works as follows: A rental equal to Twenty-five (25¢) Cents per 1 000 cubic feet of water consumed per quarter year, with a minimum charge of $1.25 per quarter year for each sewer service connection from each premise to the sewerage system.

[7] Estimated 1929 population about 2 200 for the village. and 2 500 for Miami University and Western College for Women. Passed December 2, 1924.

Said rents and charges are to become effective on the 2nd day of January, 1925, and the same are due and payable in April, July, October and January of each year, the first rental charges and rates being due in the month of April, 1925, and payable by the 15th day of the month wherein the same become due.

Section 2. Said rents or charges shall be collected and placed in a separate sewer fund and dispersed in the manner provided by law.

Section 3. This ordinance shall take effect and be in force from and after January, 1925, or the earliest period allowed by law.

AMERICAN SOCIETY OF CIVIL ENGINEERS

Founded November 5, 1852

TRANSACTIONS

Paper No. 1791

# THE ENGINEER'S GROWING CIVIC RESPONSIBILITIES

## ADDRESS AT THE ANNUAL CONVENTION AT TACOMA, WASHINGTON, JULY 8, 1931

BY FRANCIS LEE STUART,[1] PRESIDENT, AM. SOC. C. E.

There is no greater and no more lasting thing that we, as engineers and members of the American Society of Civil Engineers, can do to help the profession than to increase the esteem of the Engineer for his profession and the esteem in which that profession is held by the general public.

Our own minds and our own efforts are the forces that must bring these conditions about for us. Our own extra efforts can accomplish much, by applying our power to think to some of the essentials upon which our happiness depends, as well as to the technical matters upon which our living depends.

By the very nature of our work, the majority of our profession are salaried employees and are a part of some organization which we must take care not to disorganize. We must be deserving of the confidence reposed in us, and one of our problems is to work out a technique of service that increases our usefulness to our employers and yet makes us even more useful to mankind than we have been.

In centuries gone by when the various nations and parts of the world knew little of each other or what the earth's resources really were, all the energies of man and his helpmate were spent in providing the mere sustenance for life. As the people began to co-operate and to disseminate their knowledge, conditions began to improve until to-day there is enough for all, and will be enough for all in spite of any temporary depression.

By instinct, or by an urge not yet named, man began to lay up for the future, a part payment for what the past had given him. There are already paid for, by his efforts, and put away and recorded for the help of posterity, those things that are essential for coming generations to know that they may avoid many of the trials which beset his ancestors.

Engineers have made for themselves an economic position in our scheme of life. Their works are among the only physical examples we have of what

[1] Cons. Engr., New York, N. Y.

has gone before; they have added their share to all the knowledge which we have recorded for coming generations; and they, to-day, are among the prime movers and the creators and constructors of the dreams and aspirations of our present civilization. This indicates that there has been something beyond mere living in their efforts.

I have stressed some of these things before, but I want to try to make clear some of the urge that is mixed up with your work for a living, the urge to help your fellow man, which is, in spite of yourself, inherent in your profession.

The Engineer more than any other class knows that to-day's civilization did not just happen—it represents the knowledge of the ages, brought along by recording progress as it was made, and passing it on. You and I do not have to start from zero on any proved subject, but the "how" and the "why" have been pegged and are our's for study. You owe a great debt to the past for what it has given you, and the only way you can pay it is by contributing your bit as you go along—giving of your time and talents to your State and to the World.

We live in an Engineering Age. Ancient and modern history and a cross-section of the civilization of the world to-day seem to justify such a designation of the period in which we live. As Engineers we have been and are engaged in one of the most important branches of the art of applying the sciences to improving living conditions, which have made such a valuation of world progress possible.

We have a right to feel that the profession is doing its technical part well, and if we can incorporate into our objectives a proper study of the needs of men as well as of materials, the power of our ideals will help us to take the place in world affairs which our extra efforts will deserve.

We owe to our profession and to our country a duty to be eager for public service and for greater usefulness, and we should with resolute co-operation take a serious part in the solution of the problems which beset us all.

There exists to-day a great need and an unparalleled opportunity for Engineers to use their powers of thinking and to make proper use of information and world trends, for the benefit of mankind.

The first requisite is that we, as individual members of our profession, Engineers young and old, must be more than able scientists, more than able inventors, more than able designers, more than able constructors. We must give the same quality of thought to matters of public progress and human interest that we give to technical matters and materials, and thus we shall make our technical judgment and advice more helpful in the counsel of men.

I have always felt that, while technical and creative work is a major phase of the Engineer's usefulness, it is not enough. In addition to contributing technical knowledge to help our prosperity, we should direct more of our individual energies toward taking our place with the forces which decide ways and means, and the uses to be made of our material progress.

This requires us to take a more commanding share in the deliberations or controls of the economic, financial, and managerial energies which influence

our efforts or are influenced by our initiative, and to help them to plan a better scheme of world control of "supply and demand", and a better understanding of "cause and effect", than exists to-day. Thus, we may avoid a recurrence of such periods of depression as we now have.

We, as Engineers, should also take our part in the greatest problem of our age. This is to determine the direction in which living conditions shall be improved, and how the fruits of progress shall be stabilized and distributed in an equitable way to satisfy human wants, as they are brought about.

If we have these objectives to guide our ambitions, nothing is too great for us to attempt. If you will use only a part of the mentality with which you create material progress, to weigh and to formulate the policies upon which our happiness depends, you will become more useful to the world we live in, and you will yourselves enjoy the mental pleasures and the personal growth that come to the men whose aim is to improve the living conditions of the world.

Existing conditions make an urgent demand to-day for clear thinking by you, and men like you, in upbuilding and advancing our lagging prosperity. The reward for individual initiative and energetic effort has made our country great. This very incentive has been rewarded by such continued prosperity, that the herd instinct and avarice of men have run wild with our judgment, greatly aggravated world conditions, and brought on us all an unwarranted period of stress and strain.

The urgent question now for all is what should be done to relieve these depressing conditions in this country and abroad. The events of the past two years do not inspire us with confidence in the superior sagacity or ability of the forces that have been directing our prosperity, and we need to help ourselves.

Each one must draw his own conclusions as to how confidence can best be restored. In my opinion, the crash of prices came as a result of over-speculation, and the country suffered a loss of values and credit which had taken years to establish. The loss of such credit makes every one feel hard up and uncertain, and leaves men without the power to buy as freely as was formerly possible.

The prices of stocks, real estate, and materials are low because of a lack of confidence and credit which affects buying power. It is necessary that prices be maintained. Prices can be brought back to satisfactory values only by confidence that there will be a restoration of the business activities which have been swept away.

Too many are living on their capital, and these questions are economic, as well as political, and they seriously affect each one of us. If, in addition to the past decline of our credit, the twenty-five billions of railroad securities, including the bonds which are owned by the public, are too injuriously affected, it means a re-aligning of our whole scheme of American life.

Three matters are of great importance: Credit, which has not been controlled to prevent over-speculation; reciprocity, which should expand our markets; and a raise in railroad rates. Of these three, I believe that the

raising of railroad rates would immediately change this country's situation for the better, until other remedies can become effective.

While it is out of the usual line of thought of the Engineer, I believe that a general lack of understanding and lack of publicity in financial affairs were largely to blame for present conditions. I see no reason why Engineers should not undertake a study of a part of our economic life that has failed us at a critical time. It seems unreasonable for us to put too much faith in the statement that the orgy of speculation could not have been stopped before it reached such a phase as to cause the depression which is just beginning to clear away.

The subject of the relation of general business to finance should receive our constructive thinking. Modern banking, at the moment, is based on the gold standard, and gold reserves are maintained at specified points, so that there can be no doubt that payment will be made. In different countries the ratio of the amount of gold and the amount of credit maintained is really a measure—among other things—of the lack of trust we have in each other's ability to pay.

Gold, except as a foundation of credit, is inconsequential as money tokens in the United States—it is arbitrarily about one-fourteenth of the money or credit we use in modern times. I am not convinced that the gold standard has had anything to do with the present troubles, but I think the misuse of credit has. I believe that credit is a power, and a force, having its flows and pressures, a force created by business and engineering and finance, reflecting the economic picture of our belief and confidence in collective efforts. Like every other man-made force, it should be under control, and while amenable to the pressures which come upon it from various directions, it should be made to regulate business affairs in other ways than by the mere lending of money, and to display the danger signals by withdrawal when over-speculation seems impending.

Credit has many angles and is admittedly difficult to measure and record. Its measurement should be a function of the Government in so far as it can properly require reports from institutions that handle other people's money. It should be taken out of the fog of mystery and multiplicity of detail and made understandable to the public. The making and destroying of credit could be better controlled by many minds than by a few, and there is no better way to control and extend its usefulness than by the sunlight of publicity.

If there is the real connection between credit and our material growth which I believe there is, and if important decisions must be made from interpretations of that relationship, then those predictions or interpretations should come from a source that all can trust as unbiased and without personal financial interest. Such a source would be the Treasury or Commerce Departments of the Government, and the interpretations should be published in as understandable a form as weather reports are, for all to read.

I am not unaware of the many charts of "this, and that", by formulas of "John Doe, *et al*", but they seem to be used for tips on the stock market or

for price fixing, not for control. I want credit information collected by authoritative sources and used for objectives of value to the public.

If this theory is, or can be made, of service, why should there not be such credit reports in simple terms, and who shall say that such reports may not be of great use in the future in diversifying our efforts; in keeping our citizens employed; and in stabilizing proper distribution of our prosperity?

Aside from the regulation of credit, it seems to me one of the most important and helpful forces for permanent recovery would be the dissemination of knowledge, with a display of red lights at the dangerous points, or some method of putting it forward in such a forceful way that all must look, listen, and heed. This should cause a voluntary regulation of the surpluses of mass production, within the limits of credit available for these purposes. There must be a dissemination of knowledge which will cause a diversification of effort so as to meet the needs of the probable markets, and the citizens have a right to demand a political policy of reciprocity or commercial expansion which will broaden these markets.

As to world conditions, this country's international customers are kept out of the market by their struggles with the political diseases which beset the whole world. The net result here and abroad is a clogging of the equitable division and distribution of prosperity, which must be cleared if we are to maintain our standards of living.

Present conditions are distressing in these lines for the moment, but should improve quickly as the political diseases are cured and internal and world affairs are modernized, and the experience may be of lasting benefit to all if it changes the American's mental attitude as to his relation to world affairs and his permanent prosperity.

All human beings, of whatever race and nationality, are created with mental possibilities, and are susceptible of certain degrees of education and ambition. Yet two-thirds of the population of the globe are living on a scale that should be of grave concern to Twentieth Century civilization, and they form one of our unavoidable responsibilities.

In this country of ours, with an abundance of the necessities of life and a surplus of the products of industry, and the mentality to meet any world-wide competition in farm produce, industry, and transportation, there is no reason for an economic policy which permits five million men to be out of employment, while two-thirds of the world needs and will want our wares for generations to come for improving living conditions. Judging by past experience, they must, in fact, have them, or by stagnation be absorbed or perish.

In the early stages of the industrial life of our country, when education and immigration and an increase of population developed our chief consumers within our own borders, a protective tariff speeded the progress of the nation. The remedy now, I feel, is to call a halt on the present haphazard tariff policy and its financial fallacies, and cause a scientific application by engineers of a world-wide distribution of properly regulated surpluses, founded on a flexible scheme of world reciprocity, and a co-ordinated flow of credit to prevent abuses.

What is more, I believe reciprocity is as necessary a medium for the politically diseased abroad as it is for those at home, and that it would assist all in maintaining and improving living standards.

I feel that pioneering with reciprocity, by which I mean give and take in trade, and pioneering with education, by which I mean the spreading of the knowledge of the mental pleasures as well as of the physical pleasures our standards of living afford, in those sections which compose two-thirds of the world which is lagging behind the civilization we enjoy, would be of inestimable value to those backward sections of the world and would help us as well.

Before I discuss the subject of the railroads, let me give you my idea of what the railroads mean to us. I have served many of the best years of my life as a locating engineer and chief engineer and consulting engineer of railroads, and I feel that I with other Engineers have had a part in building the greatest monument made by the hand of man the world has ever known—the railroads of the United States and Canada. There is nothing in all human history which compares in conception and execution, immensity and comprehensiveness, and in useful and beneficial service to mankind, with our American railroads.

These railroads—from the discovery of how to use the steam engine to the present day; from the foundations of the structures of the roadbed to the roofs of the terminals; from the fenders of the piers on one ocean to the fenders of the piers on the other, and including the equipment on all their tracks—were made possible and executed by Engineers, so that what happens to them is of particular interest to you.

The railroad problem which confronts us to-day in our internal relations with our own people affects the most important single industry in our country and one we should keep in a healthy condition—an industry which to-day is being injured by favored competition and is badly in need of immediate assistance.

For the future, you might help by bringing your powers for engineering thought or research to bear on the subject of the railroads' relation to other competitive means of transportation, such as water service, and automotive service, the truck and bus, and private automobiles.

Water service (exclusive of that on lake and ocean) has its inherent limitations. It has but few points of production and distribution local to any particular canal or river facilities. For all other business not local to such facilities there is an extra cost of the transfer to and from railroads at the water terminals at each end, and such service cannot be of great moment in the railroad situation. The artificial stimulants, however, that will be used to create waterway activities are full of potential trouble and should be a matter of grave concern.

The automotive inventions have revolutionized transportation and brought on new problems.

The railroad has the advantage of car access to country-wide collecting and distributing points without the two transfer costs which are necessary in water-borne traffic en route to points not local to the water service. So, also,

the truck, within limits of its economical use for main-road haul, and with depreciation and maintenance included, has the advantage of store-door delivery to innumerably more points of collection and delivery, without the transfer to trucks at both ends which is required by rail service to the same points.

Government or State subsidy of free roadbed for truck purposes can at best only lengthen the economical length of main-line haul. It cannot change the inherent flexibility of the service, which is the real competitive feature the railroads have to meet. With this in mind Engineers, for at least ten years, have been urging the railroads to use containers and make store-door deliveries, as a gradual transition to the time when they must operate the truck service themselves.

The bus situation is a different matter, and one of costs, and each route needs a careful comparative study of rates and facilities. Its disabilities, except for street traffic, are the discomfort and waste of mental energy of the passengers and the unavoidable risks of travel on highways, due to factors beyond the control of drivers.

Inasmuch as the public is entitled to, and should have, the cheapest and best means of transportation, these means, now competitive, must co-operate. Each particular agency, is entitled to its just place and use where it is found to be the most acceptably economic for all concerned. It must, however, be remembered that our railroads are the backbone of our daily traffic and must not be crippled by preferred treatment of other transportation facilities by water, by truck, or by other methods, which would be themselves unable to handle all our traffic or even any considerable part of it, and cannot take the place of the railroad service.

In my recent trips, I passed many trains with 4 000 or 5 000 tons behind one engine, and I could not help but feel that it was a dangerous policy to gradually whittle away the revenues of such an agency. We must stop it if we can.

A statement of the problem points to the answer. On account of its flexibility, the truck is here to stay, and the railroads will have to use the truck and bus business to protect their interests where profitable, as a part of their transportation service to the public.

As to the private automobile, it has added to our troubles psychologically, and it is a great modern problem with far-reaching effect on our lives. It has cut into the railroad revenue more than all other agencies combined; but it is such a great civilizer and business maker, as well as an unexampled agency for improving living conditions, that it is worth what it cost us. Means must be found to make good the loss of revenue to the railroads from this and other causes in some other way.

I have no doubt some means will be found to overcome the slump in railroad revenues, but until then our care should be that the usefulness of the railroads to the public has not been permanently injured before the remedies have been applied.

It seems to me that the quickest and most efficient aid to the railroads would be an increase in freight rate. The railroads are entitled to it, and

inequalities could be corrected later. Then should follow an adjustment of taxes on a fairer basis, and a more liberal treatment of the railroads by the States and cities, in grade-crossing elimination matters. In due time the rate structure which has no simple rational basis, should be made the subject of scientific study by a technical body and should be taken out of the mystery class.

Railroad research is a fertile field; economies will be made in due course as they have in the past, but expenses unknown to-day will also accrue, and a net result is a time-consuming process. Under present conditions the main thing is that the railroads need help immediately, more for the general good of the public than for their owners or employees. With all their vicissitudes, they have been improving and cheapening their service to all from generation to generation. Nothing can take their place in the civic life of the nation. They are still the greatest asset for giving an impetus to prosperity. If we give them reasonable treatment the whole aspect of the situation may change in short order.

There are many other matters that might be discussed more fully, such as control of over-production which, when not controlled, caused surpluses which were never justified—a danger inherent in the use of the machine tool; or the need to diversify our efforts to meet the markets we have, which task was left to the other fellow merely because we were loath to change; or many of the mistakes that we as corporations or individuals have made; or even a discussion of the survival of the fittest. But the subject is too great for one discussion, and no full formulas will ever be found to prevent a partial recurrence of recent troubles.

Judging the present by the past, if we as a nation are willing to work, we have every right to tackle our difficulties with cheerfulness, but tackle them we must, and that is one of the reasons why I have discussed the matter at so much length. We must one and all help, each within his own capacity, for our standards of living are at stake.

These thoughts are my own and not a conclusion of the Society. In a case like this, individual thoughts are only suggestive in our scheme of things and are of value only if they can stimulate other minds to think. If we can find a unity of purpose, and change uncertainty into action, we can give some of the impulse of leadership that is needed. In any event I know we can help if we discuss these questions among ourselves. I can see that we, as a technical Society, have already helped to start trends of thought that will bear fruit. Gradually, we will be able to help evolve even more worth-while mental contributions and practical suggestions in planning to meet our economic needs.

There is still another duty to ourselves. From all sides, economic, social, and spiritual, present conditions warn us that it is important that we co-operate with all aidful agencies to make a proper technical, a proper laboratory, and a proper scientific, study of the greatest of all raw materials, man—man as an individual and man as a mass—and that we co-operate to counteract his weakness when found, and to make him, including ourselves, ambitious, energetic, helpful, and happy aids in the work of the world.

Please keep in mind for to-day and the many to-morrows which are to come, that the American Society of Civil Engineers is a great force and a great instrument for service. It requires our continuous working support and personal interest in its efforts in our behalf to keep it so. Therefore, let us all determine by co-operation, to co-ordinate our efforts and to keep the Society growing greater and greater.

By precept and example we should urge all Engineers to help each other by taking their places in technical societies, by becoming working members of their programs to advance and to help the profession, by recording their findings, and by doing their part in the many collective efforts of those societies.

In our collective relations, we should be historians as well as a part of the history of our age. The records of technical societies are our great collective contribution to coming generations. Such societies, together with universities and libraries in a broader sense, have been forming and developing and recording for posterity the educational thoughts and forces which have been advancing our civilization. These educational agencies have kept currently available our knowledge of engineering which has prepared the way, and which has enabled us and other Engineers like us to make those advances in the art of living, which will cause the present hundred years to be known in history as the Engineering Age.

The world at large, and even we ourselves, have just begun to realize the growing importance of our professional place in the scheme of life as it is to-day. I believe that the influence of engineering in the history of this age is so great that we can rightfully feel elation and encouragement as we move forward to meet our responsibilities of the future.

# "A NATIONAL RECLAMATION POLICY"

## REPORT OF THE COMMITTEE OF THE IRRIGATION DIVISION[1]

WITH EXPLANATORY STATEMENTS BY MESSRS. J. B. LIPPINCOTT AND ELWOOD MEAD, AND DISCUSSION BY MESSRS. GEORGE W. FULLER, W. F. RUSSELL, NILS A. OLSEN, L. C. GRAY, FRANK ADAMS, M. J. DOWD, C. E. GRUNSKY, S. T. HARDING, H. H. DARE, CHARLES R. HEDKE, CHARLES KIRBY FOX, RHODES E. RULE, GEORGE M. BACON, G. E. P. SMITH, R. K. TIFFANY, DAVID WEEKS, JOHN A. WIDTSOE, F. H. NEWELL, A. D. LEWIS, JOSEPH JACOBS, F. N. CRONHOLM, R. I. MEEKER, E. B. DEBLER, JOHN E. FIELD, AND THE NATIONAL RECLAMATION POLICY COMMITTEE.

### HISTORICAL STATEMENT

Under date of November 1, 1926, Joseph Jacobs, Chairman of the Executive Committee of the Irrigation Division of the Society, wrote as follows:

"The Executive Committee of the Irrigation Division at its last meeting authorized the appointment of a new committee to be designated 'Committee on A National Reclamation Policy'. In accordance with the thought that the Committee should be fairly large, should be well distributed geographically, and should be comprised of men of long experience in irrigation matters, its personnel was made up as follows:

"J. B. Lippincott, Consulting Hydraulic Engineer, Los Angeles, Calif., *Chairman.*
G. M. Bacon, State Engineer, Salt Lake City, Utah.
C. E. Grunsky, Consulting Engineer, San Francisco, Calif.
M. C. Hinderlider, State Engineer, Denver, Colo.
W. H. Code, Consulting Engineer, Los Angeles, Calif.
Burton Smith, General Manager, Twin Falls Canal Company, Twin Falls, Idaho.
G. E. P. Smith, University of Arizona, Tucson, Ariz.
J. C. Stevens, Consulting Engineer, Portland, Ore.
R. K. Tiffany, State Hydraulic Engineer, Olympia, Wash.
John E. Field, Consulting Engineer, Denver, Colo.
Joseph A. Elliott, Manager and Vice-President, Wyoming Development Company, Wheatland, Wyo."

[1] Presented at the meeting of the Irrigation Division, San Diego, Calif., October 4, 1928.

An effort was made to exchange views between these members by correspondence during the past year, but it proved unsatisfactory. A meeting of this Committee was called for the session of the Society in Denver, Colo., in July, 1927, but a quorum was not present, and no definite action was taken. The Committee, however, held a session in Los Angeles, Calif., on September 19 to 21, inclusive, 1927, at which were present: Messrs. G. M. Bacon, J. C. Stevens, John E. Field, W. H. Code, C. E. Grunsky, and J. B. Lippincott. As this constituted a quorum the Committee proceeded to business and adopted a "Progress Report" under date of September 21, 1927.

It was decided that supporting statements for this report should be written by the different members of the Committee to whom separate paragraphs were assigned and that an Editing Committee composed of Messrs. Grunsky, Code, and Lippincott should meet in San Francisco, Calif., about October 10 to review them.

Following the meeting of September, 1927, Mr. Code wrote a Minority Report which he submitted to all the members of the Committee for their consideration. In addition, a supporting statement was prepared by the Committee covering the Majority Report. The vote by letter of the eleven members of the Committee on the adoption of the report was as follows: Seven in favor of the adoption of the Majority Report, three in favor of the adoption of Mr. Code's substitute report. Seven members of the Committee favored considering the Majority Report of September, 1927, as a progress report which should be given further consideration by the Committee.

In accordance with the decision of the Committee to consider the report of September, 1927, as a progress report, a second meeting of the Committee was held in San Francisco on July 2 and 3, 1928. At that meeting there was present the following members: Messrs. C. E. Grunsky, W. H. Code, G. M. Bacon, G. E. P. Smith, J. C. Stevens, John E. Field, and J. B. Lippincott. This Committee reviewed both reports and the supporting statements and those present unanimously adopted a report dated July 3, 1928, which is a modification in some respects of the report of September, 1927. Copies of the modified report were sent to the members of the Committee not in attendance at this meeting.

---

## REPORT

By resolution the Committee limited its work to a study of policies governing the reclamation of arid lands and related matters.

The policy of the United States and of the several States in the matter of water conservation and arid land reclamation should be controlled by certain basic principles, as follows:

(1) The waiving of interest payments to land owners on Government reclamation projects is unwise. In the future Government contributions should appear in the assumption of a part of the cost of project works and not in the granting of relief to the individual farmer such as the waiving of interest charges.

The United States Bureau of Reclamation has formulated a program of construction, covering the ensuing ten years, involving expenditures of approximately $100 000 000. To the extent that commitments have been made the Bureau should fulfill its assumed obligations and, on the other hand, the land owner should be required to meet his obligations or surrender his holding in the Government project.

(2) The conservation of the water in the rivers and lakes of the country should be under public control; and in order to lay a proper foundation for the making of comprehensive plans the Federal and State Governments should gather data, compile statistics, and conduct studies necessary to determine the feasibility of projects.

(3) The regulation of the flow of streams for the prevention of floods and for the best possible utilization of the waters should be undertaken by the States, or jointly by the United States and the States under such suitable forms of co-operation as may be appropriate under the Constitutional authority now delegated to each. They should prepare and adopt comprehensive plans for such regulation and should bear an equitable portion of the cost of water storage and flood-control work when the economic aspects after full investigations are found to be favorable, and the remainder of the cost should be allocated to flood control, irrigation, power development, municipal water supply, and other purposes.

(4) Where protection against flood waters results from the regulation of stream flow by means of reservoirs or otherwise, the proportion of the cost of the flood-control work not assumed by the Federal or State Government should be assessed against the lands and other properties which receive benefit therefrom.

(5) Municipalities or other public agencies or private parties should be allowed to construct approved projects in conformity with the approved plans; subject, however, to the public control of reservoirs and to the recapture after a reasonable time by the public of any franchise or similar rights conferred on private parties.

(6) The output of power and of water at Federal or State works should be disposed of at wholesale and not at retail.

(7) Interested States under suitable interstate compacts should be permitted by the United States to undertake the regulation of interstate streams.

(8) In the carrying out of further stream-regulation work, preference should be given to the construction of regulating reservoirs and the development of supplemental water supplies for existing irrigation systems, whether Federal or otherwise.

(9) Agricultural conditions due to over-production are such at present (1928) that it is undesirable for the Federal Government, except in the case of commitments already made, to bring new areas under cultivation.

(10) The construction of new irrigation projects should not be authorized except after thorough investigation and favorable recommendation by a Board of Review. This Board should include competent construction engineers, engineers with special operating and agricultural experience, economists, and

financiers familiar with local production and marketing conditions. The State should share in the responsibility for the selection and approval of projects. In determining the feasibility of proposed projects, State lines, local interests, and political expediency should not control.

(11) When new projects are authorized, principal and interest payments on construction costs should be required of the land owner. The interest rate should be low and the principal payments extended over a long period, with no payments on principal during the early years.

(12) The plan of repayment of construction costs of reclamation should be put into operation on each unit of the project at an early date after completion. The plan of payment should be sufficiently elastic to meet the settlers' ability to pay, but no relinquishment in the terms of repayment, once they are put into effect, should be permitted.

(13) In the case of reclamation projects, it should be recognized that settlement of the land is fully as imperative to success as construction. It can be greatly stimulated by the Government or other authorities taking drastic measures to prevent land speculation. The Department of the Interior is to be congratulated on its efforts to curb land speculation in recently authorized projects.

(14) Land settlement, including paternalistic, financial, or any other kind of assistance to the individual farmer, should be treated as a local matter and should therefore be made the concern of the State or locality rather than of the United States. Aid extended by Federal Land Banks has been generally helpful and the possibility of further extension of such aid by this or similar agencies is worthy of serious consideration.

(15) The Federal Government should continue its present policy of relinquishing control of completed works to suitably organized local agencies as soon as practicable.

(16) According to the report of the U. S. Bureau of Reclamation for 1926, the total area of land provided with water for irrigation was 1 803 000 acres in reclamation projects, of which, 1 320 000 acres were being cultivated by irrigation—a record of which the country may well be proud.

# A NATIONAL RECLAMATION POLICY:

## EXPLANATORY STATEMENT REGARDING REPORT OF THE COMMITTEE OF THE IRRIGATION DIVISION[2]

By J. B. Lippincott,[3] M. Am. Soc. C. E.

In the preparation of its report on a National Reclamation Policy, the Committee of the Irrigation Division considered many points which it decided should not be elaborated or even mentioned in the report itself. The following explanatory statement is intended to give the report its proper setting. These remarks, therefore, may be considered as parenthetical or supplementary to the official report.

The Reclamation Act was passed on June 17, 1902, for the purpose of utilizing funds derived from the disposal of public lands, for the irrigation of arid lands in sixteen Western States. On June 12, 1906, the Act was extended to Texas. The law provides (Section 4), that,

"* * * upon *the determination by the Secretary of the Interior* that any irrigation project is practicable, *he may* cause to be let contracts for the construction of the same. * * * The said charges [not exceeding 10 annual payments] shall be determined with a view of returning to the reclamation fund the estimated cost of construction of the project [without interest]."

The Act has been extensively amended. The provision for non-payment of interest has been retained, but the time of payments of construction charges was extended first to twenty, and then to forty, years. Extensive waivers of construction charges also have been made. In 1914, when Secretary Lane secured the Reclamation Extension Act, the law was changed and not only the adoption of new projects, but all appropriations therefor, had to be passed by Congress. Secretary Work on several occasions declined to construct projects so authorized, which in his judgment were not economically feasible.

In order to obtain a general perspective of the problem involved the following data are presented:[4]

| | |
|---|---|
| Total area of crop land in the United States in 1924 | 391 647 372 acres |
| Crop land idle (8.7%) | 34 007 716 " |
| On the Pacific Coast in 1924 the total area of crop land was | 18 715 791 " |
| The crop land idle was 28% of this, or | 5 201 519 " |

[2] Presented at the meeting of the Irrigation Division, San Diego, Calif., October 4, 1928.
[3] Cons. Hydr. Engr., Los Angeles, Calif.
[4] Year Book, U. S. Dept. of Agriculture, 1925, p. 1380.

According to the report of the United States Reclamation Service for 1926 the total area provided with water under Federal Reclamation Projects was 1 803 000 acres, of which 483 000 acres, or 27%, was idle. It has been stated[5] as follows:

| | |
|---|---|
| Irrigable land not now irrigated (in the United States) | 30 000 000 acres |
| Wet land requiring drainage only | 30 000 000 " |
| Wet land requiring drainage and clearing | 60 000 000 " |
| Total | 120 000 000 acres |

From this it may be seen that the reclamation problem remaining is a large one.

The report of the Special Advisory (Fact Finding) Committee to the Secretary states[6] that up to June 30, 1923, the original construction cost of projects was $147 831 506. It further states: "The facts developed show that $18 861 146 will never be recovered. There will be a probable loss of an additional $8 830 000." The works built have been a credit to the Engineering Profession, the fund has been honestly administered, and the economic benefits to the West have been great. Such an extended experience is a justification for a review of the methods and results and for a discussion of the lessons that may be drawn therefrom.

### Waiving of Interest Payments Unwise

As shown by the debates in Congress at the time of the adoption of the Act, and by the policies subsequently approved, Government irrigation enterprises were confined largely to projects which at that time were too expensive and required too long to construct to make them feasible as private enterprises. They then became feasible only by a system of investment that neglected the item of interest.

The extent of the subsidy due to this waiving of interest that practically has been granted to the water users on the Federal projects, as compared to the costs borne by settlers in State districts, or on private projects, is indicated by the following cost of United States Reclamation Work to June 30, 1922:[7]

| | |
|---|---|
| Reported debits | $171 496 409 |
| Reported credits | 41 350 449 |
| Reported net investment | $130 145 960 |
| Corrected net investment (4% interest on annual net investments, compounded, to June 30, 1922) | 70 706 685 |
| Total cost | $200 852 645 |

[5] Year Book, U. S. Dept. of Agriculture, 1921, p. 430.
[6] Senate Doc. No. 92, 68th Cong., 1st Session, p. 53.
[7] *Bulletin No. 1257*, U. S. Dept. of Agriculture, p. 8, *et seq.*

The annual interest on the reported net investments plus interest on previously accumulated interest for 1922, according to the same authority, was about $7 725 000, or nearly twice the anticipated annual repayments on construction charges. Due consideration, however, should be given to the great indirect benefits that have been created by these works.

A computation of the amounts which would be due if interest at 6% were charged on deferred payments, shows that a farmer not so benefited would pay between 72 and 66% more for his irrigation works than one operating under the Federal Reclamation Law.[8] This does not provide for compound interest which would further increase the amount. Neither does it take into consideration the time during which water was supplied to farmers on Federal reclamation projects before payment of construction charges began, which in some cases has reached fourteen years.

According to the Fourteenth U. S. Census, 80% of the land irrigated in 1919 in arid parts of the United States was supplied with water by private enterprises that had received no public aid or endorsement; 6.5% had been developed by the use of Federal funds; 9.5% was served by State irrigation districts; and 2.7% was under Carey Act grants.

There is marked special legislation in selecting the settlers on 6.5% of the total irrigated area for the granting of such subsidies, while the settlers in the remaining 93.5% of the enterprises have paid full costs. If other irrigation enterprises were prosperous, such an aid to the settlers on Federal projects would not be so conspicuous, but it becomes so because many irrigation districts and private enterprises are struggling for existence.

It appears unfair that the farmers on 392 000 000 acres of land in the United States should be taxed for the purpose of supplying a large subsidy to those on only 1 803 000 acres, supplied with water by the Federal Government. This inequality is emphasized as there is an over-production in practically every branch of agriculture. It is the surplus, even though small, which breaks the price. The granting of subsidies to individuals also tends to destroy their ambition and to make them still further dependent. The report of the Special Advisory Committee (Fact Finding) in 1924, truly states (page XIII):

"The Reclamation Service has retained the full management of all but two of the projects. This has not been satisfactory. The project management and the Washington office have become targets for criticism. A dependence on Federal paternalism has settled down upon nearly all the projects, and a corresponding bureaucratic tendency has grown up within the Reclamation Service. The water users have come to look upon themselves as wards of the Government, a specially favored class with special claims upon governmental bounty; and the Reclamation Service has been tempted to accept this definition of the water users. Nothing could be more detrimental to the progress of a venture which demands, first of all, individual courage and independence of the people concerned. The extension act provides that the operation and maintenance of the project may be turned over to the water users. This should be done at the earliest possible date."

The Bureau now recognizes that the management of projects should be promptly transferred to responsible local agencies; and this is being done.

[8] *Bulletin No. 1257*, U. S. Dept. of Agriculture.

Notwithstanding the waiving of this interest charge, large numbers of the settlers on the Federal reclamation projects have not paid their construction charges on projects costing on the average $57.75 per acre.[9] In addition, the "Omnibus Adjustment Act" intended to adjust water right charges, passed on May 25, 1926, made large deductions for construction charges on twenty Federal projects. Such conditions would not encourage the ordinary banker in making further loans to settlers as has been advocated in other parts of the Fact Finders report. Neither does it offer an attractive prospect for the repayment for projects now adopted which it is said will cost from $150 to $200 per acre.

It was the unanimous opinion of the Committee on a National Irrigation Policy that farmers on reclamation projects should pay interest charges on the cost of their works as do the water users on the remaining 93.5% of the irrigated areas of arid America. It is not fair to give the new settler preferential privileges above the water users on the State irrigation districts or under private enterprises. The rate of interest charged could properly be that at which money costs the Government itself, but the Government should not be called upon to sustain this loss in order to benefit individuals. The experiments tried in California and in the State of Washington do not indicate that paternalistic treatment of settlers has resulted in any particular benefit to them.

Under the California Irrigation District Act the bond issues which have been delinquent in the payment of interest and principal in 1927, when this subject was investigated by the writer, amounted to $4 627 000, on 95 810 acres. Their total bond issues amounted to $137 000 000, on 3 915 572 acres. The delinquency therefrom was but 3.4 per cent. The prevailing bond interest rate is 6 per cent. The California law provides the same general method for the sale of lands on which payments are delinquent as with other taxes.

The report of the Special Advisory (Fact Finding) Committee relative to Federal irrigation projects states (page XI):

"On June 30, 1923, of the construction charges then due, 14.2%, or $2 537 222.46, remained unpaid, and of the operation and maintenance charges then due 17.6%, or $2 423 649.06, remained unpaid."

Of late, the Bureau has taken a stronger stand to enforce the payment of these charges.

In the case of California irrigation districts where the law is administered locally, payment of taxes is insisted upon and where there are no subsidies, better financial results have been obtained. However, in the arid area of the United States as a whole, 26% of all irrigation districts organized have failed in some period of their development, so that this method of procedure has also had its disasters. At first, these district laws were loosely drawn, and there was almost no supervision of their procedure in voting and selling bonds or letting contracts. In California, there are now close supervision and few failures. The Committee is of the unanimous opinion that a subsidy to settlers is not advisable. Where the Government has made commitments they

[9] Senate Doc. No. 92, 68th Cong., 1st Session, p. 146.

should be honored, but the same fulfillment of contracts should be required of the water user.

The most flagrant examples of repudiation on Federal projects are said to be cases where local influences from the start undertook to secure public expenditures for reclamation with no intention of making repayments as required by their contracts. Some depended upon legal flaws, but others mainly relied on political influences. This movement made no progress in Congress as long as the Interior Department stood firm for the enforcement of the law and the contracts. These waivers are said to have been first covertly and then openly advocated in past years by the Department. When this succeeded, it of course broke the phalanx of resistance and many scrambled for such benefits. When the morale was broken the enforcement of contracts became more difficult.

It is a desirable and necessary public policy for the Federal Government to build hydraulic works whether for irrigation, drainage, or navigation, for the general benefit of the greatest possible number of citizens, rather than to make these allotments of funds for individual settlers on selected areas. This matter will be discussed further.

### The Collection of Physical Data

Surveys of reservoir sites can be made promptly. Dam sites can be explored and distribution systems can be outlined quickly. However, the data necessary for a proper outline of a project, such as stream flow, rainfall, and temperature records, can only be obtained through years of continuous observation. Private enterprises are not adapted to the collection of such data; it is the province of the State and Federal Governments to make such long-time observations. The stream-gauging work of the U. S. Geological Survey is especially to be commended. It should be expanded. Some of the Western States are properly co-operating with the Federal Departments in collecting such physical data and in making essential topographic surveys.

### Regulation of Streams Should Be Under Public Authority

The determination by the Federal Government of the best comprehensive plan for the utilization of drainage systems where streams are interstate or navigable, is very important and such work is commended. It has adopted a broad policy of improving its navigable waters. Great expenditures have been made for this work. This is justified because of general public interest. Of late, many localities benefited have contributed to the cost of such improvements. The fact that certain individuals are especially benefited is not taken as the occasion for their direct assessment. A similar policy has been adopted for the improvement of main highways and large appropriations have been made therefor. Here, again, there is a co-operation between the Federal and local authorities. The Bingham Act provides for the aid of aviation in a manner similar to the Federal aid of navigation. As an example, the Federal Government now has a lighted air lane extending from New York, N. Y., to San Francisco and Los Angeles, Calif., and also one nearly completed from Los Angeles to Seattle, Wash. These air lanes are lighted at night and are

supplied throughout their courses with emergency landing fields at Federal expense. The large cities served are requested to furnish the terminal airports.

Congress at its 1927-28 Session passed[10] "An Act for the Control of Floods on the Mississippi River and Its Tributaries and for Other Purposes". An appropriation of $325 000 000 was authorized. The Act provides that "no local contribution to the project herein adopted is required." This generosity, it is stated, is due to the extent of the problem involved, and because of large previous local expenditures. Section 4 provides that benefited localities are required to supply only certain minor rights of way. The aid of navigation is not the purpose of this Act, which contemplates the construction of regulating reservoirs. Section 3 provides for the States or levee districts to maintain the flood-control works after their completion and defines maintenance as including normally such matters as cutting grass, removal of weeds, local drainage, and minor repairs of main river levees.

These provisions are in distinct contrast to the proposed Act for building the Boulder Canyon Reservoir on the Colorado River where the full return of all funds to the Government is required by firm contracts in advance.[11] Section 13 of this Act also provides an appropriation of $17 600 000 for the control of the floods in the Sacramento River for which no return is to be made. This latter work is part of a co-operative act between the State of California, local land owners, and the Federal Government. Other great projects are proposed for the improvement of inland waterways at Federal expense and without return of funds.

The Federal policy of making large direct appropriations for public works for the general development of broad sections of the country, for navigation, flood control, highways, and aviation, has been established without repayment of the amounts furnished by it. Some such Federal policy should be adopted for the general benefit of all interests, including irrigation on navigable or interstate streams or their tributaries as well. Storage reservoirs and river-control works could properly be built in large part by Federal and State funds on such rivers as the Columbia, Sacramento, Colorado, Rio Grande, and their tributaries; and the floods could be regulated for all public use (be it irrigation, navigation, water supply, or power) and in such manner that the greatest possible numbers may be aided.

The Federal Government has already expended large sums for river-control works on the Lower Colorado by direct appropriations. Navigation in this instance is only a myth. If it becomes necessary to build an All-American Canal because of international complications to protect the irrigators of the Imperial Valley and to save just portions of the waters of that stream for the development of public and private lands in the United States, it appears fair that a direct appropriation should be made for that purpose. The people have done their full share in this effort, as well as in the projects of the Mississippi Valley. Established institutions are fully as deserving of help as new projects. This would be a broader and franker policy than the selection of 6.5% of the irrigated lands for special subsidies. The general plan for

[10] Public Doc. 391, 70th Cong., 1st Session.
[11] H. R. 5773, 70th Cong., 1st Session, 4-b.

such works on interstate and navigable streams should be adopted jointly by the Federal and State Governments.

On non-navigable streams wholly within the State such works could properly be aided by the State itself, or by large conservation districts, or by the two combined. Some part of the cost of such works should be allocated to the interests benefited, but a substantial part of the expense for river regulation should be at public expense.

### Construction of Works by Public or Private Agencies

Municipalities or other public agencies, or private parties, should be permitted and encouraged in building hydraulic works; but the control of large reservoirs built by Federal authority should remain permanently under its control because of the varied interests involved in their operation. This is the present provision of the Reclamation Act. When built as a part of a comprehensive plan, in so far as possible, they should be administered so as to produce the greatest general benefit. In the case of the Colorado River project the order of importance adopted is: First, river regulation; second, water supply; and third, power.[12] When reservoirs are built by private funds it is proper to provide for their ultimate recovery by the public as stipulated in the Federal Water Power Act.

### Water and Power from Federal or State Reservoir Should Be Disposed of at Wholesale Rather than Retail

All the members of the Engineering Committee were agreed that State and Federal authority should not properly engage in the distribution of water or power to the individual consumers. The writer sees no reason why governmental authority should be restrained from installing the generating plants. It is not intended that water and power from Federal and State projects should be turned over only for distribution to private parties, but rather that it should be also delivered to either political subdivisions of the State or to mutual or private companies which have direct contact with the consumer. In cases, such as in the Salt River Valley Project, where an existing privately owned power distribution system was already in operation, it became naturally a medium for the distribution of power, just as the Salt River Valley Water Users Association with its network of canals became the natural distributor of water.

The Congressional Act of May 25, 1926, Section 46, provides:

"No water shall be delivered upon the completion of any new project or new division of a project until a contract or contracts in form approved by the Secretary of the Interior shall have been made with an irrigation district or irrigation districts organized under State law providing for payment by the district or districts of the cost of constructing, operating, and maintaining the works during the time they are in control of the United States."

Section 45 of the same Act provides for a similar procedure in the case of amendments to any existing water-right contracts. While the water is to be delivered wholesale by the Reclamation Service to the district, its actual

[12] H. R. 5773, 70th Cong., 1st Session.

distribution to the consumers and the collection of bills are very properly to be undertaken by a local organization and not by the Federal Government. This policy is to be commended. Section 5 of the Act entitled, "H. R. 5773, 70th Congress, 1st Session", relative to the building of the Boulder Canyon Dam provides as follows:

"That the Secretary of the Interior is hereby authorized, under such general regulations as he may prescribe, to contract for the storage of water in said reservoir as may be agreed upon, for irrigation and domestic uses, and generation of electrical energy and for the delivery thereof at such points on the river and on said canal and delivery at the switchboard to States, municipal corporations, political subdivisions, and private corporations, of electrical energy generated at said dam, upon charges that will provide revenue which, in addition to other revenue accruing under the reclamation law and under this Act, will in his judgment cover all expenses of operation and maintenance incurred by the United States on account of works constructed under this Act." (Section 4-*b*) "* * * and the repayment, within 50 years from the date of the completion of said works, of all amounts advanced to the fund * * * with interest thereon."

As far as the policy of wholesaling the water or power as provided in this bill is concerned, it is in accordance with the judgment of the Engineering Committee. However, the provisions of this Boulder Canyon Act are in marked contrast with the enormous appropriations for the Mississippi River where the obligation of the beneficiaries is to cut the grass on the levees.

### Benefits from Public Funds Should Be Extended to All Water Users on the Stream

It has been stated[13] that 34 007 716 acres of the "crop land" of the United States were lying "idle or fallow". In the "Mountain States", which included Montana, Idaho, Wyoming, Colorado, New Mexico, Arizona, Utah, and Nevada, out of 25 604 416 acres of "crop land", 3 705 498 acres were "idle or fallow". The area of "land in farms" increased between 1920 and 1925, in the Mountain States, 12.4% and, in the Pacific States, it decreased 3.3 per cent. The average for the United States for this period showed a decrease of 3.2 per cent.[14] In 1920 there was a gain of 500 000 in farm population in the United States; in 1921, this gain was 200 000; in 1922, the loss was 460 000; in 1923, 461 000; and in 1924, it was 182 000.[15] The decrease in farm population in 1924 due to the city-ward movement was highest in the Mountain States, or 4.3%, followed next by the Pacific and West Coast Central States.[15] Between 1910 and 1920 the increase in the total population of the United States was 13 738 354, or 14.9 per cent. A table has also been published[16] giving acreages, production, and farm values from 1924 to 1925 which shows an estimated decrease in farm values of $570 663 000. From these data it appears that agriculture is unprofitable and farming consequently unpopular.

In view of these conditions, Secretary Jardine stated:[17]

"I am opposed to bringing new areas under cultivation until we have found a market for the products we are now producing. There are two things the

[13] Year Book, U. S. Dept. of Agriculture, 1925, p. 1380.
[14] *Loc. cit.*, p. 1379.
[15] *Loc. cit.*, p. 33.
[16] *Loc. cit.*, p. 1356.
[17] *Loc. cit.*, p. 22.

Government may do to prevent injudicious expansion of farm land. It may regulate its own land-settlement projects wisely and it may discourage undesirable private projects. There is a field here for useful and legitimate Government activity for the protection of agriculture and the promotion of the general welfare. I am as strongly in favor of such activity as I am against attempts to determine economic law by means of legislation."

In operating United States Reclamation projects, 29% or more of the land under canal is not farmed.[18] In California State irrigation districts, one-third of the land is uncultivated.

As water becomes more valuable, the methods of its use are improved. A substantial conservation of water in the future may be accomplished by the lining of canals. It is also being found that larger crops can be grown by the use of less water. Because of these conditions it is probable that extensions of existing canal systems will be made without increasing the volumes of water now being diverted. A notable example of such improved efficiency is in the Salt River Valley, in Arizona.

Due to the work of the U. S. Department of Agriculture there is an increase in the quantity production per acre in agricultural lands because of improved seeds. There has also been a great advance in efficiency of farm equipment which permits of deeper plowing and more effective harvesting. This progress is now well under way and will help, if it does not completely meet (from existing farm areas), the increasing demands for foodstuffs. This further relieves the immediate necessity for increasing reclaimed areas.

Throughout the United States, farm and orchard products have been low priced since 1923. While the prices on the staples, such as corn, wheat, and cotton, are determined by world-wide conditions, the crops that are best produced on higher priced lands, consisting largely of fruits and vegetables, are fixed in the home markets. A small excess of the supply above the demand breaks the price and conversely a slight deficiency stimulates it. During this period there has been an excess of the supply over the demand, especially with fruits and vegetables. This has resulted in losses and farm abandonment. This condition is one which should not be aggravated by the reclamation of new areas.

Nils A. Olsen, Assistant Chief of the Bureau of Agricultural Economics, U. S. Department of Agriculture, has stated[19] in part,

"A prosperous agriculture can not be achieved by over-development and over-expansion which injures not only established farmers but also new settlers. * * * The process of pushing agricultural expansion too rapidly tends to defeat its own end, if that end is the establishment of prosperous families on the land. * * * The idea of promoting residence in the country unless that residence can be maintained on a profitable basis to the family is to expect an impossibility and fly in the face of modern tendencies. * * * It is obvious that from many points of view it is much more economic to meet any demand for increased agricultural production by utilizing lands already in farms than by attempting to establish new farms."

It would be a much broader policy for the Federal and State Governments to aid the farmer who is now struggling with adversity on existing farms

[18] Senate Doc. 92, 68th Cong., 1st Session, p. 26 (Fact Finders Report.)

[19] *Proceedings*, First Pan-Pacific Conference on Education, Rehabilitation, Reclamation and Recreation, Honolulu, Hawaii, April, 1927.

than to adopt a policy of reclaiming new areas whether by drainage or irrigation. There is a great need to reduce the difference between the price received by the producer and that paid by the consumer.

The argument in favor of the adoption of some of the major new projects which would result ultimately in increasing agricultural production has been stated[20] by Herbert Hoover, Hon. M. Am. Soc. C. E. (as Secretary of the Interior), in referring to the Lower Colorado River development in the hearings before the House Committee on Irrigation, as follows:

"MR. HAYDEN.—The feeling in Congress is not very strongly in favor of reclaiming vast areas of land. It means in this instance a million acres.

"SECRETARY HOOVER.—I think the answer to that would be that it would require approximately 10 years to complete the engineering work, and another 10 years before a complete use was made of the available water to those valleys, and, therefore, before production becomes very substantial there would be a period of 15 to 20 years. In that period the population of the United States will have increased twenty or thirty million, and that production will be very badly needed. I would be the last to wave the magic wand which would bring the production on at the present moment. It will probably take 20 years to complete."

It will be noted that Secretary Hoover agreed that present conditions do not justify immediate reclamation of additional areas, but he estimates that in 15 to 20 years their products will be required.

The policy adopted relative to the Mississippi River of protecting the farmers of the South who are now struggling with adversity from floods, is humane and proper. In a stream, such as the Sacramento, a dam could properly be built at Kennett, Calif., largely at Federal and State expense, which would sustain navigation, prevent floods, provide an adequate water supply for the existing farms in the Sacramento Valley and lower portions of the San Joaquin Valley, and permit of the generation of enough power to pay at wholesale rates for the greater part of the cost of the project. The distribution of both the water and power could be left to local agencies. Such a procedure would yield a State-wide and nation-wide benefit to as great an extent as the building of harbors or highways.

The Sacramento Valley is now staggering with debts of State drainage projects that probably cannot be paid. The limit of the Valley's irrigation water supply during the summer months has been reached, and navigation has been rendered impossible above Sacramento. The salt water from San Francisco Bay is encroaching on the reclaimed islands of the lower river. A comprehensive scheme involving the expenditure of large public funds for the betterment of such situations, in which the people of the entire West are involved, is commensurate with State and National effort.

Southern California now (1928) has a population of more than 2 000 000. It is increasing at a very rapid rate. Despite the fact that nearly all the surface flow of the streams in this region is used, about 80% of the drinking water has to be obtained from wells in Southern California proper. The groundwater supplies in most localities are falling. The only comprehensive source remaining is the Colorado River which is discharging in greater part in

[20] H. R. 6251 and 9826, 69th Cong., 1st Session, p. 49.

destructive floods into the sea about 16 000 000 acre-ft. per year, threatening the very existence of an irrigation district of 600 000 acres, followed by periods of inadequate low flow. By its control at the proposed Boulder Canyon Reservoir these adverse problems can be solved and made largely to pay for the cost of the river's improvement through the development of power, resulting in the great increase in National, as well as local, wealth. If this is not done there may be decadence instead of growth. The cost will be enormous; including the aqueduct, it may exceed $200 000 000. Surely such a project is worthy of both State and Federal aid. The financial plan proposed is fully justified, if not too liberal on the part of the local interests benefited.

The cost of projects in the Northwest that have been adopted by Congress during the past few years, involving a construction outlay estimated at approximately $100 000 000 for the next ten years, are said to require an outlay of $160 per acre, or more. The water users thereunder are to be given forty years in which to refund this amount without interest. In view of the past history of the Reclamation Service, with projects costing less than one-half this amount, it is the prevailing belief that these repayments never will be made. The sum of $160 per acre is sufficient to acquire good farming lands in Illinois, Iowa, Kansas, and Nebraska, where schools, roads, and other public improvements already exist and where the markets for the products are at hand and large areas are idle. Under these conditions such projects should not now be built, particularly under the present condition of agriculture. Farmers are not asking for their construction. It appears to be a better policy to aid those who are endeavoring to develop areas now occupied and in need of help.

### New Projects Should Only Be Adopted After Approval by Competent Authority

The existing law (Reclamation Act of 1902, Paragraph 4) states that the adoption of projects is dependent on the determination by the Secretary of the Interior that they are practicable. The Reclamation Service in the past, as well as at present, has in its organization many able engineers. The Secretaries have been competently advised by these men, whose judgment usually has been followed. Frequently, pressure has been brought upon Congressional representatives to force the adoption of projects. Congress, however, has now undertaken the adoption of projects. The Reclamation Extension Act (August 13, 1914, Section 16) now provides that expenditures for projects shall not be made except from annual appropriations of Congress. The Secretary of the Interior, in certain instances, because of adverse reports and his responsibility under the original act, has declined to construct projects authorized by Congress, which is a courageous and commendable attitude.

Obviously, no project should be adopted for construction unless it is physically and economically sound. The employment of competent advice both of an engineering and economic nature and its acceptance require no argument as to its propriety.

### Interest Should Be Paid

In some Western States paternalistic measures under State supervision have been adopted for the establishment of settlers on the land, including the building of houses, barns, and the installation of machinery, the leveling and fencing of the lands, and the guaranty of power bills for pumping charges. The States have not been sufficiently prosperous to cause an expansion of this policy. While success has attended some, they do not appear to have secured any unusual prosperity. Where success has marked such enterprises, the conditions surrounding their initiation and subsequent progress appear favorable enough to have induced it without such paternalistic assistance.

The conclusion to be drawn from these experiences is that a liberal measure of paternalism will not insure success. Such aid will work injury in the long run to the social fabric that will far outweigh any temporary successes that may be credited to such a policy.

A National Reclamation Policy should be built around two fundamentals: First, the creation of equal opportunities; and, second, the stimulation of individual effort.

Any policy that supplies a prop on which the improvident may lean, and that fails to provide avenues whereby the energetic and thrifty can outdistance the less fortunately endowed, is foredoomed to failure. If such aid is to be given it should not be given by the Federal Government.

### Repayments Should Begin Promptly

In the past, long delays have occurred after the deliveries of water before repayments for construction costs began. Based on the reports of the Reclamation Service, on four of the projects payments began as soon as water was delivered; on eight, the next year following. However, there are two projects in which in 1922, eleven years after delivery of water, payments had not begun and in one, the intervening period was fourteen years. A 10-year period with 6% compound interest represents 77% of the initial amount. At present, the Reclamation Service is insisting on prompt payments and is to be commended for so doing. Apparently, there is no good reason outside of political influence why these delays have been so protracted in the past.

The Fact Finding Commission properly recommends that as soon as water is provided for two-thirds of an area, the owners thereof should be obliged to begin making the payments. No long interval of time should elapse between the furnishing of water and the declaration by the Secretary that payments are due.

Any violation of this policy will deprive other settlers of equal opportunities and delay the operation of the revolving fund contemplated in the law. These delays put a premium on improvidence and are unfair to those who are able and willing to meet their obligations. The terms of repayment should be adjusted to the reasonable ability to pay. The Department of the Interior has adopted[21] the policy of decentralization and has executed contracts with thirty irrigation districts and water users' associations on sixteen projects for

[21] Annual Rept., 1927, p. 20.

the transfer to local control of the care and operation of the irrigation works of these projects. This, it is stated, has resulted in a better morale and financial standing on the projects.

### Land Settlement Essential to Success

On most new irrigation projects, whether Federal, State, or private, colonization is a serious problem. It is difficult to induce people to settle these new farm lands because generally, under present conditions, agriculture does not pay. If farming were profitable the colonization problem would largely disappear. This same argument applies to the difficulty in financing the farmer. Farming will not pay until the demand for foodstuffs catches up with the supply.

The bane of many irrigation projects, whether publicly or privately conducted, has been land speculation. If the dirt farmer can be given access to the land at its base price before inflation, his chances of success are better than if he has to pay a speculative price for it.

On the Pacific Coast, real estate agencies, with "high pressure" salesmen, frequently charge from 25 to 35% of the sales price of the lands for their commission, and require that their fee shall be paid from the first instalment of the purchaser, the real land owner usually having to wait for his compensation from deferred payments. This is hard on both original land owner and the settler. It is very difficult to overcome such speculations.

The policy now being enforced on new projects may offer a greater stimulus to the proper settlement, than any colonization plan previously attempted. Drastic measures are taken to discourage land speculation prior to the adoption of the project, by fixing sales prices of lands therein. A vigorous policy in this regard will produce a wholesome effect. The Government or State can properly insist as one of the conditions of its undertaking a project that every surplus parcel of land within the proposed district be listed with an authorized real estate agency, at a stipulated price that contains no unearned increment. The Government or State, in these recent instances, properly reserves the right to fix the price of such land. These tracts are to be offered to prospective settlers at such prices plus sufficient commission to cover overhead expenses only.

Every sale contract should be between vendor and purchaser, the Government merely acting as agent. In case of re-sale, the land must be offered through the same agency for a certain period of years until the project is safely on its way to prosperous settlement.

The Department of the Interior is to be congratulated on its efforts to curb speculation on its recently authorized projects.

### Paternalistic Aid

It has been recommended that the water users on Federal projects should be further aided by advancing loans, leveling lands, etc. It was the judgment of the Committee that if such paternalistic system is to be extended it should be through local organizations, such as possibly the State or county where

there would be a more direct interest in the return of funds and where neighbors would pass on the ability and intent of the borrower to make returns following lines perhaps as adopted by the Farm Loan Banks.

### The Accomplishments of the Reclamation Service

The Reclamation Service has constructed 120 dams, built 16 000 miles of canals, laid 3 700 000 ft. of pipe line, and has excavated 252 000 000 yd. of materials in the performance of its duties. In 1925, the estimated crop values produced on these projects was $77 608 880 on a total area of 1 432 155 acres. The engineers who have been connected with this work may justly regard it with pride. The report that the Committee has presented is not a criticism of this service either past or present. The policies have been fixed by acts of Congress and not by the engineers and executives. This report is intended to be a review of the operation of these policies and an expression on the part of those who are interested and somewhat acquainted with the results.

# A NATIONAL RECLAMATION POLICY: ECONOMIC ASPECTS OF FEDERAL RECLAMATION[22]

By Elwood Mead,[23] M. Am. Soc. C. E.

The report on a National Reclamation Policy prepared by a Committee of the Irrigation Division deals with a problem on which Government officials charged with the Reclamation work may quite properly hold other and contrary views to those expressed. This paper comments on the report as from this angle and, therefore, may be considered as voicing the essentials of another side of the question.

## A Complex Undertaking

The reclamation of arid land by irrigation is not a single or a simple undertaking. It involves the construction of works, which is engineering. It requires the settlement and cultivation of land, which is economics. It is not a success unless it creates communities of happy, prosperous homes, which is a social problem. The report under consideration was prepared by engineers. If it had been prepared by economists more attention would have been given to settlement and the creation of conditions which would enable the money spent on construction to be repaid. If it had been written by settlers more would have been said about their needs. Investigations and discussions like those inaugurated by the Society, therefore, will promote an understanding of reclamation and make future development even more valuable.

The influence of Federal reclamation on agricultural development has varied widely in different States. It has been least in California and greatest in Idaho and Arizona. The rich and populous irrigation districts of these two latter States are the creation of Federal works. Outside of California important irrigation works of the future will be built by the Government. Costs are too great and needed income will be too long delayed to make such development attractive to private enterprise. Government projects must continue to be subsidized either by not requiring interest on construction costs, as at present, or by the Government paying a part of the cost, as is proposed in the report.

The present (1928) income for building Federal irrigation works comes from four sources: (1) Payments by water users; (2) payments for power; (3) income from sales of public lands; and (4) a percentage of the income from oil leases. The first two are increasing; the last two are diminishing. The total is about $10 000 000 per year.

The works being built are large and costly. Their completion will require several years. Farm development must await the water supply; hence, there

[22] Presented at the meeting of the Irrigation Division, San Diego, Calif., October 4, 1928.

[23] Commr. of Reclamation, U. S. Dept. of the Interior, Washington, D. C.

is small prospect of any material increase in irrigated acreage during the next decade. No contracts for new construction can be made until approved by both the Secretary of the Interior and the President. This operates as a further check on rapid development.

## The Second Stage in Reclamation

There is a gap in reclamation between the completion of canals and the use of water in irrigation. The first step in reclamation is to provide water. The second is to bring it into use. This requires settlers for the uncleared, unleveled land. It requires preparing that land for irrigated culture, erecting farm buildings, and growing crops on soil baked for centuries. The cost, the hardships, and the anxiety of this second step, were always greater than was realized or admitted, and the cost is now two or three times what it was fifteen years ago—say, in 1913. An irrigation canal with unpeopled farms below it is a liability, not an asset. Income and the benefits of reclamation are realized only when the second stage of reclamation is completed.

Other obstacles to carrying out settlement and farm development have become more serious in recent years. The pioneering spirit which led settlers to do the difficult and unremunerative work of clearing and leveling the land is gone. The open country no longer appeals as it once did. The opportunities of other industries are much broader. The cost of changing raw land into farms is now so heavy that money or credit is usually needed to supplement the settler's meager capital. Economic surveys of developing reclamation projects made by committees which included practical irrigators, economic experts from agricultural colleges, and representatives of the Bureau of Reclamation show that from $5 000 to $10 000 must be spent to provide the permanent improvements and equipment of an 80-acre farm.

The percentage of home seekers with capital enough to improve and equip their farms without borrowing is very small and the number willing to invest their capital in a development of this character is still smaller. They can get more for their money by buying improved farms in established districts. The settlement and development of unimproved, unpeopled areas depends largely on tenant farmers, to whom the lure of ownership is strong, and to the sons of farmers. Such applicants rarely have more than $2 000 to $3 000, and settlers with less than $5 000 capital will need to borrow money to make their farms produce a living income. There are few projects where this money can be borrowed on terms which the farmer can meet, if it can be borrowed at all. On nearly all developing projects loans are for short periods, with interest rates which are higher than agriculture can stand.

On four projects, which have been in operation for more than ten years, those who have improved farms are prospering; but more than one-half the land is unirrigated, and 800 more settlers are needed to bring all the land in these projects under cultivation. If one-half this number of settlers could be secured it would insure the economic solvency of the Government works and the payment of the Government's debt. These settlers could be secured if there were some agency to loan money needed to erect inexpensive farm buildings and prepare the land for irrigation. They cannot be secured with-

out some credit aid not now provided. Short-time loans to buy live stock can be secured, but money for permanent development is not available.

This credit phase of settlement has been emphasized because it is a stumbling-block in the way of success. It is also a menace to the solvency of works now building or to be built. On one project, where the irrigation works will cost $11 000 000, there is no anxiety about the payment of construction costs on more than one-half the area. The farms are improved, the land has been prepared for irrigation. The owners have contracted to pay full construction costs on their entire area; cultivation and use of the water are assured. On the unimproved, unpeopled part of this project, however, the surface of the land is uneven and covered with brush or with second-growth timber. To prepare this land for irrigation, and to provide the necessary buildings and equipment, will cost from $75 to $150 per acre. If this money could be advanced and payment could be spread over 20 years, with 5 or 6% interest, buyers could be secured; but they would be reluctant to take on a clearing and leveling job for which they would have to provide all the money.

This project presents new economic problems, the solution of which needs new policies and new laws. Some of the land belongs to the State, some to a railroad company, some to individuals, and some to the United States. If these owners act together and the preparation of the land for cultivation is put into competent hands, and farm boundaries are fixed to agree with the topography of the country, the land can be made ready for cultivation in less time, at less cost, and with infinitely better results than can be accomplished by leaving this to the action of the separate owners. Each will wait on the others, development will be delayed, and money will be lost. The heaviest loser, of course, would be the Federal Government.

On another project the irrigation works being built have an estimated cost of $18 000 000. A considerable part of the land under the project is now being irrigated from pumps. The cost of pumping has so increased in recent years that it is now greater than irrigators can afford to pay. A gravity supply will be much cheaper and therefore will avert failure of settlers and bankrupt communities. There is no anxiety about water payments where the lands are settled and improved. Payments will begin, and the water will be used as soon as it is available; but there is a financial problem on 70 000 acres of unleveled, uncleared, and unoccupied land which forms a part of the scheme. The owners of this land are widely scattered. Hardly any of them expect to become irrigators. They wish to sell. There is little danger of inflated prices. The land has been appraised and the owners have agreed to sell at the appraised price, which is nominal. Cheap land, however, does not insure settlement and cultivation. Here, as in the other case referred to, credit and co-ordinated action are necessary. Part of the land is owned by the State, part by purchasers of State land grants, and part by men who acquired it under the homestead, grazing, and similar acts. A small fraction is owned by the United States. If it is necessary to wait for these independent agencies to improve and develop these farms or find settlers to do it, it will be many years before the water made available is used and before construction costs are returned to the Reclamation Fund.

Anxiety in regard to the financial outlook is met by the statement that the Government is protected in the repayment of its expenditure by district contract. It is true that all the lands in these projects are obligated to pay the entire construction cost and this obligation is a first lien on all the land, but it would impose an undue burden on the developed lands to require them to pay the charges against the undeveloped lands. A part of the project could not carry the cost of the whole. As a practical matter, solvency and settlement are closely related.

The measures for aiding settlers in farm development, suggested in the Committee's report, are entirely inadequate. State aid has been sought. Legislation to require this has been considered in Congressional committees, but investigation showed that some States lack the means to extend this aid, some are prevented from doing so by Constitutional prohibitions, and in every State there is small prospect of political support for this co-operation. The Federal Land Bank has not been, nor is it likely to be, of any assistance in changing raw land into farms. It does not loan money except on income-producing farms, and that means loans are withheld until after the problems of settlement and farm development have been solved.

There is great reluctance in Congress to do more than the Government now does. The reasons for this reluctance are not to be ignored, and it is desirable that further action be avoided and that settlers be found with money enough to make their own improvements and buy their own equipment. There appears to be little hope of this on some of the older projects or on some of those now building. It is the writer's conviction that one of two things should be done: (1) Either provide aid in carrying out the second stage of reclamation; or (2) quit building canals to irrigate unimproved land.

The latest economic report on settlement and farm development recommends that the Government purchase all privately owned, unimproved land on a project before construction begins. If this were done, it would forestall land speculation, enable roads and ditches to be laid out to meet the needs of irrigation, and prevent the imposition of heavy State and county taxes before development is completed. Whether this action is taken, it is desirable that the States be more co-operative than in the past. The rule now is to raise taxes as soon as construction begins. This imposes a burden on the owners of partly improved farms that makes payment of construction costs difficult and sometimes impossible. The heavy tax burden is one of the arguments used for political action in writing off or postponing payment of construction costs.

A bill now (1928) before Congress is intended to provide a laboratory test of aid and direction in settlement. It authorizes the appropriation of $500 000 from the Reclamation Fund. It limits the expenditure on any single farm to $3 000 and restricts loans to provide for the erection of farm buildings and the preparation of land for irrigation, the money thus advanced to be secured by a first mortgage on the land and to be repaid with interest in installments extending over twenty years. If anything is done it should be done with care. If the $500 000 is authorized, not more than $100 000 should be appropriated in any one year, and no further authorization should be made until

at least one-half these advances has been returned to the Reclamation Fund. This might be arranged through loans to settlers from the Federal Land Bank. Improvements made from these advances would make Federal Land Bank loans possible.

There is also a fear that lending money to settlers would lessen their initiative and self-reliance and tend to make them leaners on the Government. That objection was made to the Federal Land Bank legislation. The same objection applies with greater force to building canals by the Government. It might be said, "Let settlers build their own canals and reservoirs." The answer is that this is impossible because of their cost. The high cost of changing raw land into farms makes it impossible also for worthy, industrious home seekers to get started without aid. There is a kind of aid which does undermine independence and self-reliance, and another kind which strengthens hope and inspires effort. That is what wisely directed credit in farm development would do.

### Achievements of Federal Reclamation in Completing Private Development

It is well to emphasize the gratifying social and economic results which have followed the Government's activities in supplementing or completing district or private development. By taking over the canals of Salt River Valley and building the Roosevelt Reservoir, Federal reclamation rescued discouraged and helpless irrigators and made Salt River Valley, Arizona, one of the most prosperous irrigated sections of the country and a great economic asset of the State. Without similar action the Carlsbad Project in New Mexico would now be only a memory.

In the Weber Valley, in Utah, a reservoir is being built (1928) to furnish water for late irrigation to intensively cultivated land. It will more than double the value of the crops grown. This additional water supply may be likened in value to the water which puts out a fire. It will save disastrous losses in dry seasons and make possible greater profits in all seasons. There is no worry about the payment of construction costs. The water will be used and the payments made according to contract.

The Government has built two reservoirs on Snake River, one in Wyoming and one in Idaho. It is difficult to state adequately the contribution this has made to the success of irrigated farming in Idaho. Only the Federal Government could have co-ordinated the different interests necessary to carry out a scheme extending over State boundaries. A part of this stored water is being used to give an additional supply to 80 000 acres of land first developed and settled as a State irrigation district enterprise. After farms had been improved and prosperous towns had grown up, it was found that the water supply was inadequate, and ruinous losses from failure of crops were suffered in dry seasons. Towns were shrinking in population and business and farms were being abandoned. The Government, by providing what was impossible to local effort, has restored confidence and prosperity. In the Snake River development there is no uncertainty about the repayment of Government cost. A part was repaid in advance by the water users.

The improvement of an old development and the complete utilization of the resources in land and water through an entire drainage area, are being carried out in the Yakima Valley, Washington. This kind of development is specially suited to the Federal Government. It is solvent and beneficent and there is a broad field for its extension.

The passage of the Adjustment Act in 1926, inaugurated a new era in Federal reclamation. The necessity for this legislation grew out of the hard times which followed the World War. It made it impossible for farmers on some projects to meet their payments. When owners of improved farms in Iowa and Illinois were being sold out, farmers on partly improved farms, under reclamation canals, found their expenses greater than their incomes. It was impossible for them to recover under existing contracts. Congress recognized this situation and passed an Act under which the annual payments of indebtedness in some districts were extended from 20 to 30 and 40 years. The land in all projects was classified in accordance with scientific soil surveys; payments on unproductive lands were cancelled; land injured by seepage, or which from other causes would not at the time grow profitable crops, was given temporary relief from payments. The loss to the Government from this action has been greatly exaggerated. The permanent loss was estimated at $14 667 965. Some of this will be recovered. The temporary loss was fixed at $12 788 406. There are hopeful indications that a large part of this will be paid.

Delinquent payments were added to the construction debt. The Reclamation Bureau was authorized to employ economic experts and practical advisers. The foolish idea that practically every one can succeed as an irrigation farmer was discarded and provision was made for examining home seekers by a local board. This has proved a protection to the inexperienced and over-sanguine and is giving reclamation a fair chance to show its value. The Secretary of the Interior has required settlers to have not less than $2 000 in money or equipment and this leads them to investigate how much developing a farm will cost and to plan their operations with more care.

This Act authorizes the transfer of projects or parts of projects to the water users. Eighteen districts under ten projects have been turned over to local control in the period, 1926-28. Where this is done the Government is relieved from any further expense for operation and maintenance. These changes have promoted co-operation and good feeling between water users and the Government. They have improved the morale of projects and helped to increase construction payments. In 1927 these payments were more than $1 000 000 greater than in any previous year. Delinquencies once so alarming have almost disappeared. Farm practices are improving. More valuable crops are being grown. There are more acres of sugar-beets, more dairy herds, more farm flocks of sheep, more poultry, and more market gardens. In 1927, the crops produced on the 2 504 046 acres irrigated from Federal works were worth $133 207 210, which is an average of $53 per acre, or two and one-half times the average acre value of crops in the United States. The value of this one crop almost equals the entire debt of settlers to the Government. Two such crops will be worth more than the Government has spent

on reclamation since the Act was passed. Another crop of equal value is expected this year (1928).

To complete existing projects in accordance with the 10-year program submitted by the Secretary of the Interior to the President and Congress in 1926 will require about $100 000 000. As the average income of the Reclamation Fund is about $10 000 000 per year, there need be no nervousness about Federal reclamation increasing the agricultural surplus during the next decade. The endorsement in the Committee's report of this conservative plan of development and of the other economic changes wrought by the Adjustment Act is greatly appreciated.

In its limited field reclamation is one of the most difficult activities of the Government. The Act requires that all money spent shall be repaid. That is impossible, although the Reclamation Bureau has striven to live up to it. Each new project presents new conditions and requires the overcoming of new obstacles. Dams have to be built in remote localities. The suitability of crops to soils has to be tested. Communities have to be organized and markets established. Reclamation has led to a creation of wealth in land many times the cost of the works. Its contribution to other industries, to commerce and trade, entitles it to a credit and support it has not always received. From one town on a Federal project where twenty-five years ago there was nothing but range cattle, a single railroad in 1927 did a business of $800 000. The indirect benefits from reclamation include help given in solving the problems of soils and climate, improving irrigation practices, founding rural communities which are an economic and social strength to the nation, and creating a wealth in land many times the outlay for works.

## DISCUSSION

GEORGE W. FULLER,[24] M. AM. SOC. C. E.—This report is of great interest to all who have occasion to consider present or prospective reclamation projects. Obviously, there is more irrigated land than is now needed to supply farm products to the population of Continental United States. Unless a tariff schedule can be adopted with other arrangements such as to promote the successful sale of farm products abroad, the future of irrigated lands in the Continental United States will depend largely upon the relation between supply and demand as affected by increases in population. Therefore, care should be exercised to guard against the development of irrigation projects tending to cause a continuance of excess production of farm products as compared with market demands.

It is doubtful whether American citizens in general realize how this question of excess production is being affected by a marked decrease in the rate of population growth in the Continental United States. Statistics bearing on this subject have been analyzed by many writers and are well summarized by Dublin.[25] Since the first Federal census in 1790, the United States has doubled in population on an average once in 27 years. During the middle of the Nineteenth Century, however, when immigration from Central and Western Europe was abundant and the growth of the colored population in the Southern States was very rapid, it took only 20 years for the population to double.

The situation is now changed. Excess of birth rate over death rate according to the 1920 Census records showed an increase in population of about 11 per 1 000, or 1.1% per year. This indicates that it would take about 60 years for this country to double in population; that is, on the basis of uncorrected birth and death rates, which vital statisticians say should be adjusted so that the influence of existing conditions will have its due *pro rata* effect on birth and death rates for groups of persons of different ages.

The slowing up of the increase in population in this country is related to many factors. Among them may be mentioned the restriction, since the World War, in European immigration and changed viewpoints in the home with its complications as to servant questions and the continuing custom of the native stock to have small families. One of the effects of pre-war unrestricted European immigration followed by present restricted immigration is that there exists in the United States an unusually large proportion of female population of child-bearing age. Continuance of restricted immigration will prevent increments to this group from such source and hence the group as a whole will become relatively smaller with a lessening birth rate in the future as compared with recent years when the effect of pre-war immigration is still felt.

Without going into great detail it is sufficient to state that when consideration is given to the foregoing item; to the statistics of life expectancy of persons in each group, arranged in ages; and to the effect of present environ-

[24] Cons. Engr. (Fuller & McClintock), New York, N. Y.

[25] "Health and Wealth," by Louis I. Dublin, Harper Bros., 1928.

ment with its modern sanitation, preventive medicine, and personal hygiene, reconstructed birth rates and death rates are derived which indicate that it will take this country about 120 years to double in population. In fact, there are prominent statisticians who state that the population of this country will become stationary with a maximum about 200 000 000 people by 2100. Others on the contrary predict, on the basis of ultimate possible food production, a maximum of 300 000 000. Whatever may be the precise outcome as to population growths it is certain that there is nothing in sight to indicate that an increased demand for farm products justifies the early development of large new irrigation projects.

W. F. RUSSELL,[26] ESQ. (by letter).—The engineering problem of reclamation has been well taken care of to the extent that great irrigation systems have been completed; but the building of a system of canals is only the beginning of reclamation. To say that the responsibility of the Government ends with the building of canals may be compared to the manufacturer of an automobile contending that his car was finished without supplying it with wheels. The preparation of the land to receive the water and the placing of settlers to till the soil is the most important part of the reclamation of arid lands. The money invested in dams, reservoirs, and canals is wasted if this other part of the work is not done just as scientifically and well as was the planning and construction of the canals. In most cases the cost per acre for land preparation and settlement will exceed the cost of construction.

The advancement in the scientific pursuits has been very rapid, and irrigation reclamation is no exception. The man who is to succeed on the land, who is to utilize the water that comes through the canals, and who must produce from the land through the proper use of the water, must be a scientist in every sense of the word. He must acquire more scientific knowledge to be a good farmer than to conduct any other business, and it is time that the people of the United States realized not only that farming is the most important of human activities, but that the farmer is entitled to, and should receive, just and fair compensation for his investment, for his labor, and for his responsibility. Too little importance has been given to the farmer by the leading men, both in Government and financial circles.

If the projects that have been built by the Government are to succeed, the Government must carry the responsibility of completing the work, and that cannot be effected until very acre of land under the canal is producing. The settler cannot finance the preparation of the land. It requires a number of years as well as capital expenditure, to develop raw land to its maximum capacity of production. It also requires considerable capital for a farmer to support his family through these years of development.

The writer has found that a settler going on to raw land with $2 000 to $3 000 is financially embarrassed before the land can be developed to a point where it will produce a comfortable living for his family and begin to pay the capital charges against the land. This condition must be overcome by some policy of finance. It may be a loan against the land, or it may be placed as

[26] Field Superv., Colonization Dept., Lethbridge Northern Irrig. Dist., Lethbridge, Alberta, Canada.

capital cost and be added to the price of the land. It does not matter how it is done. It is the responsibility of the Government to protect the huge investment it now has, and to protect the interest of the settler, that will make the project a success.

The Government policy of financing construction is to be commended, but it did not go far enough. There are those who might say that this would be charity and that, if the Government were to undertake to supervise the development, it would be paternalism. Yet they are willing that supervisory methods be used for the construction of the dams and reservoirs, and the laying out of the canals; furthermore, they are willing that the same methods should be used in the construction of the power plants and lines of distribution; and that other lines of industry should use the same methods. They will agree that it is necessary that a policy of financing must be instituted in order that these industries should succeed; but if the same principles are applied by the Government which has already gone a long way with the work of reclamation after all other agencies would go no farther, it is charity and paternalism.

The problem of proper development of the land already under Government canals and the settlement of the same by a class of people fitted for the work is one that will require more skill and closer supervision than any part of reclamation the Government has ever attempted; and until some policy for successfully financing the unoccupied land is worked out and put in operation, the great reclamation problem will remain unsolved.

In Idaho and Arizona, farms that are properly developed, properly equipped, and properly operated, are paying their way. The families on these lands are enjoying some of the modern conveniences and necessities, and they are contented. Until the unoccupied land is in the same condition, its owners will not be able to pay its portion, and until the proper financing and supervision is available it will continue to be unoccupied.

The class of settler required for this land is no longer willing to undergo the hardships and privations of the old days. Families demand a standard of living in keeping with the times, and if the rural population is to continue to advance in education, etc., and be able to handle its business in competition with the world, there must be modern conveniences on the farm. What manufacturing concern would think of trying to operate without the latest and most efficient machinery and the latest methods to meet competition? Just the same thing should apply to the development of new lands if they are to become a success; modern methods and the best machinery must be used.

The Lethbridge Northern Irrigation District, in Southern Alberta, Canada, would never have been successfully settled had it not been for the policy of supervision and financing put in operation by the Alberta Government. After four years the Government is just beginning to see the results from the application of this policy. It has fully demonstrated, however, that it is "a step in the right direction". In less than four years the district has been fully settled with a desirable class of citizens, most of whom are contented. Fully 75% are in better financial condition than when the project was begun. Most of the settlers placed on the project have stayed. Of 738 families placed, only

26 have moved away. While many problems have been encountered and mistakes have been made, the Alberta experiment has been fully justified. No other agency could have attained the same degree of success.

NILS A. OSLEN,[27] ESQ. (by letter).—Certain conclusions embodied in Mr. Lippincott's paper were expressed by Secretary of Agriculture Jardine[28] in discussing the significance of the interest exemption on construction charges as a special subsidy to particular locations. He indicated that such a stimulus in principle represents a form of discrimination against established farmers and new settlers elsewhere, and that, in the present period, it is not justified by a need for enlarging the basis for the Nation's supplies of farm products.

At the same time he pointed out, as Mr. Lippincott has done, that reclamation is frequently connected incidentally with other objectives, such as flood control, promotion of navigation, and development of water power. Under these conditions the advisability of a particular project must be determined by consideration of the entire complex of objectives. Even under such conditions, it would be difficult to justify the interest exemption for reclamation.

L. C. GRAY,[29] ESQ. (by letter).—In connection with Mr. Lippincott's interesting paper, attention may be called to the views of the late Mr. R. P. Teele,[30] formerly of the Bureau of Agricultural Economics, U. S. Department of Agriculture. Mr. Teele had made intensive studies of these matters, and his findings, therefore, have an important bearing on the issue.

The Committee has rendered a public service by its analysis of the Federal Reclamation Policy. Mr. Lippincott might have emphasized still further the points that the exemption of interest (1) increases the local pressure to obtain Federal funds for reclamation projects; (2) tends to stimulate the undertaking of projects which would not be justified by prospective farm income if interest were considered; and (3), therefore, imposes a level of capitalization which must be written down to a lower level when the project is acquired by subsequent purchasers after the period of exemption is concluded.

FRANK ADAMS,[31] M. AM. SOC. C. E. (by letter).—The writer is in hearty agreement with most of the recommendations embodied in the report of the Committee. His remarks will be confined to those recommendations, or parts of recommendations, with which he does not fully agree.

Item (1) in the report holds that the waiving of interest payments to land owners on Government reclamation projects is unwise and that, in the future, Government contributions should appear in the assumption of a part of the cost of project works.

In considering this recommendation one should have clearly in mind that the principal object of Federal reclamation has been to reclaim areas which without Government aid would have remained idle or unproductive. In some cases, it has been the large amount of capital required for the construction

[31] Prof. of Irrig. Investigations and Practice, Univ. of California, Berkeley, Calif.

of reclamation works which put them beyond the means of private and district enterprise. Again, it has been the excessive unit cost, and the long time required to complete the reclamation through actual settlement and utilization of the land. In still other cases, it was the inability of private or district enterprises to place on the land reclaimed responsibility for paying the cost of the necessary reclamation works. In a few instances, most notably the pending Boulder Canyon development, the Federal Government has been the only agency politically competent to cope with the related interstate and international complications. The Reclamation Act was passed, therefore, not primarily to bring more land into agricultural production, but as an aid to Western development, which, at the time the Act was passed, was lagging. It was very generally accepted as a desirable measure designed to put the opportunities for development in the arid and semi-arid West on a par with those in the East and Middle West.

In carrying out the National Reclamation Act, it was both desirable and inevitable that the Government should proceed along more comprehensive lines than would have been justified in the case of strictly commercial and district reclamation enterprises. This meant not only added cost in surveys and construction, but also the opening of lands for settlement on such a scale as to involve long delay in their full utilization. In fact, few of the Federal reclamation projects are yet completely settled. The burden of settlement, which has fallen almost wholly on individuals and inadequate local credit agencies, has been a heavy one. Nevertheless, the advantage to many Western States and communities has been tremendous, and the nation has benefited greatly through this process of equalizing opportunities for its people to create homes and develop industries in those parts of the country which, although rich in resources, still lay more or less backward and dormant.

No such reclamation program as has been or is being carried out under the National Reclamation Act would be possible without a large financial contribution by the Federal Government. This has always been recognized and the contribution has been made by waiving interest on the cost of reclamation construction. This procedure has been fully justifiable in view of the purposes to be accomplished. However, the waiving of interest has not been stressed, and, consequently, the actual amount of the Federal contribution has not been known. Therein perhaps lay the chief evil of the system.

There is no question that direct assumption by the Federal Government of that part of the cost of reclamation works which it is to pay, as recommended in the Committee report, is abstractly the more desirable procedure; but will it work? That is very questionable. The writer believes, therefore, that until Congress is ready to face the facts frankly and to adopt direct Government aid, whether in the West, East, North, or South, as conditions may warrant, the present plan of contributions by the waiving of interest should not be abandoned. The work of Federal reclamation has not yet been finished because there are still desirable projects pending which can not be built without Government assistance. The present plan has worked, even if not always entirely satisfactorily, and should be retained until some other plan has been shown to be feasible. The writer is ready to assist in bringing

about a change in the public viewpoint, but he is not ready to condemn as unwise the plan that has been responsible for such great benefits as have been accomplished thus far under the National Reclamation Act.

There is another phase of the waiving of interest on the cost of Federal reclamation construction that should be mentioned, for it should be considered when and if the plan of direct Federal assumption of part of the cost, as recommended by the Committee, is put into effect; that is, the need for waiving interest during the period in which settlers on the projects are becoming established. The period during which land is being cleared, leveled, and checked for irrigation, and brought into production, is that in which settlers most need help, but find it most difficult to obtain. The land is not then earning either interest or operating expenses. Lacking help, many of the settlers fail, not only on Federal, but also on commercial and district, projects. The Government could well afford to forego interest on its projects during this period, regardless of whether interest is charged later.

Item (6) of the Committee recommendations holds that the output of power and of water at Federal or State works should be disposed of at wholesale and not at retail. If the Committee would insert the phrase, "in general", the writer could agree. Many public agencies, some of them irrigation districts, have successfully retailed both water and power and are still doing it. It is conceivable that in some cases both the Government and the States will find it desirable to retail the output, perhaps only temporarily, and a policy should not be so crystallized against such procedure as to preclude it when necessary to accomplish the largest benefit, whether to the Government, to the State, or to the consumers. Each case should be decided on its merits and not in advance by doctrine.

Committee Recommendation No. (9) that, except in the case of commitments already made, it is undesirable for the Federal Government to bring new areas under cultivation, coincides with recommendations made by numerous farm organizations, as well as by some of the agricultural economics experts of the Federal Agricultural Department.

The writer does not believe that over-production in certain branches of agriculture and in certain areas of the country at any particular time is necessarily any reason for ceasing the reclamation of new areas if the projects which would reclaim those new areas are themselves economically feasible and desirable because of their contribution to the general welfare of tributary areas. There may be over-development in the country generally at the same time that there is under-development in certain important areas. The test in beginning a new project should be: Is it economically feasible, when viewed in the light of long-time production and price trends, and is it in line with equalizing opportunity as between different sections of the country? Furthermore, can it be settled within a reasonable time? If the answer to either of these questions is in the negative, construction of the project should be postponed.

The Committee probably was led to recommend that no new projects be started at this time by the lack of needed settlers on some of the existing

Federal projects and in many irrigation districts. Admittedly, the demand for land is not active, partly because general agricultural conditions have been unsatisfactory in some parts of the country, and partly because of the small number of settlers with the necessary capital and farm experience to make a success under the generally high costs of present-day projects. However, there is need for Federal aid in some States in connection with supplementing the water supplies of existing enterprises. To cite a single example, California is studying her water resources with a view to the adoption of a comprehensive plan of water utilization. There are areas of surplus water and areas of deficiency, and the cost of equalization will be very high. The benefits to accrue will ultimately justify the expenditure, but there is need of Federal aid in financing, as well as in planning and building the necessary works. Other States have similar problems, and it will require many years for their solving. In the meantime, economic conditions will continue to change and much of the present slack will be taken up.

The writer also desires to take exception to Item (14) in the Committee's recommendations. The first sentence reads:

"Land settlement, including paternalistic, financial, or any other kind of assistance to the individual farmer, should be treated as a local matter and should therefore be made the concern of the State or locality rather than of the United States."

While firmly believing in the soundness of Governmental land settlement policies that have been successfully put into effect in some other countries, the writer concedes that the present public attitude is generally against those policies for this country. However, if the Government is merely to make existing reclamation projects successful it must do what is necessary to complete their settlement as rapidly as possible. The Government is not justified in asking settlers to go on its projects unless conditions are right for their success.

The Government should at least put the land in the projects into such condition that the new settlers can get a foothold without exhausting their meager capital and being forced to abandon their farms before they are on a profitable basis. The expenditure of $20 to $40, or more, per acre for leveling land and otherwise preparing it for irrigation is not unusual on some of the desert-land reclamation projects. This work could be done far more economically by the Government, working on a large scale with heavy machinery, than if left to the individual farmers. The writer does not advocate having the Government prepare for irrigation all the land on its reclamation projects, but he believes that when the cost of preparation is high and the prospective income per acre is relatively low, both the Government and the individual settlers would be the gainers if the preparation of enough of each farm to permit the immediate planting of perhaps one-half of it, or a minimum of 20 acres, were to be included in the Government reclamation program, the cost of this to be paid, with interest, within a relatively short period after settlement.

This would foster settlement and increase the percentage of individual success by advancing the time when the farms would be producing an income.

Failure to obtain a quick income, coupled with the heavy expense of early farm development, and the general lack of local credit, except to those who have substantial resources, is the chief cause of failure of both settlers and projects. Theoretically, the State or some local agency might do this preliminary work which is of so much importance to the settler. Practically, however, it is never done, nor is it likely to be undertaken except by the agency which is most vitally concerned, which, in the case of Government reclamation projects, is the Government itself.

There is still another function which the Government should perform on its reclamation projects but which the Committee might class as "paternalistic". This is organizing the community development and advising as to cultural practices and types of production, the latter being perhaps of most importance when the settler is just starting. Possibly the governmental agency that builds reclamation works is not the one that is best fitted to lead and advise in such matters, although it is not clear that this is the case. At any rate, some governmental agency should be charged with that responsibility, because the Government should not let go as long as its funds are still tied up. The help of local agencies of course should be obtained to the limit, and in some cases such agencies could carry the main part of the burden; but so long as the project is under Federal control, the Government should be privileged to perform such functions as are deemed necessary by those who carry the responsibility for its success. Otherwise, the Government should stay out of reclamation and confine itself to constructing major works, such as the Boulder Canyon, or some of the other large dams built by the Bureau of Reclamation. Real reclamation is not accomplished until the settlers on the project lands are well on their way toward being established.

It is exceedingly desirable that all the worthy Federal reclamation projects should reach the successful stage at the earliest possible date. The Government can afford the loss that will accrue to the Reclamation Fund through delay, but the settlers on the projects cannot, because such projects are now very largely organized as irrigation districts in which all land owners have a joint liability for the construction charges and costs of operation and maintenance. Any competent and solvent business man would supply whatever aid is necessary to complete the success of these projects that can succeed, and there is no justification for the Government not doing as much because of a fear of being "paternalistic".

M. J. Dowd,[32] M. Am. Soc. C. E. (by letter).—It is apparent that the Committee has given considerable thought and study in formulating the principles of "A National Reclamation Policy". The writer is in accord with a majority of these principles, but would like to comment on one or two of them which in his opinion should be questioned.

In considering Principle (1) it should be remembered that the Reclamation Fund is built up from sales of public land and not from taxation. The arid public land is of little value until water and labor are applied. If the original capital costs the Government nothing and it is to the interest

[32] Chf. Engr. and Gen. Supt., Imperial Irrig. Dist., Imperial, Calif.

of the country that the non-productive valueless land be made productive and if an individual can be found who will set his labor against the free capital which the Government furnishes, it does not seem as if the Government would be justified in making a profit out of the transaction in the way of interest or otherwise. Certainly all the money which comes out of the sale of public land should go back into the development of such land and in so doing the whole Nation profits by the increased wealth. Even where the Reclamation Fund is used to develop land in private ownership, which was formerly public land, the writer believes such land should not pay interest on the capital invested; but in any event, where the development concerns public land alone it seems as if the present policy of not charging interest certainly should apply.

The enforcement of Principle (9) would mean placing an embargo upon agricultural development in the West which is both unwise and unnecessary. The following quotation is taken from a speech of President Coolidge, regarding reclamation in the West:

"A country growing so fast as is our own cannot limit its considerations to immediate necessities. Many people now living will see this a country of two hundred million inhabitants. The national interest will be served by promoting the widest diffusion of population. The national security, the best social development, the wisest untilization of natural resources, all demand this. Criticism of such a program of encouragement, on the ground that there is already an over-production in agricultural products, lies in the lack of understanding that the projects take many years for development; that they furnish only a small portion of the total increased food supply required even by our increasing population; and that the utilization of their supplies lies in the development of the West itself. It is my purpose, unremittingly, to stimulate and encourage the development of these great projects by every authority of the Federal Government."

The writer believes it is a mistaken idea, as expressed in Principle (9), that reclamation should be curtailed simply because, for the moment, there is an over-production in this country of certain staple commodities. Reclamation projects that are easy of development, have been completed and those that are now being considered are not only complicated but costly, which means that future argicultural development in the West necessarily depends upon reclamation by public agencies.

A reclamation project requires from 5 to 25 years to develop. There are only about 20 000 000 acres of unreclaimed arid land for which there is a water supply available or for which such a supply can be made available. If it were all put to crop as rapidly as possible, it would not be even a serious factor in the National agricultural requirements by 1950. It is estimated that the population then will be at least 150 000 000, requiring production from about 431 000 000 acres in addition to pasture lands. In 1919, there was a total of about 365 000 000 acres in crops harvested. In other words, by 1950 the country will require about 66 000 000 acres more land for crop purposes, with the same yield per acre and the same consumption per person. If all the 20 000 000 remaining irrigable acres in the Western States are put under irrigation, there will yet remain a shortage of 46 000 000 acres

21 years hence. This indicates that, in order simply to keep pace with normal development, there should be reclaimed about 1 000 000 acres per year.

During the period of 1910-20 the population of the country increased about 15% and, in the western part, nearly 35 per cent. These Western States, and particularly California, import a great quantity of their food supply at the present time. California exports virtually nothing in quantity except fresh fruits and vegetables. The coastal cities import from without the State from 10 to 40% of their dairy products.

It is safe to assume that the population of the Western States will increase faster in the future than it has in the past, because of numerous economic conditions, such as climate and the Pacific trade. Therefore, a program of retarded reclamation simply means increased cost of food supplies for the West and a consequent slowing up of western development.

As has already been stated, the carrying out of the policy proposed by this principle means an agricultural embargo on the Western States, leaving the more humid sections of the country to develop as rapidly and as much as they may desire. With approximately 40% of the total area of the United States within the arid States, the placing of such an embargo on agriculture for the benefit of the remaining 60% is gross injustice. Furthermore, the adoption of this principle in no manner affects reclamation of additional areas in either Canada or Mexico.

In the case of Mexico, there has been in recent years a rapid development of reclamation near the American border, and many hundreds of carloads of peas, tomatoes, lettuce, etc., are coming into the United States every year. Because of economic conditions in Mexico such products can be produced cheaper than in this country. With proper protection against competition from this source, there is at present (1929) a market for a considerable increase in the vegetable industry in the United States; but without such protection, even those projects now producing fruits and vegetables will not long be able to compete with the foreign growers. Such protection is economically sound and in accord with the tariff policy of this country.

There is no question as to there being an over-production in certain staple commodities produced in the United States, but this does not hold true for all products. In the Western States, at least in California, there is a shortage of dairy products, hogs, and beef cattle. It has been noted that what often appears to be over-production is simply poor distribution. This applies particularly to the vegetable and fruit industry, where it has been shown many times that the returns to the grower are governed primarily by the manner in which the product is distributed rather than by the supply of the product. Furthermore, there should be considered the rapid increase in the use of certain farm products, such as fruits and vegetables. The saturation point for the orange production was predicted many years ago and yet, because of increased use and co-operative marketing, the returns to the grower are better to-day (1929) than they were ten years ago. As a further illustration, consider the lettuce industry in the Imperial Valley. Shipment from 2 000 acres of lettuce in 1913 flooded the market and the

prices received would hardly pay the freight; yet in 1929 about 12 000 carloads were shipped and the net profits are estimated at from $2 500 000 to $3 000 000. The same holds true for the cantaloupe industry in Imperial Valley. In 1908, the market could not profitably absorb 1 804 carloads of cantaloupes but, in 1927, more than 17 000 carloads were shipped from Imperial Valley alone and very good returns were received by the growers.

Indications all point to the end of the agricultural depression which followed the World War. Because of this, and the fact that during the intervening period there has been only a slight expansion of reclamation projects, the writer believes the time has arrived for a resumption of the development of Western arid lands.

C. E. GRUNSKY,[33] PAST-PRESIDENT, AM. SOC. C. E. (by letter).—The report of the Committee on a National Reclamation Policy is necessarily more or less of a compromise. Members of the Committee without retracting in any measure the views expressed in the report remain free to amplify their attitude toward the policy therein outlined and will, it is hoped, contribute discussions which may throw much needed light on a problem that has vexed other countries besides the United States.

In line with this thought the writer will refer to several points which should receive somewhat more attention than has been given them in the supporting statement of Chairman Lippincott.

In the first place it seems fundamentally wrong and unwise to make indirect appropriations for the carrying out of public improvements, such as land reclamation. If a project is worthy and deserving of Government aid the appropriation of funds therefor should be a direct appropriation for a specified purpose. Under the Reclamation Act the moneys received from land sales and, in part, from oil royalties drift into a fund which, for a time, was at the disposal of the Secretary of the Interior; since 1914, however, the Secretary's allotments are subject to authorization by Congress. Losing sight of the fact that such moneys would naturally have gone into the United States Treasury and have been there at the disposal of Congress, it was prescribed in the Reclamation Act of 1902 that these moneys should be used by the Secretary of the Interior for the reclamation of arid or semi-arid lands. One-half the money collected in any State should be expended within that State if there were available projects. Due to political exigency, an unnatural demand for the expenditure of funds on work of doubtful merit resulted and this fact may account for the undertaking of some of the earlier projects which should have been let alone. Believing that the proceedings under the law were unsound in principle, unwise, and not in the best interest of the development of the country's natural resources, the writer is opposed to the indirect appropriation and believes that, in this respect, a new policy should be adopted.

In the second place the aid extended by the Federal Government when wet or arid lands are to be reclaimed should not go beyond the regulation of stream flow and the control of floods. The water of rivers and lakes together with underground water is this country's most valuable natural resource. It

[33] Cons. Engr. (C. E. Grunsky Co.), San Francisco, Calif.

has been the practice to allow the title to reservoir lands to be acquired by private parties, by districts, and by municipalities without regard to the construction of works in conformity with a comprehensive plan and without Government control of the manipulation of the reservoirs. The regulation of the stream by storage should be such as to produce "the greatest good to the greatest number." Consequently, the people should never allow works for the regulation of the flow of a river to get out of Government control.

This does not mean, however, that the United States or the individual State should be the only agency for the actual construction of works. The privilege should be granted to any State, to a group of States, to municipalities, to districts, and even to private parties, always provided, however, that the works conform to a comprehensive scheme of development and that permits shall be conditioned upon use of the storage facilities in conformity with the regulations prescribed in the case of the international, interstate, or navigable streams, by the United States and, in case of other streams, by the State in which they are located.

In the third place the capital investment made for stream regulation and the contribution toward flood control by the United States or by an individual State should not ordinarily be made subject to repayment by the benefited parties. Instead of this practice which prevails under the Reclamation Act there should be delivery of the output of water, or power, as the case may be, at wholesale rates to the district or municipality or private concern which can use it to the greatest advantage. Moreover, when there is a choice of the region in which the output is to be used, due weight should be given to the potential development of the remote sparsely populated sections of the country. In the long run the large development of the outlying regions making for a maximum of decentralization will be of greatest benefit to the nation. Furthermore, commitments should not be of such a character as to curtail this development.

If, under the Reclamation Act, each district served with water had been required to pay for the water delivered to it at a fixed wholesale rate and had been left free to distribute the water to the individual farms, all the trouble in recovering the investment and carrying a project during the development period would have been avoided. The cost of carrying a project during this period, under such a program, would fall on the Government, as it should, and, in that event, this cost could be set down as the Government's contribution to the success of the enterprise.

In the fourth place the owner or original purchaser of lands which are to receive water from a reclamation project, under the Reclamation Act, has received an indirect bonus, which has amounted to 50% or more of the cost of Government works. The giving of a bonus to a farmer or to a group of farmers does not assist farming as an industry. It is unsound in principle and unwise. The prospect of such a bonus immediately adds value to the land, and this value is pocketed by the original owner; it does not benefit his successor. Moreover, while the anticipation of such a bonus by the settler on the lands of the Government project has stimulated farming activities in certain selected localities there has elsewhere been curtailment of agricultural activity.

In recent years more than 30 000 000 acres of farm lands have gone out of cultivation. This, of course, must be ascribed to over-production. Careful consideration should be given, therefore, in the case of every Government-aided land reclamation project, not only to its physical, but also to its economic, aspects, the latter being as much as the former within the province of the investigating engineer.

Thus, for example, the writer, who was early connected with the studies which preceded the carrying out of the Sacramento Valley flood-control project in California, has repeatedly pointed out that the inclusion of Sutter Basin in the reclaimed area was a mistake. This basin, which has an area of about 60 000 acres, lies in a pocket between the Sacramento River and the Feather River. Under natural conditions it was subject to inundation by annual high waters of these rivers. However, a large part of the basin land lies so high that the spring flood waters drain off early enough to permit summer crops to be grown. The State should have purchased all the land in this basin and allowed it to be submerged at river flood stages, thus functioning as a retarding basin. The State would then have received some revenue from this area when farmed to summer crops. Instead of following this course, no study of economic advantages and disadvantages was made. The attempted reclamation has burdened the land with a heavy debt and has also increased materially the cost of the control works in the down-stream reaches of the river, because the withdrawal of the basin from the submerged areas has added to the river's peak discharge at all down-stream points.

In the fifth place land settlement enterprises are local in character and scope, and should never be undertaken by the Federal Government. It should be left to the individual States to organize such enterprises and to make provisions for whatever financial assistance it may be thought wise to extend to the settlers. As already stated, the United States should contribute toward the cost of flood control and, in the case of an output of power or water from the regulation works on an international, interstate, or navigable stream, it should dispose of this output at wholesale, thereby aiding municipalities and districts in securing water supplies, and assuring the success of worthy flood control and other reclamation projects in the several States.

Finally, it is in order to explain why the Engineering Profession must concern itself with such problems as that of shaping the National reclamation policy. The welfare of the country in the years that are to come depends on the utilization and development of its natural resources along well-considered, sane lines. The ordinary citizen is prone to give thought to the immediate situation only. Legislatures are all too frequently driven to conclusions by trading with a hope for local advantage. The engineer, with his mind trained to the careful weighing of every feature which has a bearing on his problem, is pre-eminently qualified to ferret out the fundamental principles which should apply in the conservation of water and other natural resources and to determine how best these principles can be applied. It is the duty of the profession to come forward and give the country the benefit of conclusions reached in this and similar matters. The report of the Committee is timely. While

the writer believes, as shown in the foregoing comments, that it does not go far enough, nevertheless it is a "long step in the right direction".

S. T. HARDING,[34] M. AM. SOC. C. E. (by letter).—This report consists of certain specific conclusions with only limited explanation. The explanatory statement by Mr. Lippincott is in many ways a clearer treatment of the subject than the report itself, as it includes the basis for the conclusions. The difficulty of preparing a report by a large committee representing various points of view on a highly controversial subject is obvious.

In the writer's opinion, the most important element in any policy of public aid to irrigation development is the basis on which such use of public funds may be justified and the extent to which aid may be warranted. The usual arguments advanced by those justifying such aid include the benefits of the added taxable resources, increased crop production, and opportunities of insufficiently financed individuals to obtain farm homes. In its first conclusion the Committee apparently recognizes some public contribution as proper. It recommends that such contribution should be in the form of payment of part of the construction costs rather than as an interest waiver. The report, however, is entirely silent on the policy which should govern in determining the extent of the public contribution or its basis of application in specific cases. If it is a proper public policy to spend public funds in land developments where title accrues to the individual land owners, there should be some basis of policy by which the proper extent of such contribution can be determined. The first conclusion as it is now worded can be accepted by both the advocates of full Government aid and by those opposed to any aid. The former can read into the conclusion a large measure of contribution, the latter practically no aid. In the writer's opinion the Committee has omitted the most important point on which definite conclusions might have been influential in relation to National reclamation policies.

That there is need for some definite policy by which the extent of any public contribution to irrigation development can be measured, is shown by the actions of Congress in regard to such aid in recent years. In December, 1924, Congress authorized the revision of contracts with existing projects on the basis of repaying each year on the construction cost 5% of the average annual gross value per acre of the crops for the preceding ten years. Several contracts were made with existing units on these terms. In March, 1926, such contracts were made with irrigation districts on the Boise Project. The so-called Fact Finders Report[35] gives the average gross crop return per acre for 1913-22, on the Boise Project, as $38.11, of which 5% would be $1.91, and the construction cost as $80 per acre, of which 11% had been repaid up to 1924. The new contract on these terms extended the repayment period from 20 years to about 40 years. The Kittitas Unit of the Yakima Project was adopted for construction by Congress in 1925, on the same basis of repayment. The published reports of the Bureau of Reclamation show an estimated construction charge of $148.75 per acre. The economic report estimated that 96.3 years would be required to repay the construction costs on the "5%

[34] Prof. of Irrig., Univ. of California, Berkeley, Calif.
[35] Senate Doc. 92, 68th Cong., 1st Session.

of the crops" basis. In 1926, Congress approved the construction of the Owyhee Project at an estimated construction charge for new lands of $160 per acre, with a 40-year interest-free repayment period. Secretary Work reported to the President that in his opinion the project was feasible and the cost would probably be repaid.

The Boise and Owyhee Projects are located in adjacent areas in Western Idaho and Eastern Oregon. They have similar conditions of elevation, climate, crop adaptability, and transportation to markets. The Boise Project is now relatively fully developed. It represents a typical area of its class in regard to crop returns and ability to pay. If the extension of time for the repayment of an $80 per acre charge on the developed Boise Project from 20 to 40 years was justified by the inability of the land owners to pay in a shorter period, there is an apparently obvious inconsistency in expecting the undeveloped Owyhee Project to "pay out" in 40 years with twice as large a rate of payment per acre per year.

In Conclusion (11) the Committee recommends that interest should be charged on repayment of construction cost and that "the interest rate should be low and the principal payments extended over a long period with no payments on principal during the early years". What is meant by a low interest rate is not stated. A 40-year repayment period without interest is equivalent to paying 2½% interest for 40 years and having the principal written off. Apparently, the Committee had in mind lower interest rates than 2½%, or longer repayment periods than 40 years, if present costs were to be paid in full. If, as recommended in Conclusion (1), the contribution should be in principal and not in interest waiver, with interest charged at 4%, one-half the principal would have to be written off in order to amortize the remainder in 40 years without exceeding the rate of payments for the full cost in 40 years without interest.

Projects such as the Owyhee will have construction costs equal to the present value of the lands to be served after they have been prepared for irrigation. If 4% interest is assumed as a proper rate of return to the Government, based on the terms of the Boulder Canyon Project Act, the Government is making a contribution of $80 per acre to bring about irrigation construction on these lands. This apparently represents present National policies. The Committee in its report does not indicate whether it considers present contributions more or less than are justified.

In his explanation of the report, Mr. Mead states that the measures for aiding settlers in farm development are entirely inadequate, and he recommends either that construction of canals for unimproved lands be stopped or additional aid in settlement be given. If a 40-year repayment period on construction costs without interest is not a sufficient attraction to settlers having the necessary funds to develop the lands, in the writer's opinion, Mr. Mead's recommendation for stopping development for unimproved lands is clearly sound. Neither the Committee nor Mr. Mead has presented any basis justifying a larger contribution than that now effective under the present repayment terms. If this contribution is insufficient to attract settlers with means to develop the lands, it may be an indication that settlers having such means

have a clearer judgment regarding the economics of land development than those responsible for such projects. Extension of additional public aid in the settlement of irrigated lands has not proved successful where it has been tried by Western States, either in securing the returns from funds loaned by the State or in satisfaction to the settlers.

The preceding comments are not intended as a criticism of the Committee, as the difficulty of reaching a unanimous report on such a subject is fully appreciated. In the writer's opinion more specific conclusions are desirable, even if the attempt to reach them results in divisions within the Committee with subsequent majority and minority reports.

H. H. DARE,[36] ESQ. (by letter).—The State of New South Wales covers an area of 310 700 sq. miles. Irrigation projects in this State, as well as elsewhere in Australia, are developed by the State, and the Commonwealth Government is not financially interested, except in one case, the Murray River, 1 300 miles long, at the head of which the Hume Storage Dam (2 000 000 acre-ft. capacity) is being constructed (1929) at the joint expense of the Commonwealth and of each of the three States of New South Wales, Victoria, and South Australia, which are watered by the river.

Under the New South Wales Act, which was passed before 1909, the right to the control and use of all water in all rivers and lakes in that State which flow through, past, or are situated within, the land of two or more occupiers, is vested in the Crown. No person is permitted to obstruct the flow, or change the course, of any such stream, or to divert water therefrom, unless a license has first been obtained. Before such a license is granted a public inquiry is held, at which it is possible for any interested person to appear in support of, or opposition to, the granting of the license. It should be noted that the State does not claim ownership in water, but merely controls the streams in the interests of the riparian holders, the license fees collected being sufficient only to cover the cost of administration.

Apart from irrigation of their own lands by landholders, irrigation development in New South Wales is of three classes, namely,

(1) Irrigation Trust Projects, in which the works are constructed by the State, and the cost is repaid by the landholders with interest over a period of years.
(2) Private Irrigation Projects, in which works for the supply of two or more landholders are constructed and paid for by the owner of land fronting a river or lake; and
(3) State Irrigation Projects.

In the case of Classes (1) and (2) the management is local, and the Water Conservation and Irrigation Commission exercises a general supervision only, and makes no advances to settlers. With regard to Class (3), the Commission may initiate and carry on a State Irrigation Project, subject to the provision of the necessary funds by Parliament. The process involves four steps as follows:

(*a*) Acquire all the land within the boundaries of the scheme.
(*b*) Construct and maintain the necessary roads, etc., as well as works for the storage and distribution of water.

[36] Commr., Water Conservation and Irrig. Comm., New South Wales, Sydney, New South Wales, Australia.

(*c*) Sub-divide the land into irrigation farms, allot water rights to each farm, and determine the price of such water rights.

(*d*) Make available the blocks for application by means of:

(1) Purchase in fee simple (freehold), with payments including principal and interest at 6½%, extending over 36½ years; or,

(2) Lease (in recent schemes as perpetual leases), with an annual rental as gazetted, for the first twenty-five years and, subsequently, as may be determined to be the fair market annual rental value, irrespective of any improvements.

Concerning Step (*d*), water is either measured at the outlet to each block on a per acre-foot basis; or, in some cases, where meters are not installed, it is charged as a fixed rate per acre per year, covering a specified number of waterings, with an extra charge per acre for special waterings, if required.

Conditions in New South Wales are different from those in the United States, inasmuch as the control of water is vested in the State, and the Commonwealth Government has no authority or interest in irrigation development, except as a fourth partner in the construction of the head storage and locks and weirs on the Murray River. The irrigated lands developed under State enterprise are already owned by the State, or are acquired by it before subdivision.

With regard to the payment of interest on the cost of construction in the case of Trust Projects (Class (1)), which is relatively small, the annual repayments to the State include the payment of interest and those made to a sinking fund to repay the cost of construction over a period of years.

In the case of the Murrumbidgee Scheme, which is the largest of the State Irrigation Projects, the principle was laid down that the cost of the works should not be repaid, but that the interest thereon, together with certain other charges, should be recoverable in the form of rent and water rates. At that time the tenure was entirely by perpetual leasehold, but, with the subsequent change of Government policy, under which conversion to freehold is permitted, the money received from such conversion is allotted partly as interest and partly as principal toward reduction of the capital debt. The values on re-appraisal of the land held under perpetual lease after the expiration of the first period of 25 years and subsequent periods of 20 years, and on conversion to freehold, are fixed by the Land and Valuation Court, if the settlers should make application therefor. Since these values are dependent to a great extent on the marketing position, they may not represent the figure originally estimated for the cost of land plus works. Such difference in values will represent State aid to irrigated agriculture.

In connection with the Murray River, a different principle will probably be followed, inasmuch as there has been no proposal to recover from irrigation settlers in this State the proportion of the cost of construction of the head storage, which is treated as a National work for which the State must pay. The cost of distributary works, however, will be recoverable from the settlers.

It has been argued that free head-works should be a general charge on the community, as in the case of bar harbors and certain other public works, the

benefit to the State being realized in terms of new settlers gained and in increased general prosperity. There is no doubt that on the rivers in New South Wales the regulated flow resulting from a head storage is of benefit to all the riparian holders, most of whom do not hold an irrigation block included in any State Project. To apply the principle of "betterment" to these holders would be difficult, and it is not possible under existing law.

The experience in New South Wales in regard to assisting settlers on irrigation farms is in accord with that in the United States, as referred to in Mr. Mead's paper, namely, that:

(1) Due to the increased cost of developing farms, and to the uncertain position as to markets for their produce, there are only a few settlers offering to enter irrigated lands; and
(2) Such settlers as are applying for farms have in very few cases sufficient capital to carry on without assistance. Such assistance is rendered by the State, either through the Water Conservation and Irrigation Commission, or through the rural bank, which raises its money by the same methods as an ordinary trading bank. This money has to be used for rural development purposes, either by way of advances to individual settlers or to co-operative groups.

The bank makes advances on irrigation farms by overdraft on current account, repayable on demand, with interest (at present) at 6½ per cent. Settlers must have the means to effect some improvements before the bank will assist. Advances are limited to certain percentages of the value, depending on the nature of the improvements. Irrigation settlers are not offered more advantageous conditions than those on non-irrigated holdings. Although it is now the policy to have the bank arrange for the financing of irrigation settlers, there are still a large number assisted by the Commission. These include some of the earlier settlers, and also the soldier settlers who took up farms without any capital, in accordance with the land settlement policy adopted at the termination of the World War. Following on the increase in the cost of production, and the fall in market values with regard to some of the products, a re-adjustment is being made in the case of the soldier and, also, of some of the civilian irrigation settlers.

The Coomealla Area, which is the largest irrigation project of the Water Conservation and Irrigation Commission, is situated on the Murray River. It embraces about 110 holdings, each ranging from about 15 to 25 acres, and they are used exclusively for fruit growing, principally vine fruit and citrus. Assistance is given by the Commission by only charging the full water rate at the expiration of five years after the granting of each block. In the intervening years a reduced water rate, progressing from one-fifth of the total upward, is charged. On application by the settler the payments of all monies due for rent or instalment of purchase money and other charges, is suspended for periods extending to 3 or 4 years from the date of granting the block, according to the class of planting, and subject to a charge for interest at 6½ per cent. At the end of this period the amounts thus suspended are compounded, and the settler is then required to enter into negotiations with the rural bank, or to obtain necessary financial assistance otherwise, to pay off the

money due the Commission. During the period up to which the debt is taken over by the bank, the Commission makes advances against improvements on the same scale as that allowed by the rural bank, and before any such advances are made a valuation is prepared of the settler's assets, so that at all times the State is in the favorable position of having a secured asset for any money advanced. These advances are also suspended, with interest at 6½%, on the same understanding with regard to their being taken over by the bank at the date fixed.

Blocks were granted to settlers on this area in 1926, and most of the blocks have been allotted in about three years. The settlers have been either the sons of landholders from the surrounding district, or laborers previously employed in irrigation work. In most instances these men have had very limited capital, but they have had experience, and the result has been very satisfactory, because most of the improvements have been carried out expeditiously, and at low cost. The average of the advances made to date (1929) only represent a little more than £100 ($485) per settler. During the 1928 season the production of vine fruit from a number of the blocks has been quite considerable. The bank will be called upon in 1929 to take over the debts of some of the earlier settlers. It is willing to do so because the assets are substantial.

If the marketing position remains satisfactory, the Coomealla Settlement gives promise of being a successful one, but without State aid the position of the majority of the settlers would have been impossible. It has been only by judicious assistance that these men have been able to make good, and, were it not for State assistance, very few of the blocks on the settlement would have been developed. Such assistance, it should be noted, has been made only after a careful investigation of the assets on each block, and after a report from the local manager, who is in close touch with the settlers, and is in a position to form an estimate of the personal qualifications of each. With such safeguards the writer is of the opinion that the principle of State aid is a sound one.

CHARLES R. HEDKE,[37] M. AM. SOC. C. E. (by letter).—An expression of opinion from engineers whose major experiences were obtained in irrigation, on a policy which embraces the basic principles which they now believe should govern, in the future, the National Reclamation Policy, would be valuable and would carry authority and weight in the solution of a very important problem. Such, doubtless, was the aim of the Executive Committee of the Irrigation Division when creating the Committee. Furthermore, to clothe the report offered with the endorsement of the entire Irrigation Division is a worthy effort, but it cannot go unchallenged, because it is felt that many interested members have not been satisfied by the report as a whole. Several of its principles are suspected of error equal to those in the present policy and, what is more serious, the report does not reach far enough to correct the vital and underlying weakness in National reclamation. A most general review of the experiences and lessons from past results seems clearly to justify one viewpoint at least, namely, that the entire problem is much more serious than the curt report of the Committee would indicate. The "Explanatory Statement",

[37] Cons. Engr., San Antonio, Tex.

issued by the Committee as supplementary, is also not satisfying. It should have preceded the report and should have contained more data and arguments to support some of the principles used.

A policy for a National problem as large as reclamation cannot be framed by stating merely the engineering features involved. Clearly, it must include other and vastly different fields of endeavor. Nevertheless, engineers have been largely in practical control of Government reclamation; they have guided the affairs of that undertaking, and are, therefore, responsible in a very large way for the results obtained.

Somehow, National reclamation has not been an outstanding success in itself. There are many who feel that it should have been successful, and, therefore, several attempts have been made to ascertain the reasons for the developed weaknesses in order to propose changes and remedies. The Special Advisory Committee appointed for the Secretary of the Interior to investigate the results of National reclamation and to recommend changes in the policy gave considerable time and thought to the problem. It proposed corrections which provided a tendency of direction apparently not in line with the opinions of the Committee of the Society. This Society Committee, furthermore, is at variance with the present National policy in some of its original principles.

The Committee of the Irrigation Division doubtless represents a wide range of opinion and is, therefore, entitled to considerable respect. It follows readily, however, that the engineers directly attached to the problem are as well qualified to pass judgment as the Committee. Between these two groups there are apparently some differences of opinion, not as clearly expressed as they might be, and which must be reduced to a clearer understanding before the members of the Irrigation Division can vote intelligently on the report. There is evidence of another group, comprising those who cannot reconcile their experiences with the new principles of the Committee, nor with the present policy of National reclamation. A training that touched the early field of private irrigation enterprises and their financing and grew upon the fundamentals developed from those efforts cannot easily rid itself of certain lessons derived from the successful irrigation developments in the country. Neither can the engineer, with experiences derived from contacts with problems of large financing, reconcile the lack of principles for the security of cost payments under Government reclamation with the statements made of the great values created by these developments.

The following viewpoints and conclusions are offered in defense of the principles underlying private irrigation enterprises. In presenting these in contrast with the principles of the Committee and the Government no spirit of personal criticism is intended, and it is only hoped that some thoughts will be given which may disclose a new application for an old principle, or suggest to the members of the Irrigation Division the deep and serious matters involved in the report. Only the principles that cover the apparent differences between private irrigation developments and Government reclamation will be included.

*Principles Underlying Private Irrigation Developments.*—The final test as to the feasibility of every reclamation project must lie in the answer to the question: Can it be made to pay? In that answer are involved all the engi-

neering features, all the farm development features, and all the operating features of the project (including its farming), balanced with all the economical soil production features of the entire country. The first three of these can usually be reduced to quite definite figures, representing one side of an equation as costs with profits and losses, while the other side contains the doubtful factors of probable values and returns. The weight of the doubtful side of the equation must still enter the final decision, not as a set of definite figures, but rather as a feeling based on experiences obtained from contacts in the broad field of business. The simplest irrigation developments (those intended for the production of native hay in the mountain valleys) and the most complicated developments of private and Government projects should go through the same steps of investigation to reach the final answer regarding feasibility. The following test question is not unfair and should be kept in mind: Has this practice been followed as thoroughly for Government as for private reclamation?

Farm production costs and the business of farming are not yet as clearly understood among engineers as might be expected. Statistics on the business of farming are easily obtained, which tend to show that it is neither attractive nor profitable. At present (1929), so much is heard about "farm relief" that care is necessary to prevent ideas from becoming distorted and unsound in considering the principles underlying irrigated agriculture. Farming, when considered on the average American business basis, is doubtless not profitable and, what is more important, it has never been profitable in the American sense of the word. Something beyond the strict business of farming has enabled that industry to exist, and even to attract people and grow to its present status in which it has the weight to undertake measures to better its condition.

The present farm relief effort reaches much further and has a much deeper meaning than temporary relief for the farming industry. It is clearly intended to Americanize the industry, and the underlying hope is founded on that vision and faith which has made other American industries grow and prosper. Farming in consequence has a much better prospect now than ever before, and both private and Government reclamation advocates can revise their estimate of the need and can urge underlying irrigated agriculture. However, the economics of the farming industry were the same when the large areas of private irrigation enterprises were built as when the Reclamation Act was passed, and they have continued much the same to the present time. The business of farming cannot be blamed for the difference of success existing between private and Government reclamation. There is something else that is wrong.

*Controlling Differences Between Private and Government Reclamation.*—The waiver of the interest charge, as provided under the original Reclamation Act, now appears to be blamed, under the principles of the Committee, for the failure of the repayment of costs to the Government. The underlying reason for taking that position must arise from the subsidy feature which the Committee has attached to that financial concession. No discussion is given which justifies its viewpoint, and apparently it was accepted so readily by the Com-

mittee that any contrary view might receive scant consideration. Nevertheless, the writer wishes to direct attention to the much more plausible reason which can be given to the "no interest" feature, when it is considered to provide an offset for the financial differences, anticipated as natural and inherited, between Government and private reclamation.

*First.*—The approach to every private irrigation enterprise is through its ability to create some underlying values and make some money. This always furnishes the urge for the development. The approach for every Government project is clearly through politics. This furnishes the final force which determines the time and place for every Government development.

Politics recognizes but little economic difference between the project with a climatic location of 4 000 day-degrees of heat available for the growing of crops and one with 10 000 day-degrees, or between a project with an estimated cost for water development of $60 per acre and one for $120. There is, nevertheless, a wide economic difference between a project that has 10 000 day-degrees of growing heat available per year under a water cost of $60 per acre and another project that has 4 000 day-degrees under a water cost of $120. Private enterprises have always faced and met, as far as possible, the economic adjustment necessary between the ability of a project to produce and the ability of the project cost to produce. The forces of politics in Government projects superseded the forces of economics in private projects and, in consequence, there was imposed, at the outset, an unequal inherent difference in the ability of the projects to pay.

It was clearly the field of the engineer to equalize this difference as far as possible in the original set-up of the projects, but equalization was apparently disregarded then and its correction is now attempted by concessions and releases. Claims for adjustments of this character underlie the inter-project feeling for an even break from the National Government. There is little to be gained by citing the success of several Government projects in contrast with the many marginal ones. For example, the water users in Montana instinctively feel a grievance against the Government for the handicap imposed on them when their results are so often compared with those of the water users in Arizona and New Mexico. Government reclamation has been treated as one large undertaking, made up of many large units, and there is now no escape from the resulting viewpoint of reasonable equality and justice from the Government.

*Second.*—The next difference existing between private and Government irrigation involves the bases and principles used for the value and ownership of water.

The principles developed from private irrigation, as reflected by the laws and Court decisions in the arid States, revolved around the viewpoint that water had a distinct and separate value and that ownership was as positive and actual for the water as it was for the land. The principle that ownership of water could only be obtained through its use was much the same as that applied for the acquisition of public lands from the National Government. These principles simply mean that for undeveloped public property, where additional values were created through private effort, ownership could well be

given to all. The transformation of the water in a stream into the products from the soil made additional values for both water and land and thereby created the reason for ownership to both. It followed naturally, from private enterprises, that the maximum value of water was obtained from the maximum crop value per acre and not from the greatest number of acres that water could be made to cover. It was a principle established by private enterprise to let the value of the water adjust its economic application.

The practical application of these principles somehow was lost under Government reclamation. The settler on a Government project was given the impression that the payments contracted for by him were for construction only and that they attached to his land. Water value and its ownership were never made clear to him. In early mutual enterprises the fundamentals regarding water became so clear that confusion was never possible thereafter. Private owners did their own work of construction for water, and it then represented a tangible asset of considerable value. Under extended developments, in which some money for construction was borrowed for short periods, water value was still held clear and definite, because the security for the personal notes used was taken on the value of the water more than on the value of the land held by the borrower.

There are sections in this country even to-day (1929) where the collateral for all the usual farm loans is the water stocks available. They are well suited and liquid assets, and they have a ready market because the conditions with which these companies have surrounded their stock make it possible to buy and sell that ownership and transfer its use within reasonable limits. The principle of water value and ownership was carried still further by them under complex stock companies which arranged to borrow considerable money and gave as security a mortgage on their property, works, and water rights, which clearly represented water value. Sound development was made on this basis everywhere in the West.

The first step toward National reclamation, represented by the Carey Act, was based on the principle of water value and is sound fundamentally to-day, no matter what its minor weaknesses may be. The Irrigation District method for water development appeared next; it superseded the National Reclamation Act. It was based on the plan of using the land as additional security for the water loan. Somehow, it now appears that this feature led to the viewpoint that the land was the most important if not the only asset, and, in consequence, much trouble was encountered by irrigation districts. Next appeared National reclamation, by means of which the settler was given the land and the water value was not recognized as any collateral, so there was in reality no security for the cost of the water development. In fact, the entire procedure made it appear to the water user (as he was most unfortunately called) that what he was expected to pay for was a license or a concession charge for the privilege of farming on a Government project. Such certainly was not the intent of the law, and some fundamental principle was clearly overlooked or disregarded to create such a result.

No principle is outlined in the report of the Committee that provides any change toward security of any kind whatever for the repayment for Gov-

ernment cost of water and, therefore, the report has not reached the fundamental source of National reclamation difficulties. The present tendency in State irrigation district laws is more and more toward the personal-ownership aspect for water and value, and if that principle is sound for irrigation districts it may be well to consider it for National reclamation.

*Third.*—In this section the difference discussed relates to comprehensiveness in private *versus* Government reclamation. It still appears to be the general opinion that the remaining opportunities for irrigation developments in this country are too large; that the cost repayments are impractical for private enterprise to undertake; and that the National Government alone can do this work. Within the meaning of private enterprises, which is taken as everything other than National and State developments, it should be remembered that about 90% of the total irrigation of the country has been accomplished. The viewpoint controlling comprehensiveness, as provided from the experiences and results of private work, is quite different from that used for National reclamation.

Private enterprises first made use of the water from the normal flow of the streams. When this flow became insufficient a supplemental supply was provided by small reservoirs which were filled from the flood flow. When the practical limit of diversions from the average seasonal flood flow was reached, the next step consisted in providing a large reservoir, situated in the bed of the stream, which was used for the hold-over supply from large to small run-off years. In that manner the entire available water supply was developed under the continual influence of the demand for more water by having additional land directly available. The period intervening between the use of normal stream flow and the creation of large reservoirs has been a long one in private developments.

In the meantime, a most important result of irrigation was disclosed. Return waters, obtained naturally or from drainage, were found to be considerable and their re-use introduced another stage in comprehensiveness. The private method for stream development consisted of four distinct stages; took many years to complete; was financially sound for each step, since the method itself created the demand for the water; and the final costs were less than under the one-stage Government reclamation method. Comprehensive development was actually reached through the four-stage method; it has been far from complete in the case of the Government method.

Comprehensiveness in Government developments clearly consisted in reaching for the limit of the physical features involved in each project at the outset. No hesitancy is apparent on the part of the Government in going as far as possible: (*a*) For size of storage attached; (*b*) for size of distribution provided; (*c*) for permanency of construction furnished; and (*d*) for such other features which appealed to the public of the section, equalized the expenditures between the benefited States, and involved large sums of Government money. No attempt was made to start anything smaller which would grow larger as financial strength was created by water demand from sound farm developments. The basis used for the physical set-up was wholly in keeping with all Govern-

ment undertakings, and there resulted a depressing effect because the projects never became economically adjusted between water supply and demand.

This uneconomical feature in Government comprehensiveness resulted also in depressing private irrigation which was directly discouraged by the large water filings made and embargoes imposed. A correction for this condition appears in the principle now generally advocated which provides that the Government undertake only the construction of the controlling feature in any stream development, such as hold-over reservoirs for flood control, power, and water supply, and that water be sold thereunder to all approved users when and as the demand exists, whether they are municipal, irrigation, or power organizations, whether they are large or small, and whether the projects are existing developments or new ones. The concept for Government comprehensiveness appears to be changing to Government conservation; therefore, some unwise feature must have been operating on the former basis.

*Fourth.*—Another difference exists between private and Government viewpoints in regard to the aspect of land inclusions under a project. This affects directly the marginal lands. Because of their topography, soil, economic development costs, or economic location in the project, these lands are seen to be unable to stand the cost of the water-supply burden by the owner or settler, at least during the beginning period of the development. The existence of such marginal lands under Government reclamation is now doubtless indicated by the 28% of the land idle on the projects. They clearly represent a heavy dead load. The reduction of this load has apparently been slow and difficult and has created the major problem for the present Reclamation Commissioner.

Managers of private irrigation enterprises fundamentally base their unit costs on the unit of water supply available or developed. They may convert that figure to an acreage basis, but acreage is never the controlling factor in their computations. Their projects have grown strong and sound on the water-value principle, and its practical application has provided the natural and automatic exclusion of all lands not suitable to stand the cost of the water burden. Water is the commodity product of private irrigation, and its use has been allowed where and in those quantities that best suit the buyer of the product. The market for the product is considered carefully and is always one of the controlling features in determining feasibility.

Government reclamation definitely attached the water to the land. Wherever this attachment was suspected of being unable to transform the potential values of both water and land into actual values, sufficient to make them attractive, both have remained unused and, in consequence, the attachment seems unsound. Fixing the place of use for water by any one other than the party paying for it, is unwise according to private irrigation principles. Water and land must go hand in hand, each assisting the other; it takes both, used jointly, to transform their potential values into actual values. Increments in the value of each are the objectives of private irrigation.

Attaching the entire increment of value created by irrigation, whether potential or actual, to the land is unsound according to private irrigation experience. Land speculation simply consists of attaching an unearned increment of value, due to possible irrigation, with some or even all of the water

value, to the land. Speculation was really aided under Government reclamation by having the value of the water unencumbered, because it was unrecognized, and therefore it was easily attached to the land by others as an unearned land value. Land speculation has never been serious in places where there was any fair excess of land to which water could be applied and on which it must be used in order to get any substantial increment of value.

No unsound colonization is possible when the provision is made that the entire increment of water value (due to its use and above its construction cost) is arranged to accrue to the user of the water. The best control for sound development, as seen from the lessons in private enterprises, is to have available considerably more land than the available water can possibly cover, with the further condition that the right to the use of the water will accrue to the first in time of use and payment of cost. A principle which would provide a sound economic relation between the areas of land and the water available for Government projects will correct much of the weakness inherent in such projects.

*Fifth.*—The standard of engineering for the construction of Government reclamation projects is now generally accepted as the standard of the country. Credit and praise must be accorded the Engineering Profession, and the Reclamation engineers in particular, for the character of the works built. Substantial and lasting benefit has resulted to private irrigation from the problems of design and construction solved under this development. However, engineers in private practice have never been able to dovetail all the Reclamation standards into any one project and fit them into a cost analysis acceptable to the owners and backers of private enterprises. The Reclamation standards are not in line with the experiences and results obtained in private developments. Private enterprises must obtain their initial water cost as low as possible because (1) margins are computed as more than this cost; (2) the prevailing interest charge equals the original cost in about fifteen years; (3) the true direction and tendency of the best suited system of cropping for the area are disclosed in about fifteen years; and (4) because a value will be created for the re-use of return waters sufficient to pay for the cost of the drainage. These four reasons all converge for a re-adjustment of the construction and financing of a project at some later period and hence the permanency of construction can be made more suitable and economical at that time than can ever be anticipated in the beginning.

The principle that the permanency of construction shall more nearly parallel the values created by its use has resulted from private developments. This is clearly in line with all private developments and, more particularly, with farm developments. Confusion should not be made between permanency and safety. National reclamation inherited a high standard for its construction just because it was National Government work. No other basis was possible and the statesmen responsible for the Reclamation Act doubtless knew such would be the case. The time-honored standards for all Government work were imposed on National irrigation at the outset, and a burden thereby resulted that was not attached to similar private enterprises. To justify and

offset that inevitable condition may be one of the reasons why the law-makers provided for the waiver of the interest charge.

The principles that create the differences between private and Government irrigation enterprises may be summarized in ten items. Private developments provide that:

(1) The broad foundation between the natural and economic forces involved should be made sound.
(2) Water is a National natural resource like land and should be treated in all economic and legal aspects as being similar to land.
(3) Comprehensiveness is best obtained by separate steps, each of which should be made financially sound before the next is taken.
(4) Because there is much more land than water available in the arid regions, conditions should be provided that only the best lands, under an economical project set-up, will ultimately secure the use of the water.
(5) The permanency of construction should be made parallel to the values of the water they create.

In contra-distinction to Principles (1) to (5), the following refer to National irrigation, which uses:

(6) Political expediency for projects, instead of economics.
(7) The "forever public" ownership of water basis, in its security aspect for water value.
(8) National comprehensiveness, instead of public conservation.
(9) The inseparable relation of public water to land, in its appropriation basis.
(10) Permanency of construction in line with other Government construction, in its work of reclamation.

It is apparent from Principles (6) to (10), inclusive, that: (1) Most of the fundamental and controlling forces underlying National reclamation are quite natural and inherited; (2) they all operate quite differently from those underlying private enterprises (Principles (1) to (5)); (3) they all circumscribe results and add burdens; and (4) undoubtedly the statesmen responsible for the Reclamation Act instinctively felt these differences and knew their financial effect so that they met it, in the best manner possible, by waiving the interest charges. It appears to be a strong case of attempted equalization and adjustment and nothing like a subsidy in any possible sense. It seems to be entirely wrong to change that interest waiver feature until the principles underlying National reclamation are changed. Viewing that feature in this manner leaves no basis for an alleged subsidy and consequent paternalism stressed by the Committee. In fact, a thorough analysis of the inter-project value for the financial offset through the interest waiver feature may disclose more inequalities and may show that some projects are entitled to even greater concessions before they are on a par with each other and with private enterprises. This much seems certain: Whatever waivers, releases, and concessions have been given thus far to the various projects, they were well founded and were justified under the inherent conditions attaching to National reclamation.

The interest-offset feature in the present policy is still wise and will remain so until a better understanding is had of its true meaning. The principles of

protection and correction are introduced and admitted by this feature, and it will remain such until a sound economic adjustment is made of the whole problem. It is the wisest feature in National reclamation because it will some day straighten out forever the absolute foundation of irrigation, namely, the economic and legal aspect of water. It does not subsidize the remainder of agriculture for the benefit of the few who have been experimented upon for National reclamation. The Committee has not reached the underlying weakness in National reclamation by its principles for a new policy.

It may be well to return to the subject of irrigation districts. Organized under State laws, these districts have been given a quasi-public character and, in consequence, their leaders have had a tendency to follow along the lines of National reclamation in the matters of value and ownership of water. Furthermore, they have been supervised by the States which introduced the features of water conservation, project comprehensiveness, and construction permanency, along the lines of the National policy. They were then, through necessity, so set up and "geared" that a burden was imposed on the present to conserve and provide something for the future. Wherever this burden has been too great the irrigation districts have had difficulties. Wherever an offset feature was provided to relieve those imposed conditions the difficulties have been less. The waiving of the interest charge was not possible nor practical for them, but, nevertheless, some other offset feature, having the same result, must be introduced and made effective in order to insure that such projects may become sound and feasible.

This offset feature may take the form of an income from a hydro-electric by-product wherever possible, or as revenue from the taxation of property that has been benefited by the development, and doubtless other ways and means will present themselves. The whole field of irrigation district experience has made it clear that some offset must be provided wherever any tax is imposed for requirements beyond the immediate and strictest reclamation needs of the new settler. New irrigated agricultural developments alone cannot stand the burden of conservation, comprehensiveness, and permanency, and where these burdens have been added to reclamation the entire experience therefrom shows it is unwise to attempt it. The interwoven character of the farming industry with the other industries of the country makes it reasonable to consider that even the entire industry should not alone stand that burden. It appears that there should be some principles in the report designed definitely to allocate burdens, if Principles (8) and (10) are considered essential.

The National Government rightly and naturally should assume the original ownership and control of the natural resource of water. Some of that resource should rightly and naturally be then turned over to the individual States, and it follows readily that some of it should be made inter-State. When, however, the character of that resource becomes so complex as to involve many States, and its control is so interwoven that responsibilities become unnatural, even for inter-State relationship, then the National Government must exercise its parent duty and step in to meet the problems involved. The plan for Mississippi River control is then clearly National and is primarily intended for protection

to large property values and many people. The Boulder Dam situation is still a project, while the control of the Mississippi River is a problem, and Congress evidently has taken that view of them. The principles suggested for the control of floods offered by the Committee are not sufficiently clear to provide a basis for the allocation of the costs entailed, and it is suspected a considerable problem is involved therein.

The stressing of the economic aspect of the agricultural industry seems out of proportion in the report of the Committee. The cropped area of Government irrigation, in a quarter of a century of effort, represents less than 0.4% of the cropped area of the country. The idle lands mentioned by the Committee as existing in the Rocky Mountain area and along the Pacific Coast are doubtless nothing more than the marginal lands which have been found unprofitable under the changing conditions of supply and demand through the general development of the country. That process of elimination has been going on for a long time and will continue, because lands which once were profitable only on account of their location to markets, have become unprofitable under the extension of the transportation systems of the country. Every agricultural area is now able to compete effectively with every other area, as far as its availability to markets is concerned, and, therefore, the profit problem is resolving itself more and more into determining crop adaptability, or the ability of Nature to produce. Consequently, some areas are certain to become idle when faced with fundamentally adverse conditions.

Adjustments of like character have gone on in every industry and must be faced in agriculture. There is certainly a benefit to an industry to furnish conditions in which it is possible to produce output values 2.5 times as much as the average. It is a significant fact that irrigated agriculture is in the lead for value of gross production per acre in the industry. It is, therefore, the soundest basis for farming in the country and so, if any curtailment is made, it is clearly in error to place it there. Land settlement is becoming more and more a problem of creating advantages in one location over that in another, for the people already in the farming business. The arrival of a new settler, on an irrigated project, does not necessarily mean that he is a new farmer.

In conclusion, it is evident that National reclamation is still an experiment. It is apparent that every one concerned with the problem, including the land owners on Government projects, desires changes. Some of the suggestions offered are so fundamental that a wide departure from the present policy is involved. It would seem to be a sound beginning policy to undertake correction of existing projects first. The act of postponing all new projects might develop some weight for the step, but this should clearly be understood to be for no other reason than first correcting wrong tendencies in the present policy. Correction seems a case for education, involving so many phases of the problem that it must start at the bottom, where it is believed the most difficult part of the problem lies. Engineers have had so much to do with this Government undertaking that they can well afford to busy themselves to bring about the first changes. Congress has been lenient, but not complimentary toward the results obtained. That unwise things have been done to date is no serious criticism. The principle of waiving of interest charges is considered and

agreed to be an unsound financial policy and should be among the first of those corrected. However, merely to remove that feature, simply because some one considered it a subsidy, will not correct the present weakness in National reclamation. Finally, that feature is luckily in the present Reclamation Act and policy of Congress and is considered to represent a far-reaching principle of correction, wisely introduced by real statesmen, for the missteps in the march of progress, and, therefore, in it now lies the greatest hope for the solution of the fundamental problems involved.

CHARLES KIRBY FOX,[38] M. AM. SOC. C. E. (by letter).—Numerous timely and important papers on irrigation and related subjects have appeared in *Proceedings*, but for some reason the climatic conditions and the relation between the acreage cost of the system and the gross acreage crop values seem to have been overlooked.

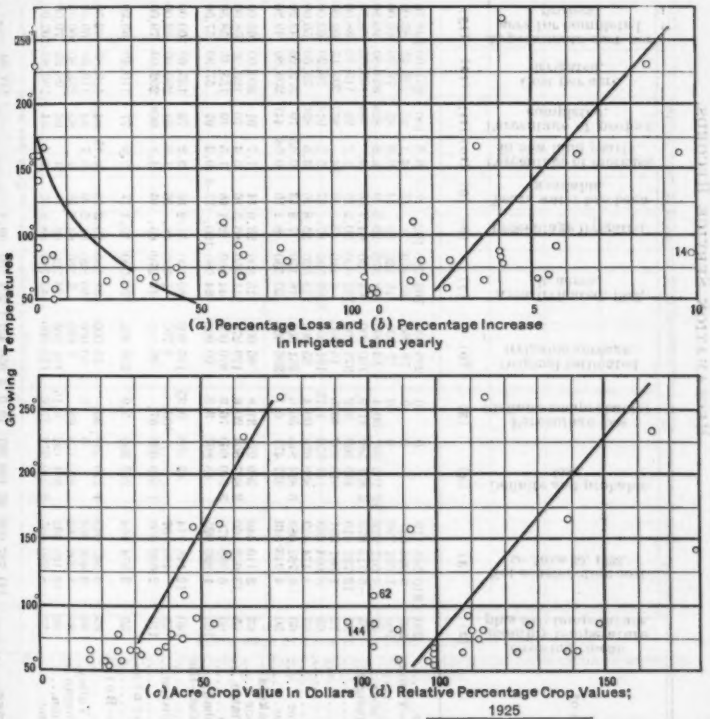

FIG. 1.—CROP AND IRRIGATION DATA FROM RECORDS OF U. S. RECLAMATION SERVICE.

Some time ago the Reclamation Service published data relating to the costs, crop values, etc., of its projects. These data are available for quite a period of years, over the entire West, and presumably are comparable, since

[38] Cons. Engr., Los Angeles, Calif.

TABLE 1.—COMPILATION OF CROP AND IRRIGATION DATA FROM THE UNITED STATES RECLAMATION SERVICE RECORDS.

| Project No. | State and name of project. (1) | Growing (mean monthly temperature plus 50°) temperature. (2) | Net construction cost to June 30, 1923. (3) | Definite and probable loss. (4) | Percentage loss (definite and probable). (5) | Original estimated irrigable acreage. (6) | Area irrigated, 1923, in acres. (7) | Percentage irrigated. (8) | Years water has been available. (9) | Percentage of increase in new land yearly. (10) | Percentage of project completed. (11) | Cost per acre irrigated. (12) | Approximate cost per acre for completed project. (13) | Yearly maintenance cost per acre irrigated. (14) | Number of water users, 1923. (15) | 1919-23 (10-year), average crop value per acre. (16) | Percentage of crop value to cost per acre, irrigated. (17) | Percentage of crop value to final acreage costs. (18) | 1923 crop value per acre. (19) | Percentage of $\frac{1923}{1919\text{-}23}$ crop values. (20) |

they were compiled by one organization. The Reclamation Service Fact Finding Commission compiled data relating to the losses, etc. In Table 1, the writer has approximated the mean monthly temperatures from the U. S. Weather Bureau records (see Column (2)). The values in Columns (11) and (15) are from the annual reports of the U. S. Reclamation Service. Columns (3), (6), (7), (9), (12), and (14) contain data from the *Reclamation Record*[39] and the data in Columns (4) and (19) are from the *New Reclamation Era*.[40]

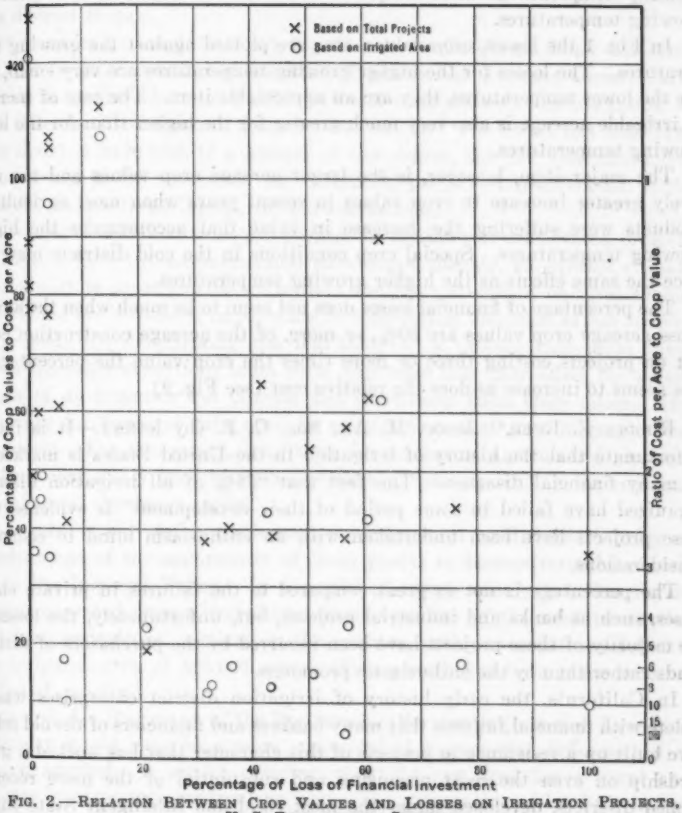

FIG. 2.—RELATION BETWEEN CROP VALUES AND LOSSES ON IRRIGATION PROJECTS, U. S. RECLAMATION SERVICE.

The remainder are computed as follows: Column (5) $= \frac{\text{Column (4)}}{\text{Column (3)}}$; Column (8) $= \frac{\text{Column (7)}}{\text{Column (6)}}$; Column (10) $= \frac{\text{Column (8)}}{\text{Column (9)}}$; Column (13) =

[39] *Reclamation Record*, December, 1923, p. 314, and August, 1923, p. 274.
[40] *New Reclamation Era*, February, 1926, p. 18.

$\frac{\text{Column (3)}}{\text{Column (11)} \times \text{Column (6)}}$; Column (17) $= \frac{\text{Column (16)}}{\text{Column (12)}}$; Column (18) $= \frac{\text{Column (16)}}{\text{Column (13)}}$; and, Column (20) $= \frac{\text{Column (19)}}{\text{Column (16)}}$.

Most crops start to grow when the mean monthly temperatures range from 42 to 48° Fahr., but the growth at the lower temperatures is slow and for that reason 50° Fahr. was selected as the base (see Fig. 1). The cumulative mean monthly temperatures were computed above that base and were called the growing temperatures.

In Fig. 1 the losses, crop values, etc., are plotted against the growing temperatures. The losses for the higher growing temperatures are very small, but, for the lower temperatures, they are an appreciable item. The rate of increase in irrigable acreage is also very much greater for the higher than for the lower growing temperatures.

The major item, however, is the larger acreage crop values and the relatively greater increase in crop values in recent years when most agricultural products were suffering the decrease in value that accompanies the higher growing temperatures. Special crop conditions in the cold districts may produce the same effects as the higher growing temperatures.

The percentage of financial losses does not seem to be much when the annual gross acreage crop values are 50%, or more, of the acreage construction costs, but on projects costing three or more times the crop value the percentage of loss seems to increase as does the relative cost (see Fig. 2).

Rhodes E. Rule,[41] Assoc. M. Am. Soc. C. E. (by letter).—It is indeed unfortunate that the history of irrigation in the United States is marked by so many financial disasters. The fact that "26% of all irrigation districts organized have failed in some period of their development" is evidence that these projects have been undertaken with an enthusiasm blind to economic considerations.

The percentage is not so great compared to the failures in private enterprises, such as banks and industrial projects, but, unfortunately, the losses in the majority of these projects have been incurred by the purchasers of district bonds rather than by the enthusiastic promoters.

In California, the early history of irrigation district enterprises was so replete with financial failures that many bankers and financiers of the old school have built up a resistance to projects of this character that has worked a great hardship on even the most promising and substantial of the more recently formed districts, developed under the most rigid and intelligent State supervision. In districts having most favorable conditions of water supply, soil, climate, transportation, and demand for lands by legitimate settlers the bonds have had to be sold at discounts which have made the actual interest rates paid by the districts as high as 7 or 8 per cent. Nevertheless, despite the difficulties of financing and the high interest rates that these districts have been forced to pay there has been a tremendous expansion of the irrigated areas in

[41] Civ. Engr. (Rule & Rule), San Diego, Calif.

California almost entirely under the irrigation district method. Between 1912 and 1926, one hundred irrigation districts were formed with a total bonded debt of $120 000 000. The total area involved was 3 500 000 acres, which is greater than all the Federal projects combined. These districts have met their financial obligations as they came due in almost every instance.

The reasons for the success of these projects can be summarized into the following items: (1) Adequate water supply; (2) favorable climate; (3) good soils; (4) good marketing conditions; and (5) a bonded debt within the ability of the district to pay.

Before an irrigation district can issue bonds the California Bond Certification Commission, consisting of the State Engineer, the Attorney General, and the State Superintendent of Banks, makes a comprehensive investigation to assure that the district meets these five conditions. The result has been that all the districts have had, to a greater or less degree, the one vital characteristic necessary to the success of any irrigation project—attractiveness to the adequately financed, intelligent, industrious farmer.

In comparison with reclamation projects in the interior arid States, projects in California have two environmental advantages, namely, an equable climate and proximity to great population centers and their attendant cultural advantages. These are of utmost importance in considering the colonization feature of a project. In determining the feasibility of a project that lacks these features the other conditions must be so favorable that they offset the disadvantages of an intensely hot climate and remoteness from large cities. The opportunity for financial gain must be greater than that in a more pleasing environment. For this reason, conditions for marketing agricultural products must be exceptionally good to induce settlers to take up land in the reclamation projects of the desert region.

That settlers will suffer unpleasant environmental conditions in order to take advantage of the opportunity of large profits is demonstrated by experiment in the Imperial Valley. In a period of twenty-nine years, this region has been converted from a forbidding desert into one of the most productive and richest agricultural sections in the country, with a population of 60 000 on an irrigated area of 525 000 acres. This growth has been made without subsidies of any kind.

It is probable that many of the Reclamation Service projects that have been in difficulty would have been more successful if a somewhat different policy had been adopted. A settler entering upon the raw land has a great and sometimes hopeless task confronting him. The preparation of land for irrigation, building of home and barns, purchase of farming equipment and stock, learning new methods of farming necessary under local conditions, building of roads, schools, churches, and all the service utilities necessary to a prosperous community, all require capital, intelligence, and an indomitable courage that the average land seeker does not possess. Unfortunately, too many of the settlers on reclamation projects are those who have failed in their previous endeavors and are seeking new opportunities in a new land. In most cases the causes of their original failures are still present in their new environment

and they either abandon their efforts or hold on by a thread without contributing any support toward building up the wealth of the community. The burden of development is on the few industrious and, in most cases, adequately financed pioneers who understand farming and are fully aware of all the difficulties that must be overcome.

If conditions were such that a larger number of the latter type could be attracted to settle on the land, development would be more rapid and failures fewer. If the amount of original capital required for a settler to establish land on an earning basis were less, a larger number of settlers of the right type would be attracted to it. This might be accomplished by including in the project construction some things that now are accomplished by the expenditure of cash or labor on the part of the settler. As Mr. Mead suggests, this might include leveling of land and the construction of roads. Community buildings and utilities might also be included in some instances. Any steps along these lines should be taken with caution and after due consideration of all factors. A small scale experiment should be instituted before great expenditures of the public money are made. The experiences of some Utopian colonization schemes should not be forgotten.

As suggested by the Committee, subsidy by the Government should take the form of an assumption of a part of the total cost of the project rather than aid to the individual farmer. Local subsidy should be largely of a similar nature. Regarding the latter, there is no question in the writer's mind that, in many instances, such measures are justified. The development of new agricultural areas creates wealth and affords means of livelihood for the inhabitants of the towns and cities. That a State or county is justified in lending aid to reclamation projects within its limits cannot be denied. Another form of assessment against those indirectly benefited is the inclusion, within an irrigation district, of cities and towns lying within the irrigated area and the taxing of these lands by the district to pay the interest and principal on a part of the bonded debt. In many cases these cities and towns would not exist if it were not for the irrigation projects, and virtually all business in them can be traced indirectly to the agricultural back country. Surely a part of the cost of the project should be borne by these lands.

George M. Bacon,[42] M. Am. Soc. C. E. (by letter).—There seems to be a tendency to regard the report on a National reclamation policy as inimical to the U. S. Bureau of Reclamation. It would be very unfortunate if implications were read into this report which did not really exist.

The supplementary remarks by Mr. Mead comprise a well-reasoned argument for aid by the Bureau of Reclamation to the prospective settler on present and future projects. As a general proposition there should be no quarrel over this; on the other hand, if the Bureau should take over this work—and it seems to be the proper agency—it would still form only a small part of that in which it can be rightfully engaged.

In the West, engineers are rather familiar with the conditions that have caused some of the projects to be, for the present at least, failures from a financial point of view. The fact of such failures is not vital and it would

[42] State Engr., Salt Lake City, Utah.

be difficult to find any enterprise involving the expenditure of $125 000 000 in which mistakes of considerable size were not made. The immediate and proper question is the avoidance of similar mistakes in the future and there is much doubt in the minds of the Committee whether such steps are being taken.

The fundamental idea in setting up the Reclamation Fund was that it should be a revolving fund and that expenditures from it should be repaid. This idea has been departed from to the extent of at least $14 000 000, according to Mr. Mead's figures, and there is no question as to this being an entering wedge for further departures. There are many who argue that the indirect benefits derived from construction of the various projects more than outweigh the losses, but it seems to the writer that this argument does not go to the root of the situation. If the construction of projects which do not pay is to be gone into for their indirect benefits, it should be definitely understood before the project is started. It may possibly be that the funds for Federal reclamation should be spent for indirect benefits, but it is obvious that any policy of that kind, or tendency in that direction, is extremely dangerous. Should it be tolerated it would mean that projects were built for sentimental reasons, or on account of political pressure, and it might be pointed out that the pressure for the construction of the various projects almost never comes from those who have to pay the bill. The prominent advocates of new projects to bring in raw land will be found to be, not the farmer, but various urban interests and organizations.

The Committee sought to stage lines upon which the work of the Bureau might be continued with benefit to all, keeping within the fundamental limits set by the establishment of a revolving fund, and that its report seemed to be critical as to some of the work done by the Bureau should not be misunderstood.

It should be noted that for years the Bureau has been limited to a large degree in its choice of projects. The law now requires a specific appropriation by Congress for the various projects and most people know how appropriations are usually obtained. The writer feels that the Bureau could be safely trusted to pass on the economic merits of a proposed project and, with the understanding that a project must pay, limit the construction of new projects to such as are economically feasible. There is no question in the minds of engineers competent to judge that at least two projects are being constructed at the present time which will not pay in this sense and others of this nature are not far distant.

The danger of Mr. Mead's plea for help to the prospective settler is that new projects which will not pay, may be started with a tacit understanding that, if anything does happen, a considerable portion of the cost will be written off and then various aids will be offered to prospective settlers. Following this line of procedure one step further, the day may come when the money furnished to aid the settler need not be wholly repaid and then the argument can again be advanced that the indirect benefits warrant such a course.

There are signs of a growing belief among careful students that from now on history, as to growth of total population, or rural population, will not repeat

itself in this country. It is even believed that the total agricultural area under cultivation at present is ample to provide for the needs of the country for a long time. Speaking of the arid and semi-arid West there is no question at all that the total area under cultivation is capable of great increase in produce once its present water supply is supplemented. There are many thousands of acres of land on which production is curtailed because the water supply falls short before the end of the crop season.

The policy in all ordinary business is to bring the plant up to full capacity before enlargement but, as far as agriculture is concerned, the exact opposite has been, and still is, strongly advocated. It is very difficult to realize the unconscious pressure which is being exerted all the time in favor of an increase in agricultural area; and it is still more difficult to realize how little of this pressure comes from the man who is supposed to come on to this new acreage, pioneer to a large extent, make a living, if possible, and then pay for the cost of the project.

Many people draw an analogy from the industrial field and point out how products in an industrial line are absorbed beyond any forecast which has been made. They seldom stop to think that as far as staple food products are concerned there is a definite limit beyond which it is impossible to go after people are well fed. The analogy does hold in part in the case of what a few years ago were considered food luxuries and, as the standards of living become higher, the power to absorb such luxuries will increase. As to these luxuries, it will undoubtedly be many years hence before anything like what might be termed a saturation point is reached.

The picture that Mr. Mead paints is accurate and important, but the point to be borne in mind is that this is by no means the whole picture. As he intimates, one kind of picture would be drawn by engineers, another by the settler, another by the economist, and probably another by the politician. The consideration of vital importance is that these pictures fit into the frame of the law as laid down by the Congress of the United States; if they do not, they cannot be regarded as a fair presentation. Many of the policies advocated by the enthusiastic friends of Federal reclamation are good in themselves but, as long as they have to be paid for by money which is supposed to be repaid, there should be a definite understanding that a business transaction is involved and that obligations to be undertaken are as binding between the Government and individuals as between private parties.

G. E. P. SMITH,[43] M. AM. SOC. C. E.—Any discussion of a National reclamation policy must involve the question of the legal basis of Federal activity in land reclamation. This is fundamental. On what basis does the U. S. Bureau of Reclamation function? On what basis does Congress authorize an occasional new project? Is it by virtue of National sovereignty; is it by sufferance of the States; or is it through contract or understanding between the sovereign Federal Government and the sovereign States?

Fundamentally, this Federal activity rests on an ephemeral and insecure basis. National irrigation projects in the United States have been so monu-

[43] Prof. of Irrig. Eng., Univ. of Arizona, Tucson, Ariz.

mental in character, so spectacular, and so widely heralded, that many people (perhaps a majority of them) now take it for granted that land reclamation was written or implied in the list of powers delegated to the United States in the Constitution. On the contrary, all matters of such character were retained under control of the individual States. It is by urgent invitation of the people —virtually by invitation of a State—that the Federal Government "enters the picture" and executes a project like that of the Salt River Valley, and it is the bonus or subsidy that makes the Federal aid acceptable. Without the subsidy the States, or the districts, with few exceptions, would execute their own projects in due season.

The Federal Government has limited delegated powers. Because the States felt that they had delegated power too generously, the first ten amendments to the Constitution were adopted at an early date to check the newly created "monster". In all ages people have had occasion to fear the power of governments. A stirring address[44] by Lincoln Bush, Past-President, Am. Soc. C. E. has served to emphasize the ever-present possibility of mal-administration either for political purposes or for private gain. The larger the unit of government is, the more difficult it becomes for the people to retain control of it, and there is increasing evidence that the United States Government has reached the safe limit. President Coolidge has stated that "unless bureaucracy is constantly resisted, it breaks down representative government and overwhelms democracy". President Hoover stated that:

"The greatest need at Washington is to decentralize the National Government and to pass back into the hands of the people the responsibilities which have been gradually taken from them."

The authority for the Reclamation Act of 1902 is found in Section 3 of Article IV of the Constitution, giving Congress the power to dispose of and to make all needful rules and regulations respecting the territory and other property of the United States. This, however, is a proprietary right and not a sovereign power, and has been so stated, emphatically, by the Supreme Court of the United States.

Section 8 of the Reclamation Act provides that the Secretary of the Interior, in administering the Act, shall proceed in accordance with the laws of the States. If this provision had not been included, it would still be true that the Act could be administered only with the consent of the States. Therefore, at the outset of each Federal project, the Secretary of the Interior, or the Bureau of Reclamation, has made application to the State for an appropriation of water, in the same manner as an individual or a corporation.

The speaker is aware that many people, notably certain people of Southern California, would like to have the situation reversed, and some have come to believe that Federal sovereignty includes control of irrigation water supplies and of water power; but, no doubt, "the wish has been the father to the thought". A very few attorneys, who have been reared in the atmosphere of Federal bureaus and whose vision, therefore, is limited, have devised a theory of law by which they claim Federal ownership of Western waters. Those gentlemen arrived eighty years too late. Perhaps in 1850 the Supreme Court

[44] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1646.

would have given consideration to their theory, but, to-day, when such theory would upset the machinery of law for control of water rights in the various States, and likewise require the reversal of a score of important decisions, the Supreme Court would give it scant attention. In a few cases in which the contention has been advanced, the Court has charitably ignored it.

The general control over the waters of the State is a sovereign power and is vested in the State. The powers of the Federal Government are limited to the control of navigation. As owner and proprietor of lands that are irrigable from streams, the Federal Government has the usual circumscribed rights to utilization of the streams for the irrigation of those lands, subject to the sovereign control by the State. Many Supreme Court decisions can be cited in support of this, and the decisions are unequivocal.

The worst thing, therefore, that could have happened to the Imperial Valley was for the Swing-Johnson Bill to become a law as written. In that bill, Congress attempts: (*a*) To allocate a portion of the waters of the Colorado River between States; (*b*) to restrict the effective appropriation of water in the United States to about 80% of the water supply; (*c*) to develop 450 000 firm h. p. of Arizona's potential water power over the protest of the State, the benefits resulting therefrom to go to other States; and (*d*) to build a project of unparalleled dimensions, 88% of the cost of which can be justified only as a power project. The remaining 20% of the water supply would be allowed to flow into Mexico, where squatters' rights to it would be secured by shrewd and powerful owners of Mexican lands, and, later, these rights may be confirmed by treaty.

The Engineering Profession has failed in its inability to develop, and agree on, a logical, just solution of the whole problem while there was opportunity. The task belonged rightfully to the State engineers of the seven States, to evolve a plan of development that would be just and advantageous to all the States. The case will be precipitated into the Courts and may drag along through many years (as in other cases of water litigation) and in the end the Federal sovereignty will be defeated.

Imperial Valley should not be asked to wait twenty years for a reasonable degree of flood protection, nor to wait at all for an additional water supply for late summer, which admittedly is its greatest need. Both these desirable results could be brought to fruition in three years, if politicians and city boosters could be eliminated and well-established engineering principles could be brought to bear. The silt problem is a minor issue and will be solved incidentally.

Inasmuch as the proposition has been here advanced to differentiate between interstate and intrastate rivers, it becomes pertinent to examine the legal possibilities of this proposal. It is advanced as an idealistic solution. One practical effect would be to give California control over its water supplies, while the control of all water resources—main streams and the smallest tributaries—in States such as Idaho, Montana, Colorado, New Mexico, and Arizona, would be surrendered to the Federal Government. Presumably, this would have to be accomplished by an amendment to the Federal Constitution.

About 1916 the Committee of the Judiciary of the United States Senate was directed to report on the rights of the Federal Government relative to water power of streams within the respective States, and the report was made by a sub-committee[45] consisting of the best constitutional lawyers in the Senate. The majority report was written by Republican members, who might be expected to lean as far as possible toward Federalization. The minority report was even more pronounced in the declaration of State control of streams.

In effect, this report states that, as regards water power and irrigation, there can be no differentiation between interstate streams and intrastate streams, and in all matters other than those of navigation, the ultimate authority and control over waters rests in the State. The status of the Federal Government as owner of abutting lands is not different from that of other owners.

The Sub-Committee states[45] its opinion regarding the rights of the Government under the commerce clause of the Constitution, as follows:

"The mere grant by the Federal Government of authority to construct a dam in a navigable river, not for purposes of navigation, but really for the creation of a water power, is merely a license or permit, the effect of which is that if the dam is constructed and operated conformably to plans approved by the Government, it will not be deemed an obstruction or impediment to navigation. And in such case the Government would be authorized to charge a nominal license fee for inspecting and passing upon the plans and for watching over the work to see that it conforms to the plans and is properly maintained; but the regulative power of the Government would not extend to the use of the water for other purposes than navigation and interstate commerce. In such a case it seems to us that the Federal Government has no water power to sell or charge compensation for, for it is only authorized by the Constitution to regulate interstate and foreign commerce, which in this case means navigation."

Concerning non-navigable streams, the report contains the statement[46] that:

"The leasing of the water-power site as a part of the riparian lands of the Federal Government does not in and of itself confer the right to create a water power. At most * * * it merely confers the common-law right of usufruct in the water. If any other or further use of the water in the stream is required, the right to such use must be obtained from State authority, and, therefore, it is difficult to see how water power can be established in such cases without the co-operation or consent of the State."

The report of the Sub-Committee is based on the text of the Constitution and upon the interpretation of it by the Courts in many cases cited. There is no "pussyfooting"; the report is very conclusive. It should be mentioned, however, that in States in which riparian rights do not and never have existed, the case for the Federal Government is even weaker than that stated.

The object of the foregoing discussion is to emphasize two facts: First, regardless of what any individual thinks, the National policy relative to reclamation should be, that the States, and not the Federal Government, have sovereign powers over the control and utilization of streams in matters affecting irrigation, water power, and domestic use, and in all matters except those relating to navigation; and, second, that it is not desirable to change the present order.

[45] Senate Doc. No. 246, 64th Cong., 1st Sess.

[46] Hearings before Committee on Irrigation and Reclamation, U. S. Senate, 70th Cong., 1st Sess., on S. 728, January, 1928, p. 131.

If, however, it is deemed advisable and expedient that the Committee on A National Reclamation Policy should recommend an amendment to the Constitution delegating greater authority to the National Government with respect to control and utilization of the water supplies of the country, it is well to consider some of the obstacles that will be encountered.

First, consider the Pittman Resolution[46] adopted by the Conference of Governors and Commissioners of the Colorado Basin States at Denver, Colo., August 29, 1927. It is a carefully prepared, succinct statement and declaration of State sovereignty over water supplies. This resolution was developed to final form by the legal representatives of the Basin States and was signed by representatives of six States, the seventh, California, asking to be excused from voting.

Can the Committee cause a "right-about-face" on the fundamental attitude of the Western States as expressed in that resolution? Will those States be impressed by arguments relating to greater efficiency of control emanating from swivel-chairs 3 000 miles away? In passing, it may be remarked that every principle enunciated in the Pittman resolution is violated in the Swing-Johnson Bill.

It is not in the West only that the Committee will meet obstacles. New York State has engaged the Federal Power Commission in a death struggle over the control of water power of navigable streams (one of which is international), and the Federal Power Commission has gradually receded from its early assumption of jurisdiction. Will New York capitulate when its battle is just won? The State of Maine not only exercises control over its water resources, but has a law forbidding the exportation of hydro-electric power and thus far that unique law has held its ground. The Southern States also are locked in a struggle with the Federal Government over control of water power. Will they listen to an appeal from the Society to surrender their authority to the Federal Government?

The answer is, No. If the Committee advocates nationalization of the rivers, in any degree whatsoever, it will succeed merely in invoking violent criticism.

It is said sometimes that public necessity creates law; this is illustrated by the growth in power and influence of the Interstate Commerce Commission during the past two decades. However, in the matter of control and utilization of streams, the States are managing those functions satisfactorily at present. If one State feels aggrieved against another, it is not without legal remedy, for each State has the protection of the U. S. Supreme Court, and there is the alternative method of settling conflicts in interests by interstate compacts. Necessity cannot rightfully be urged as the argument for National control of the utilization of water resources.

If the Federal Government can say that a dam shall be built here and that there shall be no dam there, it involves the decision that one valley shall be granted rights of appropriation and another shall not; in other words, the States would lose control over appropriation of water.

It is probable that the compact method should be encouraged, at least in many cases. However, one of the most highly respected engineers, an authority

on water law and a Californian, has stated his misgivings over the injection of the compact plan. Several excellent compacts have been negotiated, notably those between the States of Colorado and Nebraska and Colorado and Kansas; the latter, however, is not yet ratified. The Colorado River Compact was a "dud" because it was negotiated in great haste, for Congress in its unwisdom had decreed that the Commission should expire at the end of the year, and because, although some of the seven States had made elaborate studies of their future needs for water, others had made no studies and had no basis on which to negotiate. The Colorado River Compact could now be amended or rewritten so as to be acceptable to all seven States, if the commission could be re-established. President Hoover has suggested[47] that the Gila River System should be exempt from obligation to furnish water to supply the quantity to be allocated to Mexico by treaty. This amendment would be welcomed by the State of Arizona, if the other States should accept it.

If the functions of storage may be analyzed as three in number—river regulation, irrigation, and power—then it is desirable for Federal activity to be restricted in a large measure to regulation, to a less extent, to irrigation, and least of all, to power. Applying this to the Colorado River, the Federal Government should build storage for about 6 000 000 acre-ft. capacity on the head-waters. The expenditures required would be less than $20 000 000, and thereafter Federal aid would not be necessary for the combined irrigation and power projects which would inevitably follow at other points on the river. The Gila River is being brought under control by many dams, built and projected, and long records of stream flow prove that no other tributary between the mouth of the Green and the Gila Rivers is a menace to the lands along the lower river course.

Is it desirable to force rapid extension of reclamation? There are two distinct points of view prevalent with respect to this question. For convenience of reference they may be called the conservative and the promoter viewpoints.

The conservative viewpoint may be described as follows. If social and economic conditions warrant additional agricultural production, then men trained to the soil, who are ambitious to develop and own a farm, will appear voluntarily, or they can be found. These men, by early rising and sustained industry, by thrift and careful management, will transform a sagebrush desert into fruitful fields, as their fathers have done before them. This has been the rule in Arizona. The only deviation from the rule that the speaker recalls, was the building of many small homes on one corporation-owned project; but the people who moved into those homes soon went away.

A healthy, voluntary land settlement fluctuates with agricultural prosperity. When agriculture is prosperous, there is a strong demand for farms. In 1919, a project in Southern Arizona, with about 300 land units, was settled so rapidly—by trained farmers—that the land was literally taken away from the promoter. At the outset the price was $150 per acre for raw land with water, but when men stood in a long line waiting impatiently for their turn

[47] Conference at Grand Canyon, Ariz., summer of 1928.

to be shown over the tracts, the price was raised to $250, with a cash payment of $75 per acre. As might be expected under the circumstances, the promoter over-estimated his water supply and over-sold the project.

The other viewpoint is quite different. It starts with the fact that potentially productive land lies idle. To reclaim it means interesting applications of engineering, local prosperity during the construction period, and the growth of near-by cities and villages. "Manless land" and "landless man" must be brought together, whatever the obstacles. If, as in the seven years since 1921 no land hunger exists, it must be stimulated; homes must be erected, fences built, the land graded and prepared for cropping, and some live stock must be placed in the corral.

There is a danger that, if much paternalistic effort is made for the settler, he will sit on the doorstep during the hot summer days, trusting that this mysterious Government which has done so much will come forward and cut the weeds and spray the bugs. Furthermore, such a beneficent Government certainly will not insist that he forego a new shiny automobile or a summer vacation in order to pay annual charges for operation and maintenance.

The psychological effect upon the settler in the two cases is entirely different. In one case, he realizes that his success depends upon his own initiative, his industry, and good management; in the other case, he starts with a feeling of dependency and is likely to adopt a "Micawber" attitude.

Paternalism in Government is based on an assumption of a *quasi*-fatherly relation, involving supervision of business and social concerns, on the theory that the people are incapable of managing their own affairs. It is ill-adapted to the virile Anglo-Saxon race. Why should the Federal Government build homes for farmers any more than for laborers where some other new industry is under way?

There is little doubt that big, costly projects have been developed too fast in the 25 years since 1903. If a 10-year holiday should be declared in reclamation, it is doubtful whether settlement would catch up with the supply of good land now available with irrigation water supply. If farming were merely a mode of living and land values were low, there would be some reason for arguing a "back-to-the-land" movement, in order to reduce the congestion of population and to increase the percentage of those who love the open air and the freedom of country life. Irrigation farming, under projects involving $80 to $160 per acre for water supply, is, however, a business proposition of the first rank and should be assured of rapid settlement and of success from an economic standpoint before any commitments are made. Inadequate settlement has caused more failures of irrigation projects than any other one thing.

In the case of large, difficult projects, governmental aid is necessary and justifiable, and the present form of this aid—the waiving of interest—should be called by its true name, which is subsidy. It is an important advantage to the country as a whole to have a successful agricultural project developed and put on its feet. If it is not successful, the advantage disappears; it becomes a liability.

To what extent is the subsidy justifiable? Surely the Federal Government should not create farms and deliver them gratuitously to a limited few farmers. The question of what percentage of the cost should be borne by the Government is too often neglected. It should be recognized that the major advantage goes to the farmer, the next in order to the community, the next to the State, and the last to the Nation. Why not adopt the plan used in financing elimination of grade crossings, by which the railroad, the State, and the city divide the cost. If a State is appreciative of the value of a new development and desires it earnestly, it should participate in the subsidy, instead of buying it from Congress through the demoralizing political method of trading votes. Many of the Federal projects have been, and are being, secured by purely "pork-barrel" methods. It may be advanced that the State is too poor; this is not true. If the State is unwilling to match the Federal aid, it is evidence that the project is unsound and ought not to be built.

Recently authorized projects of the Bureau of Reclamation have been over-subsidized. As an illustration, the Kittitas Project, in Washington, is designed to cost $160 per acre. The land owners are obligated to pay annually a percentage of the gross crop returns, estimated to average $2 per year,[48] so that the period of repayment may extend over 80 years. The present worth of a promise to pay $2 per year for 80 years is $39. Owing to the long interest-free interval before repayments begin, the face value of the paper contract is even less than $39. The farmer, therefore, is asked to pay less than one-fourth of the construction cost. Surely no one will claim that it is worth $121 or $140 per acre to the Nation as a whole to have that tract irrigated. It may be at some future time when the food supply is inadequate and when other areas are fully occupied, but not at present. It will be interesting, also, to see whether the land owners find some adroit way of capitalizing so great a bonus when resales are made.

There has been considerable protest, especially in the Middle West, against artificial Governmental stimulation of agriculture through extension of area. There is much more justification for protest by older, half-settled projects, especially those promoted without governmental subsidy, because the new projects compete actively for the limited number of competent potential settlers.

The U. S. Bureau of Reclamation has made an enviable record for the character of its works, which have been designed judiciously, with a view to appearance, safety, adequacy, and, in particular, permanency. Comparatively few engineering mistakes have been made. The thoroughness with which the relatively poor foundations of the Elephant Butte Dam were strengthened and protected reflects great credit upon engineers of the Bureau and the admirable *esprit de corps* infused in the organization by its first Director, F. H. Newell, M. Am. Soc. C. E., is a model for all time.

R. K. TIFFANY,[49] M. AM. SOC. C. E. (by letter).—The discussion of a National reclamation policy takes on new interest since President Hoover has

[48] *New Reclamation Era*, February, 1927, p. 18.
[49] Cons. Engr. (Tiffany & Langloe), Olympia, Wash.

proposed certain radical changes in the handling of Federal reclamation and in the closely allied subject of public lands in the Western States.

The following suggestions may help further to clarify some of the ideas mentioned only briefly in the report:

1.—What is the fundamental basis of Federal aid for reclamation? Is it not to make habitable and productive for the public benefit areas of land that would otherwise be permanently desert waste? The Federal Government has taken up no projects that could be developed by other agencies.

2.—The steady growth of America has justified the traditional National policy of encouraging agricultural development. Recognizing the errors and occasional economic waste involved, who will deny the tremendous value to the whole Nation of the Homestead and Desert Land Laws, the Western Railway Subsidies, and the Reclamation Act?

3.—The desert lands of the West, although now largely in private ownership, are essentially a public burden. They cannot be developed by private enterprise, nor, in most cases, by the States.

The whole country needs the timber, mineral, wool, and other essentially Western products, and the growing commerce of the Pacific. To grow and prosper, the West must have, in due time, the production of its irrigated lands. The entire Nation will benefit from a policy that, under an orderly and economic plan, will make these lands available.

4.—The reference to "interest" in Conclusion (1) of the report should be understood to refer only to the period after the settler is upon the land, bearing in mind that the settler is doing a public service in developing the land, if there is a real economic need for its products.

5.—The Committee has outlined a National reclamation policy. It may be helpful in considering this question to have a tentative program for the immediate future. The writer suggests the following:

*Tentative Five-Year National Reclamation Program.*—

(*A*) Concentrate on study of means and methods to bring existing projects to successful conclusion, and turn them over to local management as rapidly as possible.

(*B*) Reconsider the so-called "Ten Year Program of Construction". Make a market survey of each district or project, covering local, National, and State markets for the probable production of each project and so modify the construction program as to bring in new land only when and where it appears that its products can be absorbed at prices profitable to the farmers.

(*C*) Apply the reclamation organization and any surplus funds to the building of reservoirs useful to flood control, irrigation, and power. These reservoirs and controlling works should remain under Federal control and should not be charged to the land.

(*D*) Study methods of decentralization by which States, or local organizations within the State, would build canals to be financed by the Federal Government under plans perhaps somewhat similar to Federal Land Bank organization.

DAVID WEEKS,[50] ESQ. (by letter).—This report is constructive in that it suggests a basis for broadening the scope of the activities of the Federal Government for the benefit of a larger number of American people throughout the entire United States. It is also to be commended because it provides for the apportionment of costs on a more rational basis than has heretofore been possible.

The Committee proposes: (1) Public control of water conservation and stream regulation; (2) allocation of costs among benefited interests, including the State and Federal Government; (3) disposal of water and power at wholesale; (4) regulation of interstate streams under interstate compacts; (5) construction at the present time for stream regulation and to provide supplementary water supplies for existing systems and not for bringing new areas under cultivation; (6) thorough investigation as to feasibility prior to construction by a board of review composed of engineers, agriculturalists, financiers, and economists; (7) repayment of principal, and a low rate of interest by land owners for costs assessed against farm lands; (8) control of land speculation; and (9) the relinquishment of control of completed works to suitably organized local agencies.

It is fitting that such a board of engineers should confine its findings to engineering matters. This it has done with the exception of casual recognition of the agricultural situation and its relation to reclamation and a brief reference to the important problem of agricultural development.

*Federal Reclamation and the Agricultural Surplus.*—Federal reclamation projects have provided homes for a rural population of nearly 150 000, and upon these lands crops valued at nearly $1 500 000 000 have been produced. Growing urban centers have been made possible in different parts of the arid West where industries vital to the development of other natural resources have been established. In these Western cities are large numbers of workmen whose families are supported by the agriculture of Federal reclamation supplemented by the products of range, forest, and mine. Automobiles, farm machinery, furniture, and other commodities are brought into these thriving communities each year from Eastern factories. A growing Western demand for Eastern products gives employment to those seeking refuge from the depressed rural areas and increases the purchasing power for farm commodities in Eastern urban centers. The taxable wealth of the Nation undoubtedly has been increased by Government activity in reclamation.

Nevertheless, the Eastern economist has asked, "What has been the cost of these benefits?", and Federal reclamation has been called upon to account for its share in the agricultural surplus. Those interested in the development of the Western States believe that Eastern economists have been unmindful of the real problems of irrigation development, and have diverted their energies from some of the more important issues confronting Western agriculture. Instead of expressing a desire to help to make irrigation a success, their one objective has been to prove that reclamation is a failure and that it contributes to the agricultural surplus. If it had not been for a group of Western en-

[50] Prof., Coll. of Agriculture, Div. of Agricultural Economics, Univ. of California, Berkeley, Calif.

thusiasts who had desires equally as strong to establish a set of opposing facts, the statements concerning reclamation contained in the numerous lists of remedies for the agricultural situation, might have been taken as final. If the advocates of Federal reclamation have been a little too zealous in their determination to win their case, they have at least shown that there are two sides to the question.

In 1927, less than 0.85% of the gross value of all crops in the United States was produced on Federal irrigation projects. Although small in comparison with the total value of all crops, commodities produced in these projects were of vital importance to the States in which they were raised.

Arguments have been written to the effect that although small in amount, the production on Federal projects has an important depressing effect on prices. These arguments are based upon the economic concept of inelasticity of demand. This is simply a technical way of saying that a small increase in production causes a large reduction in price. The limits of this discussion will not permit an elaboration of the many commodities produced on Federal reclamation projects. It might be well to consider the effect of Federal reclamation on the price of potatoes. In a similar analysis of this commodity the error was made of considering the effect of supply on price without giving recognition to the effect of price on supply. Consideration of the normal growth in demand was also omitted.[51]

The production of potatoes in the United States in 1928 has been estimated by the U. S. Department of Agriculture at 462 943 000 bushels. Since this production was more than 50 000 000 bushels above normal, the price was depressed. This excess above normal production was caused by conditions favorable to crop growth and to an increased acreage following the exceptionally good prices in 1925 and 1926. The activity of the Federal Bureau of Reclamation cannot justly be charged with these mal-adjustments inherent in the potato industry. The normal production of potatoes in the United States has increased since 1910 at the rate of about 3 500 000 bushels per year. Fluctuations above and below the normal trend have been accompanied by opposite tendencies in the price per bushel. (See Fig. 3.[52]) The normal increase in production on Federal reclamation projects has been about 500 000 bushels per year. (See Fig. 4.) The normal per capita production of potatoes in the United States decreased from 3.8 bushels in 1910 to 3.6 in 1920 and 3.4 in 1928. The trend of the purchasing power of potatoes has been upward for many years. The difficulties of the potato industry are caused by violent fluctuations in production and prices and not by an increase in the total normal supply.

*The Net Effect of Federal Reclamation on the Potato Industry.*—To say that Federal reclamation had no effect upon the potato industry would be as erroneous as to say it depressed prices 4 cts. per lb. Local cases could probably be found in which a shipment from some Reclamation Project might have upset some local market. The most important effect, involving a larger number of producers, would be that a certain acreage of land which, with the growth of

[51] See Millard, Peck, "Reclamation Projects and Their Relation to Agricultural Depression: Farm Relief," *Annals*, The Am. Academy of Political and Social Science, Vol. 142, 177–185, Philadelphia, Pa., March, 1929.

[52] Year Book, U. S. Dept. of Agriculture, 1928, p. 806, Table 202 (1929).

the potato industry, would have been used for growing potatoes, has necessarily been devoted to something else. Without following out the intricate adjustments which might result from such alternate use of land, the net result might logically be the substitution of a comparatively small acreage which is producing potatoes in Reclamation Projects for a somewhat larger area of stump land in the East or West which otherwise might have been cleared for producing potatoes or some other crop.

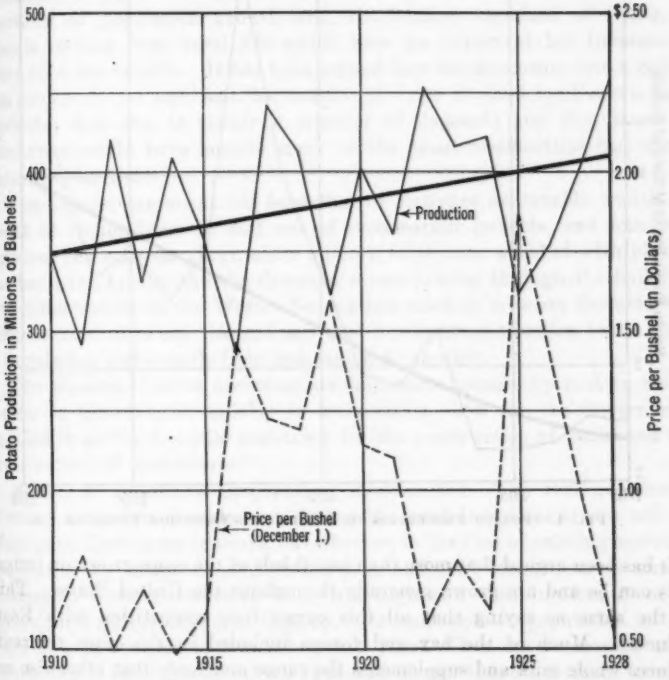

FIG. 3.—TREND OF POTATO PRODUCTION AND POTATO PRICES IN THE UNITED STATES.

If production in Federal projects had been suddenly superimposed upon United States production, especially with respect to potatoes, economic forces would have set about reducing production in succeeding years. This would have taken place on a few farms, marginal for potato production, in and out of Federal projects. The result, over a period of years, would have been a normal production and the price but slightly different from what would have existed without Federal reclamation.

Instead of being superimposed upon the production of the country as a whole, however, the acreage of all crops added each year since 1913 by Federal reclamation has been only about 76 000 and of potatoes the average acreage added each year has been less than 2 300. Even the addition of this small

acreage, if not offset by increased demand, would be followed by adjustments in production if the effect upon price was such as to warrant it. In the meantime, however, there has been some increase in demand. Indeed the annual fluctuations in production from other causes probably have so far overshadowed the effect of irrigated potatoes that statistical analysis would fail to find it.

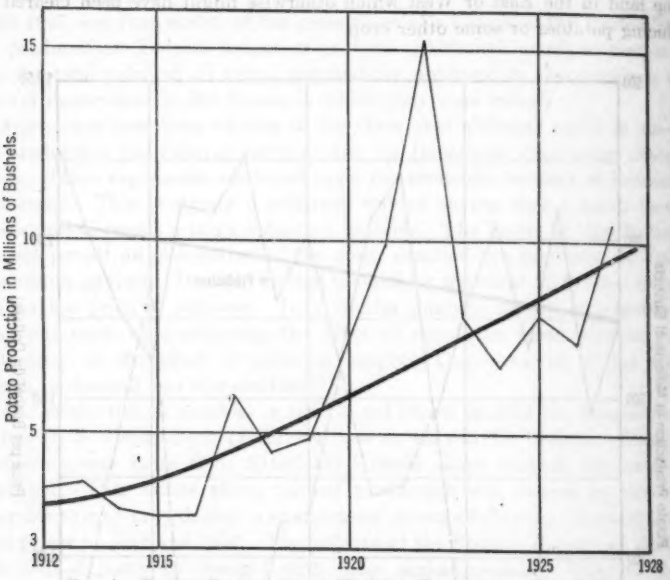

FIG. 4.—POTATO PRODUCTION ON FEDERAL RECLAMATION PROJECTS.

It has been argued that more than two-thirds of the crops grown on irrigated lands can be and are grown generally throughout the United States. This is not the same as saying that all this comes into competition with Eastern producers. Much of the hay and forage included in the crops referred to produces whole milk and supplements the range and feeds that otherwise could not be fully utilized. The remainder, if it finds its way into Eastern markets in one form or another, either supplements other sources of supply by filling in seasonal deficiencies and reduces imports, or fills a demand for a special variety or quality of product.

The situation is somewhat different in California where perennials are the most important irrigated crops, but these difficulties again are inherent in the particular crop industries of that State. Difficulties in adjusting land utilization to market demand and the tardiness with which decreased production responds to decreased demand result from the years required for a tree crop or vineyard to come into full bearing. Distress resulting from over-production of individual crops because of the market and production characteristics of these industries should not necessarily be charged to reclamation. It is, however, one of the difficulties which reclamation development faces and no doubt

reclamation in certain local areas has forced land into the production of crops already in a condition of over-production.

*Does Reclamation Create New Life and New Wealth?*—An outstanding omission in the arguments against reclamation is the failure to recognize the organic growth of Western communities made possible by irrigation development. The many arguments concerning the extent to which reclamation creates its own demand have been founded for the most part on inadequate knowledge. It is a difficult question which cannot be answered by mere compilations of figures on imports and exports. There are the fundamental questions of population growth and distribution, standard of living, and psychic returns from rural life which have an important but immeasurable effect upon net benefits. It has been argued that the shipments into a reclamation project do not represent the creation of a new demand for Eastern factory products; that this is simply a transfer of demand; and that these same purchasers would have bought many of the same commodities had they remained in the East.

The counter argument has been that of statistics on taxable wealth, shipments of commodities in and out of reclamation projects, and numbers of churches and schools. Arguments on both sides have wreaked with bias. No one has tried to measure the dynamic forces arising through the building of new communities in the West. No one has tried to measure the extent that reclamation creates new life and new wealth in contradistinction to the transfer of population and wealth from one region to another.

The answers to these questions are important because upon them rests the answer to Government activity in reclamation—how far the Government is justified in giving financial assistance for the construction of works and in the development of agriculture.

*Economic Questions Confronting Reclamation.*—The real question confronting irrigation development during the next few years is not one of its effect upon Eastern agriculture, but whether, in the face of existing agricultural conditions, an irrigation project can gain sufficient momentum to come into production with construction costs still high and with incomes from many agricultural enterprises still lagging. Urbanization of population is taking place at a rate which is increasing each year. That the percentage of rural population is declining is only a symptom of two important facts in relation to reclamation. In the first place, it indicates that cities are offering better opportunities for the masses than the farms and, in the second place, it is an indication of important changes in methods of agricultural production.

Agricultural production is becoming industrialized. Capital is replacing man power. How fast and in what form this tendency will take place in the future is not known but it is becoming increasingly difficult to create a farm under irrigation on a par with those already established. Until more adequate machinery is set up for financing modern agricultural development in a project after it is brought into existence, it is doubtful whether new reclamation, especially under present conditions, is possible.

Inasmuch as such financing of agriculture has not met with favor and because the possibility of doing so has not been successfully demonstrated in

the United States, it may be logically concluded that reclamation of new areas at the present time is likely to result in the loss of a large part of the funds thus invested. A policy of curtailment is, therefore, wise. Two important observations should be made, however. Curtailment of reclamation, except in certain local areas, as a solution of the agricultural surplus problem is of minor significance. In fact, on the basis of knowledge now available, it is safe to state that the promotion of reclamation is just as likely to help the agricultural situation as to impair it. This question, however, is in need of more intensive study. Of greater significance than its effect upon the agricultural surplus is the reclamation policy, which should evolve from a desire to help reclamation to success rather than to bend every effort toward its destruction.

The plan proposed by the Committee, unless supplemented by a more adequate consideration of agricultural development, thus perpetuates the one-sidedness of reclamation. Irrigation works have usually been readily financed. The plan of the Committee will make it still easier to bring large irrigation works into existence. A lag of agricultural development behind irrigation construction is one of the chronic ills of reclamation. It is not peculiar to periods of depression. It represents one of the most important costs. The lag between irrigation construction and agricultural development will be increased if a supplementary plan is not worked out, which will make possible the synchronization of agricultural development and irrigation construction. To synchronize agricultural development and the construction of irrigation works, it will be necessary to build projects more in accordance with agricultural needs and then to bring them promptly into production. If the Federal Government engages in reclamation, specializing in the construction of storage works, agricultural development should be the "concern" of the Federal Government at least to the extent that contracts with States, for the joint financing of works, should carry provisions stating how that important phase of reclamation is to be done.

*Economics of Agricultural Development.*—Perhaps wisely, the Committee avoided the difficult agricultural and economic problems of land development under irrigation. It is because they are difficult and not well understood and because they are not engineering problems that they have not been given more consideration.

"In the case of reclamation projects, it should be recognized that settlement of the land is fully as imperative to success as construction." This statement the Committee follows with the further assertion that,

"Land settlement including paternalistic, financial, or any other kind of assistance to the individual farmer should be treated as a local matter and should therefore be made the concern of the State or locality rather than of the United States. Aid extended by Federal Land Banks has been generally helpful and the possibility of further extension of such aid by this or similar agencies is worthy of serious consideration."

Recent experiments in land settlement and rural development in California have met with unfortunate circumstances, which have been given various interpretations by the public. No attempt has yet been made to give proper weight

to the different elements which have caused the difficulties. The general conclusions have been that the plan failed. Therefore "the entire plan is wrong". History is replete with similar instances. A close investigation of the facts of the case would reveal that the California experiments were overtaken by the same agricultural depression which has kept Congress busy since about 1920, that construction was carried out at high costs during a period of optimism and repayment and settlement took place under conditions of low agricultural prices and pessimism. There were many other elements in the situation, however, some of which might rightfully be charged to fundamental weaknesses in the original plan, others which were injected into the plan by ambitious legislators and public officials, and still others arising from the newness of the undertaking. No attempt has yet been made to profit by this experience and to perfect the plan or even to make an entirely new plan.

This attitude toward land settlement is in part caused by the recognition that there is plenty of "dynamite" in any plan of land settlement and in part to the attitude of the public toward agricultural expansion. Both these reasons have prevented the further development of land settlement methods and they account for the attitude of this Engineering Committee in proposing to have its monumental structures built as far as possible away from this "dynamite". Those who have fearlessly recognized the importance of this aspect of reclamation to the extent that they have thrown their entire lives into it, have been criticized by a public and an Engineering Profession which have not been educated to the importance of irrigation development in the West and which have not understood the real need and purpose of working out a technique of agricultural development.

*Needed Institutions for Agricultural Development.*—Outside the California experiments and inadequately supported efforts on the part of the Bureau of Reclamation, no attempt has been made to devise some form of institution for local improvement and government which will give to rural areas the same advantages that municipal governments have in constructing and financing development much broader in scope that the mere construction of irrigation works. When such an institution is created, it must meet the rigid requirements which the American public demands.

*There Must Be Provision for Financing Modern Farm Development.*—Existing credit agencies shun new agricultural areas. This is because they have no assurance of having principal with interest repaid to them. Their experience is that defaults have been numerous. The settler has not had the opportunity either to demonstrate his own ability or the productivity on his farm. The hazard, therefore, is great. When commercial firms decline to make loans on the basis of 50% of a conservative appraisal, how can an institution be set up for extending even more liberal credit with assurance of having it returned? One answer to this question is, "Don't do it". Another answer is, "Reduce the hazard by selecting the settler, classify the land, require repayment on a basis that will make it possible for a man of small means to meet the installments, and give him all the advice and direction possible while he is improving his farm". The first leaves the problem unsolved. The second suffers the criticism of being paternalistic.

*The Plan Shall not Be Paternalistic.*—Webster defines parternalism as the:

"Principles or practices of a Government that undertakes to supply needs or regulate conduct of the governed in matters affecting them as individuals as well as in their relations to the State and to each other on the assumption that it can best determine and secure their highest welfare."

It is argued that the liberal extension of credit and the giving of advice and direction in the early stages of farm improvement is paternalistic to a degree that settlers acquire the habit of leaning on the Government in matters in which they themselves should learn to become self-dependent.

*Reclamation and Agricultural Development Must Be Free from Political Influence.*—Hand in hand with paternalism is political interference with economic tendencies and practical business necessities. Political influence has caused infeasible reclamation projects to come into existence and has obtained alms for the unhappy settlers who were induced to locate therein. State and Federal Government agencies charged with the execution of reclamation and agricultural development plans should be as free from such influences as it is possible to make them.

*Cost of Reclamation and Agricultural Development Should Be Apportioned Among Those Receiving Both General and Special Benefits.*—If benefits to the Nation as a whole could be determined accurately and if, when determined, political machinery and the Courts would permit assessment of the Federal Government for those benefits actually enjoyed by the American people at large, the question of a policy of subsidizing reclamation would be a simple one, complicated, however, by questions regarding the proprietorship of Western oil and mineral resources. Benefits will probably continue to be determined inaccurately. Courts will adhere to precedent in regard to assessments for general benefits. Political machinery will probably continue to be arbitrary in the formulation of public policy. Ownership of the resources of the Public Domain will continue to be the subject of fiery debates in Congress. Subsidy, under such circumstances, cannot be granted on a basis commensurate with public benefit. Moreover, even with subsidy, many of the ills of reclamation would remain unsolved. Dams could be constructed and irrigation canals built at no cost whatever to the settler, and there would still be difficulties to overcome, greater than any of those surmounted by the engineers in the construction of such dams. The question, therefore, of deciding for or against the subsidy in reclamation is not the most important to be determined in the formulation of a National reclamation policy.

*A Suggested Plan of Procedure.*—The first step to decide is whether reclamation in the Western States is conducive to sufficient public benefit to warrant an attitude of support rather than antagonism on the part of the Federal and State Governments. Anticipating the outcome of such deliberations, it may be decided that it is best to curtail the reclamation of new areas for the present, but that it is wise and constructive policy to do what can be done to make existing projects successful.

The difficult question at once arises as to what crops can best be grown on the various lands, now within projects, which are lying idle or are producing crops that cannot pay the costs levied against them. In this connection

the rate of assessment, availability of settlers, their probable qualifications and capital, types of farm organization, size of farm, methods of production, and total capital requirements must be considered, in addition to physical factors affecting crop adaptation and economic factors of prices and markets.

Having determined the optimum combinations for successful agriculture, the problem which is still unsolved must be faced. Where is the capital coming from? Should it be supplied by the Government? The last question has been answered by popular acclamation with a decisive, "No!". Whether this answer is right or wrong it represents a situation which is an element in the whole problem. The alternative is to make the financing of farm development safe enough to attract private capital. Before this can be accomplished experiment and demonstration will be necessary. If it is unwise for the Federal Government to engage in supplying credit for agricultural development as a regular practice, at least it would seem permissible for it to develop from ten to twenty farms on a purely experimental basis. This has long been recognized as being within the proper scope of governmental activity. These experiments should be carried on without limitations as to the total amount of capital to be applied to any one farm, as has been done in the past.

What is needed is more information regarding what that limit should be. Instead of cutting the farm to a size to fit the settler's pocketbook, the size should be determined by experiment at the optimum. Of course, ten or twenty farms would not answer all the questions which are still unanswered, but it would be a means of bringing out the important elements. Overhead expenses could not be charged to this small number of farms. Adequate capital should be appropriated for the experiment which should prove of value to agriculture under irrigation throughout the West. Part of this appropriation would be returned through the repayments on the farms. A part must be charged to experiment. The first experiment should be free from the difficulties of community organization. Later, with the knowledge gained, a special study could be made of the advantages and disadvantages of group settlement.

Because of differences of opinion on these matters held by the U. S. Bureaus of Reclamation and Agricultural Economics, the research and experiment should be directed by an economist selected by the joint action of both Bureaus. It should be the duty of this economist not only to develop technique of farm development under irrigation and determine capital requirements, but to suggest the type of administrative organization and financing program necessary to make possible the successful completion of reclamation projects.

JOHN A. WIDTSOE,[53] ESQ. (by letter).—The two supporting papers of this report contain views that will contribute much to the development of a successful reclamation policy. They do not mention, however, the most important fact connected with the Federal irrigation movement, namely, that land reclamation as a National activity, is rooted deeply in National policies, not politics. Federal reclamation is an expression of a twofold desire: To possess the entire country by full and profitable settlement and to establish more firmly

[53] Liverpool, England.

the most important source of National stability—agriculture—by providing landless, land-loving men with farms. That is a National concern. National reclamation policies, therefore, must look to ultimate rather than to immediate results.

There is a veiled fear in the report of the Committee that Federal irrigation may interfere with private business, and that rigorous restrictions, therefore, must be set up. Such interference would be a misuse of the Reclamation Act. Federal reclamation activities should concern themselves primarily with projects that private enterprise cannot, or will not, undertake. In fact, this has been done. Few, if any, of the splendid major structures of the Bureau of Reclamation would have been built with private capital. The Government ventures have encouraged, not competed with, individual enterprises. The greatest recent private irrigation development in America has been inspired by, and coincident with, the growth of Federal irrigation. The wealth of experience gained on Federal projects, systematically gathered and published, is used profitably on private enterprises. Indeed, the Federal projects have not brought the Government into business, but rather have increased private business.

The present field for Federal irrigation is probably the completion and rounding out of existing projects, private and governmental. Many private projects are unfinished and they represent large money losses. The Reclamation Fund could bring these into profitable operation, and salvage some of the losses. Other projects, established and profitable, face with dread the inevitable dry year. Insurance can be provided by a supplementary supply of water from high-priced, storage reservoirs, which can be built on the terms of the Reclamation Act, but are beyond the scope of ordinary banking practice. Then, also, small pioneering communities, "in the very raw," are scattered about in the desert, waiting for help—aside from their own toil—to construct the little reservoir and canal necessary to bring the meager reward of their efforts. Such enterprises are disdained by the banker; for such communities the Bureau of Reclamation can render the service clearly implied in the original Act.

Reclamation is not accomplished overnight; it requires periods of time beyond those recognized in the market place. Financial elasticity must be available for successful reclamation. Men cannot, under ordinary conditions, reclaim the desert in one year or in ten years. Men grow old and leave their sons after them to convert the dry desert into desirable homes. Governmental assistance must be given often at an immediate loss, but with ultimate gain The form which this assistance took in the Reclamation Act was the use of interest money in the construction of the projects. The capital was to be repaid, but no more was expected of the water user. No better or fairer plan has yet been devised. The suggestion of the Committee that the necessary assistance should appear in "the assumption of a part of the cost of project works" and that the water user should pay interest on the remainder, seems fraught with much danger and difficulty. Primarily, it invites loss. How much of the cost should be assumed? Should the first settlers, when the project is new and struggling, pay the same rate of interest as those who

come on later, when much of the pioneer work has been done? It would be better to cling to the wise statesmanship of the original Act.

Lack of knowledge concerning the principles involved in reclamation by irrigation has led to considerable losses on Federal projects. Much has been learned since 1900. The errors of the past need not and will not be repeated. Looking forward in irrigation is the present problem. The past can be used to help in the solution of difficulties and not as a means to frighten later settlers.

Among the mistakes of the Federal irrigation venture, none is more glaring than the assumption that to provide water for land is the essence of a successful irrigation project. The human factor is ignored. The error, indeed, went further in the assumption that water was more important than land or man. Alkaline water on good land, or good water on land of low productivity, spells failure; the best of water on the best of land will yield no success unless the man, by inborn power and by necessary help, can use the combination of water and land profitably. The stern dictum of the future must be: (1) Do not impound or divert alkali water for irrigation purposes until Science can show how such water may be used safely; (2) do not build irrigation works for lands of low productivity, until Science has taught owners how to farm them profitably; (3) supply the water user (the man who is to combine water and land into a unit of civilization) with knowledge, tools, and money, if necessary; and (4) vary the annual repayment with the possible annual income. If the Reclamation Service is foolish enough to bring water to infertile lands, or to lands beyond favorable markets, then it must be content to let the water user have ample time in which to pay.

Mr. Mead's contentions are sound. Successful irrigation cannot be expected in the future unless social and economic conditions are given first consideration. The best of engineering structures—ample water, fertile soil, and good markets—are demanded; but the man who uses all these factors, determines the success of the combination, and his needs, which are more difficult to meet than the stresses and strains of the dam, must be the concern of the new day in reclamation by irrigation.

One cannot have an intimate knowledge of conditions in Europe and take very seriously the cry of agricultural over-production through irrigation expansion. The relative area under the ditch is too small and the rate of increase in population is too great. With every coming decade men will look for more land, not for limitation of the agricultural area. Lands are reclaimed under the ditch, slowly, and the building of new irrigation works and the opening of new projects come with equal deliberation. It cannot be otherwise.

F. H. NEWELL,[54] M. AM. SOC. C. E. (by letter).—The value of a National reclamation policy must be judged by the practical, not theoretical, effect of such policy on the prosperity, the comfort, and the health of the Nation as a whole. It is to be assumed that the report of the Commitee of the Irrigation Division has this National, as contrasted with local, viewpoint in mind. If, for example, the drift of affairs should be such that the Federal policy,

[54] Formerly Chf., U. S. Reclamation Service; now Pres., The Research Service, Inc., Washington, D. C.

in promoting the reclamation of 1 000 000 acres, should result in the delay or should discourage the States, irrigation districts, or corporations organized under State laws, from reclaiming 2 000 000 acres of better land, then there must be something wrong. Not that this is an established fact; the tendency is there.

The first point made in the report, that of the unwisdom of waiving interest payments, emphasizes this tendency. Its effect is that of a subsidy, one by which less than 7% of the owners of irrigated lands, those on Federal projects, enjoy interest-free advances, while more than 93%, that is, land owners on State or corporate projects, must pay in full. To state it in another way; "It appears unfair that the farmers on 392 000 000 acres in the United States should be taxed for the purpose of supplying a large subsidy to those on only 1 803 000 acres, supplied with water by the United States." If this condition exists then the answer seems obvious as to why irrigation is not more advanced in many States and irrigation districts, and also why efforts are concentrated on getting more Federal appropriations. As long as kindly Uncle Sam, with his boundless wealth, will advance the money, it would be a waste of time to bother with other ways and means.

This easy credit, however, has not been an unmixed blessing. A reason assigned for the large percentage of failures of the farmers on Federal projects has been that these men, stimulated by the prevailing speculative spirit, have been less cautious; they have tried to handle 80 acres or 160 acres and, with lack of capital and experience, they have fallen deeply into debt. They might have fed their families, got less into debt, and acquired skill on smaller units.

The way in which this remarkable situation has come about, should be kept clearly in mind in evaluating the points of the Committee report. Most engineers have forgotten, if they ever knew, how these remarkable precedents of easy credits were established; how it happened that land owners on Federal irrigation projects are exempt from interest payments and form a class apart from other debtors of the Government. To get the full import of the Committee report, it is desirable to sketch briefly the points from which a start was made and the direction taken during the last quarter of a century in the development of the present policy.

When the Reclamation Act was signed by President Roosevelt on June 17, 1902, it had been preceded by nearly fourteen years of investigation initiated by Maj. John W. Powell under the authority of Congress (Acts of March 20 and October 2, 1888). Topographic and hydrographic surveys leading to the selection of various desirable projects, by 1901, were well under way. Thus, when Theodore Roosevelt became President it was possible to give him sufficient information to enable him, in his first message, to bring the needs of the country forcibly to the attention of Congress.

During preceding decades rapid progress had been made in irrigation; millions of acres of arid land had been irrigated by individual or co-operative effort; other millions of acres had been selected or purchased for reclamation. The rate of growth of irrigation at the beginning of the Twentieth Century, however, was slowing down. The economic reasons for this were not then

fully understood. Attention was concentrated upon certain obstacles which might be removed by the Federal Government and which, if removed, it was believed, might stimulate further development by individuals and State aid.

The great waves of westward movement of people, which marked the Nineteenth Century, had begun to subside, but the impulse still remained; there was demand for more land to be opened. This was on the assumption that the pioneer spirit still continued. Here was a fallacy; the true spirit of pioneering had been overshawdowed by the spirit of speculation. What really dominated was the thirst for pioneer profits rather than for homes on the land. Appeals had been made to each of the Western States to recognize its opportunities and responsibilities. As an entering wedge the Carey Act was passed in 1894 permitting the States to select public lands and initiate reclamation projects within their boundaries. Much enthusiasm was aroused, but the States did not rise to the opportunities; the conditions were such that under the Carey Act neither the real pioneer farmers nor the investors succeeded.

Without going deeply into the economic conditions, it was then assumed that a new impetus would be given to Western settlement if the Federal Government would take the lead in a series of experiments. Year after year unavailing efforts were made to obtain appropriations from Congress for building irrigation works. It was not accomplished until the rather ingenious scheme was devised to avoid making an appropriation. The result was achieved by diverting certain moneys before they became part of the general funds in the Treasury. This scheme circumvented the "watch-dogs of the Treasury" in the Committee on Appropriations.

It was urged that by the use of this special fund the Federal Government could build certain large works, the nature of which was such that they could not be undertaken by private capital, or even by the States, for the reasons either that the lands were owned by the Federal Government, or because there were certain interstate and international difficulties involved, or from the fact that the first costs were so large as to be practically prohibitive.

This condition should be kept in mind in order to understand the starting point of the National reclamation policy. In choosing among the large number of projects presented at that time, one of the first requirements was that any project to be considered should consist of public land; next that there should be some obstacle insurmountable by private agencies, such as State lines or of rights of a character such that they could be acquired only by the Federal Government. Moreover, it was a requisite that the enterprise should be of such nature that it was improbable that private capital could succeed.

At that time it was not a question of choosing the easier or more attractive projects; rather the reverse. Practically all the easy or cheap enterprises had already been undertaken; the various States had already selected, under the Carey Act, millions of acres including schemes which then seemed practicable. The requirement was that the Federal Government should undertake in each State one of the "rejects", or an enterprise so vast that private capital, even if aided by the State, could not hope for success; or it should

confine its efforts to places where interstate and international complications existed. For example, one of the first determined upon was the Milk River Project, on the Canadian border, necessitating a treaty with Great Britain. Another was the Newlands Project, in Nevada, involving interstate relations in storing water and on which large areas of public land then remained.

It is possible to go down the list and indicate for each of the original enterprises the particular difficulty to be overcome and which formed the basis for selection. Some of these obstacles have been forgotten, but at the time they were the chief determining factors. In each case as careful a study as possible was made, not only of topography and hydrography, but also of climate, soil, prospective crops, and markets, as well as of the economic features which might be expected. There was, of course, relatively little known at that time concerning the behavior of soils under irrigation, but the experts of the Department of Agriculture were consulted. They subsequently conducted experiment stations on the projects such as to make available a vast accumulation of facts for future guidance.

This National reclamation policy was gradually modified in detail as successive Secretaries of the Interior were called upon to act in specific cases. The principal changes in the original policy came when Secretary Lane, confessedly weary of endless importunities, took steps to put the responsibility upon Congress. Here was the breaking point from what might have been called the Rooseveltian policy of executive decisions. Up to that time the various Secretaries of the Interior, co-operating with the Secretaries of Agriculture, had selected the best available experts, appointed committees or commissions, and had acted on the advice of these engineering, agricultural, or economic boards. After Secretary Lane set aside this policy there resulted, in the opinion of many engineers, a sacrifice of scientific and technical expert opinion.

According to the ideals of the founders of the National reclamation policy, the results should be judged, not so much by the area of lands irrigated, nor by the total value of products, as by the influence for good upon individuals and associations of citizens. Federal reclamation has added 10%, or less, to the area of irrigated lands in the arid region. It has done this by overcoming what at the time seemed to be insurmountable obstacles and not by following the easy course. In studying the results of reclaiming this relatively small area of irrigated land, by the use of Federal funds, the question may well be asked whether the outcome has helped or hindered further developments. Has it aided in the prosperity of the 90% of land irrigated by other than Federal funds? Is the Federal Government carrying out its early promise of stimulating individuals, communities, and States to increased activities in building up the arid West, or the reverse?

The nation-wide publicity given the affairs of the beneficiaries of the National bounty has tended to obscure or minimize in the minds of the public the far greater activities of the ordinary agencies of reclamation. The situation, to-day, in this respect is illustrated by the condition in Palestine where the well being of the 10% of Jews impresses the world as being far more important than that of the 90% of Arabs. So in the mind of the

public the prosperity of the West has appeared to be tied up with the 10% of land owners under Federal projects; the great growth in agriculture, industry, and transportation through the 90% of private and corporate effort appears to be forgotten. To this extent results are not good.

In another respect also those acts, sometimes regarded as Federal interference with States' duties and opportunities, have the result of delaying various enterprises. It has been argued that the defects of the Carey Act would have been quickly remedied if hopes had not been pinned to the Federal Reclamation Act. This was passed at about the time that financiers and statesmen were discovering remedies for the difficulties encountered by State administration of irrigation enterprises. It is argued that instead of stimulating the States—as had been hoped when the Federal Government began to overcome physical obstacles, as well as interstate and international difficulties—the reverse took place; the State officials, instead of emulating these efforts, sat back to see the outcome.

Criticism has been made of the waiving of interest payments to be made by the owners of lands which have been reclaimed and made valuable by the use of Federal funds. At the time that these payments began to fall due, the idea was disseminated (and not discouraged) by Secretary Lane, that the rich and kindly Uncle Sam would not oppress any land owners; on the contrary he would grant them every possible favor. This attitude was in effect an invitation, especially when coupled with the statement, made on the floor of Congress at the time of the passage of the Reclamation Act, to the effect that the land owners would repudiate these debts. Thus, there came about an active campaign, not of outright repudiation, but for an indefinite extension of time. The effect of this was not confined solely to debts owed by land owners to the Government; it was seriously argued that other wealthy institutions, banks and loan companies, should also be generous. On certain Government projects the spirit of repudiation was so strong that financial houses hesitated or declined to do business in the localities, because of a general lowering of moral or financial standards due to the encouragement laid at the doors of Federal officials. It is not to be inferred that there was not real hardship in many cases. Under the present system, however, full discretion cannot be used by Bureau officers. All debtor land owners must be treated alike; hence, the breakdown.

Remember in this connection that the Secretary of the Interior deals with the people on the project, not as farmers, but as land owners; and also that a large proportion of these land owners (debtors of the Government) do not cultivate the land themselves; they are non-resident landlords. Some are bankers, business and professional men, clerks, and laborers trying to earn a living in town and renting the land to tenants. Due to these conditions the burden laid on the back of the actual cultivator of the soil often has not been diminished by executive leniency. Because of these easy terms given to the land owners and resulting speculation, the land prices have sharply advanced. The man who actually works in the fields has not been benefited.

The point which immediately concerns engineers, economists, and other citizens is as to whether the States, the irrigation districts, and corporations have been stimulated by the Federal activities. It may be asked whether these agencies might not have been more effective if the Federal Government had kept out of the field; the course of events might have forced the States to attack the reclamation problem through the terms of the Carey Act or some needed modification. All this is hypothetical, but leads to the conclusion that, with the experience of a quarter of a century, there should be a modification of Federal reclamation policy along the lines proposed by the Committee and one that will bring about a larger and better prosperity through encouraging these State agencies.

A. D. LEWIS,[55] ESQ. (by letter).—After a tour of inspection in America in 1913 the writer commented upon the irrigation situation as follows:[56]

"The result achieved in settlement is, after all, the measure of success in irrigation. Failures in irrigation schemes have resulted not so much from bad engineering as from lack of a proper understanding of the agricultural conditions and of all that is involved in the human aspect of settlement". * * *

"The chief lessons learnt were that settlers are not attracted to these schemes as rapidly as was expected and that difficulty is experienced in getting full payments from a large proportion of the settlers. * * * The supply of settlers with sufficient experience and capital is limited. * * * It is worthy of note that the American Government has not yet adopted the policy of loan advances (in cash or stock) to settlers to help them over the first few years."

During the sixteen years that have elapsed, the U. S. Reclamation Act has frequently been modified, numerous Commissions have reported, and the Reclamation Service has been unjustly abused and re-organized, but it appears that no complete solution of the difficulties noted in 1913 has yet been evolved in America. The history of Government efforts in irrigation has been very similar in South Africa, although conditions are less favorable to success. The surface of the country is very steep and denuded. The supply of water from annual rainfall and other sources is very small and erratic, and the cost of constructing storage works is excessive. The entire problem is further complicated by a heavy silt load in streams. The population density is less than 10% of that in the United States; marketing conditions are worse; and the tendency of political agencies to rush forward with new projects or to obtain special patronage for old ones is at least equal to that in America.

Despite these difficulties, irrigation received a tremendous impetus because of the ostrich feather industry, which is peculiar to South Africa. Dealers were prohibited from exporting the birds and this resulted in a very profitable monopoly of the market. Alfalfa was necessary for raising ostriches and it could be grown locally only under irrigation. From 1906 to 1913 the average price of feathers exceeded $13 per lb. and profits of at least $300 per acre yearly were made. As a result of these large profits, vineyards and other established crops were uprooted from the existing irrigated lands and were replaced by alfalfa crops. There was a frantic rush to build new irrigation works, many of which were merely primitive furrows to divert the intermittent flood flows

[55] Director of Irrig., Union of South Africa, Pretoria, Union of South Africa.
[56] "Irrigation and Settlement in America," by A. D. Lewis.

from rivers. The industry was based on a fickle, feminine fashion and "all the eggs were in one basket." The standard of profits was far greater than the general average for irrigation farming. In 1914, fashions changed, the World War broke out, a severe drought occurred, and the industry crashed. The value of the export of feathers fell from $15 000 000 in 1913 to less than $20 000 in 1918, and a post-war agricultural depression supervened.

From 1914 there was a feverish demand for storage works generally to alleviate the unfavorable conditions and especially to save the farmers who had spent their capital on flood-diversion projects. To date (1929) the total expenditure for irrigation in South Africa is about $35 000 000 and nearly three-fourths of this expenditure was authorized by Parliament during the period from 1914 to 1920. It is now almost certain that the Government will not recover even half of this sum. Had the works been spread over a longer period and had active steps been taken to check speculation and to insure the rapid settlement of the area brought under irrigation, there might have been hope of recovering a larger part of the expenditure, but certainly not all of it. Since 1924 very few new projects have been sanctioned and the question of subsidizing future works is now under consideration.

Some of the projects are built and operated by the Government, but most of them are managed by co-operative irrigation district boards to which the Government has loaned money at 5%, payable over a period of thirty or forty years. Most of the land is privately owned, and the unit costs per acre of irrigable land have been about $130, which is probably double the cost of projects in the United States. In South Africa the physical difficulties are greater, but the higher prices that prevailed after the war (when most of this work was done) accounted for part of the higher costs. The better projects, however, were begun first and the unit cost of future developments in arid areas is likely to be even higher.

It will be seen, therefore, that difficulties in South Africa and in the United States are very similar. Engineers in South Africa have followed every phase of irrigation activities in America, always watching for the discovery of some magic process which, without any direct financial loss to the Government, will rapidly convert the desert places into smiling gardens peopled with healthy and prosperous families. Lack of success in the United States warrants the fear that there is no such process.

By waiving interest charges, irrigation projects of the U. S. Reclamation Service have been subsidized at least to the extent of 40% (the ratio is apparently more than 70%, according to Mr. Lippincott). In addition, considerable capital and operating expenses have been cancelled. That is a sad picture which, after twenty-seven years of effort, can only be described as direct financial failure. Some of the causes can be remedied, but others will continue for many years, and the conclusion seems inevitable that under present conditions Government effort in irrigation cannot be made profitable in a literal sense. Similar effort in the immediate future will involve heavy financial subsidies. The case for the immediate extension of irrigation on a considerable scale will have to rest on the indirect advantages, particularly

those that are expected to accrue after a longer period even than a generation or two.

Throughout the world irrigation on a large scale has only been immediately successful under two essential conditions: (1) When the physical aspects are such that the works would be exceedingly cheap; and (2) when there is a large and frugal population, crying out for agricultural expansion because the opportunities for their absorption into other more profitable forms of occupation are restricted.

India fulfills both these conditions. Spain and Italy fulfill the second, and, in regard to some of the earlier works, the first condition; but in later works both countries have found it necessary to resort to subsidizing. The density of population in America is scarcely one-third that in Spain and one-sixth that of Italy; the relative density of the agricultural population is still less; the standard of living is far higher; and towns and industries continue to offer a more attractive occupation. The problem of attracting settlers to irrigated lands is only a part (the more expensive part) of the general problem of encouraging agricultural settlement and development; and as long as the Government attempts to force the natural tendencies of a population it is likely that subsidizing in some form will be necessary. Judging by results throughout the world and by the standard of direct financial success, it seems as if the United States has been premature in anticipating a genuine land hunger. South Africa has been still more premature in attempting to recover the entire expenditure, with interest, under much less favorable physical and economical conditions and an even weaker intensity of land hunger.

Without entering into the question as to whether it is desirable that irrigation should be pushed ahead by Government, even if it involves an immediate direct financial loss, it should at least be pointed out that in such countries as Spain and Italy, where irrigation is an old problem, the greatest prosperity is generally to be found grouped around the old irrigation works. The road to this prosperity has seldom been an easy one. Safety and security have often been reached only by a process resembling that by which the soldiers of Cortez crossed the watery gaps in the Mexican causeway over the dead bodies of the advance guard.

Assuming that a Government has decided to continue irrigation developments with subsidies there are a few aspects of policy that might be added to those presented by the Committee. These fall under three heads: (1) a steady program of reconnaissance and construction; (2) subsidizing by additional expense for development and settlement in preference to, or prior to, reduction of expenditure on works; and (3) taking the task of rate collection completely out of the range of politics by placing it in the hands of private institutions or banks.

*Steady Program.*—It is unfortunate that the popular demands for new irrigation developments generally come like sudden devastating floods and they often synchronize with periods of agricultural depression or political elections. They prevent an adequate preparation; they upset all economical arrangements as to staff and construction plant; they cause land to be brought under

irrigation before the advent of a steady flow of settlers; and they are apt to disturb market conditions. It is most important that a more or less steady program should be arranged over a long period. Furthermore, there should be no relaxation in the forces of reconnaissance, so that the necessary investigations may go on steadily well in advance of the program of construction. These considerations are more important for irrigation developments than for any other form of public works because essential factors, such as hydraulic and meteorological measurements, can only be properly assessed after long periods of observation.

*Subsidizing Developments.*—The remarks made by the writer in 1913 as to the slow rate of development and settlement seem to be equally true to-day (1929). If an irrigation project could be built to deal with a slowly expanding demand with the same facility as in the case of railways, roads, telephones, etc., the slow rate of development would not be such a serious factor. Unfortunately, in most irrigation developments, the major part of the ultimate expenditure on works must be incurred at the beginning. A simple study in arithmetic of compound interest and accumulating overhead charges will demonstrate quickly the absolute need of hastening the full development of the land affected by the new irrigation works. Experience has shown that under the existing arrangement (which relies on the private capital of comparatively poor people) development requires at least three times as long as it would with all the necessary capital available at the beginning. Even waiving the interest on capital expenditure for works has not proved sufficient to draw from private sources the capital needed for rapid development on such lands.

If a business that can hardly meet current interest and overhead costs after 20 years can be made to reach the same stage after 5 years, there is a considerable sum (corresponding to lost interest and overhead expenditure during 15 years) that could be utilized better as a free gift in the beginning to accelerate the development. The case becomes even stronger if the slow development of the land under conditions that now exist is not on the soundest possible basis and if the Government, with experienced and trained workers and capital resources readily available, can achieve better development as, for example, in leveling the land, which will result in a greater return from the water made available by the capital expended in the works. It seems preferable, therefore, to give the first subsidy in the form of free capital for accelerating development of the land, but to leave interest charges on at least part of the capital cost of the works so that its accumulation and excessive overhead costs may be a continual spur toward accelerated development. There will be complications in dealing with those who have already developed land from their own resources and in seeing that an early settler does not take all the advantage at the expense of a later purchaser; but there are complications of this kind in every form of Government bounty.

*Collection of Rates Through Banks.*—There is nothing so damaging to the financial credit of irrigated areas as the deferment and accumulation of rates that form a first claim on the land. A common failing of certain politicians is to endeavor to gain immediate favor with their electors by exercising the

utmost pressure to obtain these deferments. By placing the collections in the hands of banks this kind of political interference will be considerably reduced. Stern action on these lines will also be the best cure for inflated values of land and for the undesirable survival of unfit settlers as well as speculators. These are all very prevalent evils under existing conditions. Moreover, bank management will tend to dampen the activities of those who press for the immediate construction of new projects imperfectly investigated while relying on similar pressure at a later date to evade payment.

JOSEPH JACOBS,[57] M. AM. SOC. C. E. (by letter).—It was during the writer's term as Chairman of the Irrigation Division that the Committee on "A National Reclamation Policy" was created, and his letter to the Committee, at the time of its appointment, included the following paragraph:

"In deciding to create this new committee the Executive Committee felt that reclamation matters, particularly in respect of State and Federal relationship thereto, were just now in a state of transition and uncertainty, and that a correct solution of what the governmental attitude should be, required the careful consideration of able men entirely familiar with the subject of reclamation. This is a matter of great economic importance not only to the West and South, where reclamation activities will be greatest, but to the nation as a whole, and it is believed that no other group of men are better equipped, nor indeed anywhere nearly so well equipped, to contribute constructive thought and analyses of these matters, for the advice and guidance of Congress and of State legislative bodies, than is a group of carefully selected engineers, such as is represented by this committee."

That the Executive Committee's apprehension at that time was well founded is evidenced in a growing restlessness concerning reclamation matters and a steadily increasing spread of propaganda directed toward discrediting and discouraging further Federal reclamation activities. So pronounced has this trend been that, on August 26 and 27, 1929, a Western States Governors' Conference was held in Salt Lake City, Utah, to review the situation. However much or little one may agree with the findings of the Committee report, it is gratifying to note that in the solution of important economic public questions which have distinct engineering correlations, engineers specially qualified for the task are willing to contribute their time and their trained judgments to the analyses of such questions, solely for public benefit. This, of course, is as it should be.

The writer finds himself in general, although not in complete, agreement with the findings of the Committee. While these findings have been set forth in clear, unmistakable terms, each of them is so important as to have merited some accompanying discussion and supporting data, and the value of the report would have been further enhanced by a prefatory review of the Federal Government's past irrigation activities, its problems, and its accomplishments. Mr. Lippincott, in his subsequent explanatory statement concerning the report, sensing this curtailment, supplies many of these missing data, and it is to be hoped that the Committee can incorporate some such statement as an integral part of the final report.

[57] Cons. Engr. (Jacobs & Ober), Seattle, Wash.

The writer cannot accept, without qualification, the implications of Principles (9) and (10). It seems to him that the Committee is unduly exercised over the bugaboo of over-production. With a present annual importation of $800 000 000 of foodstuffs, and with a population growth of 1 500 000 per year, over-production in the United States, if it be a fact, cannot long continue and, in any event, it constitutes no sufficient warrant for long delaying the commencement of those major projects which cannot possibly be brought into full yield short of 20 or 30 years. Moreover, agricultural production is not wholly a National problem. It is, to a considerable extent, a regional problem also, and the desirability of an irrigation project the products of which may have, largely, a local distribution, should not be judged too rigidly by National considerations of possible over-production. Local economics must be accorded its due weight in reaching correct final judgments.

Principle (10) declares that the State should share in the responsibility for the selection and approval of projects, and the writer would add that the State should also share in the financial responsibility for the project. State co-operation should be made a condition precedent to the extension of Federal aid. The State's interest in reclamation is greater and more immediate than that of the Federal Government, and second only to that of the settlers on the project. All these agencies should co-operate. If a State, through lack of courage and enterprise, or because it has not sufficient interest or faith in its own development, is unwilling to assume part of the responsibility for that development, it is not entitled to Federal aid. It has no moral right to ask the Federal Government to assume, on behalf of the State, a responsibility which it (the State) is not willing to share. If, in some instances, present State Constitutions inhibit a practical financial co-operation as here contemplated, this can be remedied by Constitutional amendment. A well-planned co-operation should result in more carefully selected projects, in a saner and more rapid settlement, which is all-important, and, finally, in safer project investments for all concerned. If States deem such Federal aid and co-operation of value, they will soon correct any Constitutional defects that stand in the way of their securing it. The formulation of the details of a practical co-operation, of course, will require careful consideration.

Many, no doubt, will take exception to the Committee's condemnation of the waiving of interest on construction charges (Principle (11)). Some substantial reasons can be advanced for the interest waiver, particularly as part of the original Reclamation Act with its otherwise too drastic payment terms; but the writer believes that the weight of argument, and sound economics, favors the stand taken by the Committee. The only financial concessions that irrigation needs from the Federal Government are a low rate of interest, long terms for payments (not less than 30, nor more than 50, years), and the absorption by the Federal Government of the interest charges accruing against unoccupied lands during the period of settlement. The last-named concession may be regarded, not as a subsidy, but as a payment by the Federal Government for its share of the benefits resulting from irrigation development, and the Federal benefits from such development are by no means inconsequential, whether considered from the social, industrial, or military viewpoint.

With these concessions, any project worthy of development should be able to meet its obligations as they mature. Not only is it the writer's opinion that the projects can pay, and that it is just that they should pay, a low rate of interest on terms as specified above, but that, unless the Western States are willing to accept such a consummation, Congress will soon refuse approval of any further extension of Federal reclamation beyond present commitments. If such acceptance by the Western States was not justifiable on any higher grounds than expediency, it would have ample, practical justification on that basis alone, because the return to the Government of its investment with a fair rate of interest is probably the only basis upon which land reclamation can be depended as a continuing Federal policy.

The authorities responsible for a National reclamation policy, as Mr. Lippincott points out, should have in mind the creation of equal opportunities and the stimulation of individual effort; but they should also have in mind that reclamation must be founded on so sound a financial basis that the return of construction costs, plus a reasonable interest charge, is assured. Otherwise, it is not enduring and, sooner or later, must inevitably forfeit Congressional support. It should also be sufficiently broad and adaptive to contemplate the needs of the entire country. People of the West are too prone to interpret reclamation as meaning only the watering of arid or semi-arid lands. From a National viewpoint, however, and this is an all-important viewpoint, the irrigable lands constitute only a small part of the reclaimable lands of the United States. About 25 000 000 acres have already been reclaimed by irrigation, and it is estimated that a like area may yet be served economically by water. The swamp-land area, however, approaches 100 000 000 acres, and the logged-off land area is practically the same. The remaining irrigable area, therefore, represents scarcely 15% of the remaining reclaimable lands.

They of the East and the South, where the major part of these unreclaimed lands lie, are just now (1929), more than ever, voicing the sentiment that the Government's future reclamation policy shall not concern itself solely with arid lands, but shall embrace these other lands as well. It is pointed out that, whereas the Government has expended millions (about $185 000 000) in aid of irrigation, practically nothing has been done toward reclaiming the swamp and cut-over areas; that the cost of reclaiming these areas would be no more, and generally would be less, than present costs of irrigation; and that they lie nearer the centers of population and, therefore, could be more readily colonized. These arguments appear plausible and may be sound. They merit investigation and consideration in formulating a National reclamation policy.

There has been some suggestion in recent years that the Federal Government confine its activities to the construction of storage works and, on the theory that these are required for flood control, that the Government assume all construction and operating costs, and make the waters thus stored available, without charge, for irrigation and other uses. (This should not be confused with President Hoover's tentative plan, as presented by the Secretary of the Interior at the Conference of Governors at Salt Lake City, on August 26, 1929.) So far as irrigation is concerned, the suggestion is subject to the following objections:

(*a*) In some cases it would be a fictitious basis for Federal aid, for there are districts where there is serious need for irrigation storage and little, if any, need for flood-control storage.

(*b*) In many instances storage may represent but a small part of the development cost. The Columbia Basin Project, for instance, and such projects where magnitude or other conditions impose a necessity for Federal aid, would never be built if the National Government could construct only the storage works.

(*c*) Unless the stored water is charged for (and this charge, if made, should be actual cost) its allocation can become a matter of political favoritism and political spoil. Allocation to various agencies on the basis of priorities, needs, and benefits, and with a fair charge for water on long-time contracts, is more rational and business-like than supplying free storage water. The cost of that portion of the storage works that is properly attributable to needed flood control should be borne by Federal and local governmental agencies; that portion which is necessary for the improvement of navigation should be borne solely by the Federal Government; and those portions which are for the benefit of domestic, irrigation, and power uses should be paid for ratably by those agencies. A fine business integrity is thus preserved, and unnecessary paternalism avoided.

(*d*) To charge nothing for storage water makes the Federal Government figuratively and actually a "wet nurse" to irrigation projects, and that is good neither for the Government nor for the project. A worthy project can, and is willing to, pay for its necessary water supply.

F. N. CRONHOLM,[58] M. AM. SOC. C. E. (by letter).—No matter how business-like and favored a new reclamation policy might prove as to return of capital invested in irrigation works, the fact remains that settlers who chance to acquire good land which, because of its physical conditions, can be quickly and economically farmed, will prosper; and the settlers not so fortunate will fail. As long as the study of the problem is narrowed or confined so that it does not go beyond bringing water to each farm unit, there will be little, if any, improvement. Probably no one knows the relative cost per acre of making lands ready to seed as against that of bringing water to the farm. It is reasonable to assume that the cost is more per acre to bring a farm to the same plane of perfection as the irrigation works, and if this is approximately the case, the writer feels that the settlers' viewpoint on the problem has not been given as full consideration as it should have. Certainly, the magnitude of this phase of reclamation would seem to warrant greater analysis.

The writer believes that more should have been done as regards Government reclamation projects than merely bringing water to the highest part of a farm unit. If it is reasonable to have the works built by the Government as efficient, as lasting, and as dependable as they are, then it seems reasonable that the lands served be as well provided. Truly, they are inseparable; so if there is justification for excellent dams, diversion structures, canals, and laterals ready to serve, then there is like justification for the canaled area leveled and, in every particular, ready to farm.

What the U. S. Bureau of Reclamation needs, if it does not already possess it, is a policy enough ahead of the times so that when a project is completed everything about it will be attractive. An irrigation project is, after

[58] Los Angeles, Calif.

all, although indirectly, a kind of plant intended to produce food, and once it is commenced it is not complete until the land is made ready to farm. Directly from the viewpoint of the State, as well as that of the Federal Government, the main purpose of a project undertaking should be the building of a community of happy, wholesome people.

There are vast areas of desert already peopled to the benefit of both State and Government, and such work by all means should continue. There are also vast areas elsewhere, long since settled, that are dying or that are already dead. It should be the business of the Bureau of Reclamation to plant an example, as it were, here and there throughout such localities and revive crop output by working the land to capacity, making the community idea of settlement so attractive that people will abandon other places that are hopelessly isolated and impossible to live in happily or to farm profitably. The cost of such community building should be pro-rated among those benefited, namely, the settler, the State, and the Federal Government. Make the sum to be refunded by the settler such that he can pay both the principal and interest and always feel decently cheerful about his contract as compared with what he might have done elsewhere.

What about the vacant areas of existing irrigation projects or extensions? Before they can be disposed of must these lands not be made attractive? Truly, there is more involved than the reasonableness of the annual maintenance and the repayment of construction charges. The prospective farmer will estimate, as best he can, to what extent he will be obliged to apply what monies he has toward getting the land ready to produce. Whatever the outcome, there is no sound logic in permitting "Tom, Dick and Harry" to hazard monies invested by the Government by allowing them to level land, even at their own expense. The preparation of the surface soils for the application of water as done by settlers has, in many cases, been against best crop output, against economic application and use of water, and a permanent detriment compared to what would have been the case had leveling been rightly done in the first place.

For instance, consider the case of a farm unit on which the surface soils happen to be more productive than those of greater depth. These rich soils are likely to be wasted by finding lodgment in hollows, whereas they should be saved to spread over the surface as the farm unit is leveled. However, the settler is much like any other person. He is apt to overlook many things; in fact, he may be obliged to do so because of the necessity of producing something before he "goes broke". Time is a factor. He will eat up what he has before harvest time if he does not hasten planting. Therefore, saving top-soil becomes secondary as does the methodical preparation of the surface. The settler plants first probably an already level patch, irregular in contour. Water is brought to this naturally level piece of land by short-cutting across the farm unit—meandering around this hollow and that bump. He has now permanently disfigured, as well as destroyed, his unit for future maximum economic crop output.

Water is brought to land for a purpose, and it is the purpose in which the entire nation, as a people, is primarily interested. Therefore, while water is

indispensable in arid regions, it is but a means to an end, and this objective should be the same in Alabama as it is in Idaho. In the beginning the purpose of the green spots to be created by the U. S. Bureau of Reclamation in the deserts of the Western States was, it is stated, for food production in given areas, and at the time this was assumed as ample reason for expending monies for irrigation works; possibly so. At any rate, it brought about a beginning by creating a department in the Federal Government that should continue in the good it is doing and can do. The objective of food production of long ago must be enlarged upon, however, or changed, in order that it may be more Nationally adapted. Make this purpose as applicable to Alabama as to Idaho. Let the objective be community building, reviving of soils, and promoting the interests of the settler. Do work in every State for the purpose of bringing up the average. Make irrigation works, stump pulling, land leveling, draining of swamps, or adding fertility to soils secondary in so far as they are but a means of bringing about the objective. Preparing lands to the point where they are ready to farm and offering them to people at a price and on terms that are attractive and well within their ability to pay is an undertaking that—coupled with assistance and guidance needed in the matter of suited crops, market outlets, etc.—would provide a greater certainty of return of investment to the Government than when the Government undertakes to do but one of the major necessities, such as bringing water to land. The program should include any assistance or guidance needed in the matter of choosing suitable crops, market outlets, etc.

Converting rough, raw land into producing farms has been done by settlers poorly fitted, both as to knowledge and money. Poor and humble as many of them were, each one must have believed that his progress would be forward. As a matter of fact, many people lost their entire savings and quite permanently wrecked themselves. Every one having a part in this first work was forced to a lower standard of living for quite a time and, as a result, no one of them is inclined to bestow gratitude. If it costs from $60 to $120 per acre to bring water to a farm, it costs on an average about as much again to prepare land ready to farm, that is, with the understanding that the work is done as lavishly and completely in one case as in the other. Therefore, it seems that the settler, in preparing his land to farm, even though inadequately, has certainly done his part, whether it was on a Federal or a private enterprise.

To expect private enterprises to solve the problems of Federal Government undertakings is of no use. Policies and methods of merit, differing from those applied by the Government, have always been available and would, undoubtedly, have been adopted forthwith in the beginning had such policies and methods been most adaptable. The writer has observed that the Government has always been progressive. The men responsible for making decisions since the infancy of the Reclamation Service are to be commended, and, considering the magnitude of the work accomplished, have an enviable reputation in that they made so few mistakes. The Government's most questionable projects are poorly located from the point of view of marketing and climate. The idea that the more private a project is, the more successful it will be, or

the more public it is, the more hazardous it will be, should not be taken too seriously. Take Imperial Valley as an example. This project is what might be termed "half and half" since it is not entirely Government and not entirely private. It has ample area so as to be representative; it has many sunshine hours, exceptional growing climate, and fair marketing conditions. At that, it has seen many "ups and downs" and most certainly, it is not yet "out of the woods". Comparisons are to no end and, as previously stated, of no value.

What irrigation projects lacked at the time the Government began its work was scope. Irrigation practice, outside of possible district projects, was strictly commercial, first, last, and all the time. Works were built with total disregard to future upkeep, and it was the settler who shouldered the burden of paying the cost as well as a profit to the promoters. Salesmanship was a main feature because good and lasting works could be slighted or needed features could be eliminated altogether, depending on the amount of sales talent. As a consequence, people settled the areas more out of the hope and glowing promises engendered by high-powered sales talk than because of any material thing of worth. Re-sales resulted, and the next settler was able to benefit somewhat by the labors of the man he succeeded. While this may be irrelevant and immaterial and of no moment, the writer believes that if private and district projects had gone another step toward making lands ready to farm and had been leveling land when the Government entered the field, the Government would have adopted such a policy also and, to-day, all projects would be better off financially and their settlers more prosperous.

Perhaps the most serious lack was the foregoing, namely, the absence of land leveling as a practice in project construction. Besides there was the mistake of using too generously, in estimating acre costs, the lands within the reach of the projects' distribution systems. Many of these lands, on detailed examination, would have been excluded. The suitability of the rougher lands, from the viewpoint of the prospective settler and his ability to pay, was not studied as completely as it should have been. Fitness of lands to farm should have been given the same study as the building of irrigation works.

It is all right in 1929 to say that twenty-five years ago project settlers should have been only those with $5 000, or more. That was considerable money in 1904, and people who moved about in covered wagons were, for the most part, hard-working folk glad of employment in the building of project works. Often it was these same people who, later, out of hard-earned savings, became project settlers. Such people are gradually disappearing like the buffalo and the antelope.

The only solution to land settlement projects, whether or not the question of water is involved, or whether the work is done by the Federal Government, or by private or district organizations, is to do more toward making lands ready to farm. Even to-day people with $5 000 or $10 000 are likely to wear too good clothes for farming. What, in fact, is there against helping, or rather, creating opportunity for, the man with $2 000, or less? There are many such worthy people, and, generally speaking, if the Government is interested

in social uplift and community building through giving impetus to crop output and organizing marketing, then it is these people who have the greatest need.

If there is ever a time when a man needs all his allotted land in shape to farm, it is in the beginning. For instance, if in a given locality it will require, ultimately, say, 80 acres to support a family in an American way of living, then it is imperative that the entire unit be ready to seed as soon after settlement as growing seasons will permit. The size of a farm unit should, in any case, be sufficient to support the average family properly, and allow for growth and education. Decent, respectable living with forward progress contingent on honest effort can rightfully be expected by any man willing to work to improve his condition, and under no circumstances should the Government lend itself to an undertaking that would hazard such progress. Most certainly it did this during the early project settlement and, in fact, does so now every time it permits a settler on raw land not ready to seed. Such risking of a man's chance is diametrically opposed to what the Government's purpose should be.

In spite of the foregoing, the U. S. Bureau of Reclamation ranks high in accomplishment. There is no organization in the nation that is cleaner, or that can show more good per dollar invested. The Service must become more human and more National in scope. It must do reclamation work that will draw people from various States to a given locality for a specific purpose and thus create new life and bring hope nearer realization. At present, the problem is, what to do with unsettled parts of existing projects so as to hasten their settlement. The writer suggests the following as a beginning:

1.—Choose a project having unsettled land that is so situated geographically that additional crop output could be profitably marketed.

2.—Furnish maps showing the topography of each farm unit in the rough and others showing how the same land will look when it is leveled, ditched, and diked, and the necessary control structures are in. Show these maps to the prospective settler in order that he may see what is before him as well as choose what particular unit of those available he likes best (allowing progressive settlement only).

3.—Level, not part of the farm, but all of it; and do this following the most approved method according to soils, in a manner allowing for a reasonable range of crops. Lay out the work so that the farmer may manage without hired help if possible. Keep in mind economy of water for the good of crops.

4.—Besides leveling the farm, turn the water on to it; if, in wetting, any areas settle, re-level that area. Make sure the entire unit is ready to plant. Furthermore, provide outlet for surplus irrigation water and, in the farm layout, give some thought to possible future ground-water relief should that become necessary.

5.—Do not prepare lands to seed until the area has been applied for by a qualified settler who shall be required to put all the land in crop beginning with the first growing season and keep it in crop for two full seasons before he is allowed to file on the farm unit.

6.—Have each prospective settler acquire the necessary credentials to become a conditional settler from a local board entrusted by the people of the project with determining an applicant's fitness, the board not being limited by a prescribed minimum money requirement.

7.—Collect in advance project maintenance charges. Add the cost of leveling and otherwise preparing the farm unit to project costs against the land, and of the total take a fair amount to be amortized in a reasonable time by the settler. Have him make the first payment and interest on deferred payments prior to the third season and yearly thereafter without fail. Make the amount to be ultimately repaid the Government of such size that the farmer will not fail because of it, but, at the same time, make it an obligation generally conceded as ample.

8.—Do not charge for water used during the first two seasons. If the prospective settler pays all other expenses involved in cropping the entire unit twice, and makes ready to begin paying off the project debt by the third year, he will be doing well. After all, the would-be farmer will compare every location available to him, weighing advantages against disadvantages, before finally deciding on a particular project and what it has to offer. Once a man has become involved in a proposition, it is well that he continues to be satisfied.

9.—Build no project without the prior approval of the State, or States, within which it is located, and then only on condition that the State, or States, be interested enough to guarantee the Federal Government the full amount of estimated costs in case of the settler's failure to meet the terms of his contract.

The foregoing list resolves itself into a plea for "ready-to-farm lands" and would involve a great deal in the matter of organization, although, presumably, the educational work needed for its authorization and the procuring of needed monies are the more difficult of accomplishment. It is acknowledged that something must be done to settle lands on Government projects now vacant. Personally, the writer cannot help feeling that preparing farm units ready for seeding would bring sufficient settlers of the right kind to these areas.

In further clarification of Suggestion No. 7, it seems possible and equitable to the farmer as well as to the Government to fix a rate of interest on deferred payments that will, in the end, make up the amount written off in the beginning so that, as a matter of fact, the Government will be repaid in full. In this way the Government would not be a money lender charging rental, as it were, for its money, but the farmer would be paying interest nevertheless. For instance, say the project costs $150. The Government would only charge the farmer $75, but it would charge him interest at a rate which, in a certain term of years, would ultimately repay the total project cost to the Government.

If something along the lines suggested could be authorized, the writer feels sure that it would succeed. Making lands ready for seeding should be done for the Southern States as an experiment, and with the two demonstrations, one in the West and one of fair acreage in the South, the writer believes that an adaptation of the U. S. Bureau of Reclamation to greater National good could be attained, and, in turn, the objectionable political phase lessened. The good the Service would then be doing would be more broadly understood and welcomed.

R. I. MEEKER,[59] M. AM. SOC. C. E. (by letter).—The National Reclamation Act of 1902 was framed with the purpose of using monies from the sale of the public domain in the arid and semi-arid West for the reclamation of other arid lands. Under the Oil Leasing Act of 1920, 52½% of the income from oil and minerals from public lands was added to the National Reclamation Fund, and, under the Federal Water Power Act of 1920, 50% of income from that source was also added to the Fund. Federal reclamation to date, therefore, can be stamped as Western aid to Western development since Western resources have been used to finance irrigation development.

Income from public lands in the arid States is dwindling. Future irrigation projects as outlined by surveys will be large and costly and with a much greater unit cost per acre than during the twenty years since 1910. Many proponents of reclamation are advocating greater Federal participation. The supplemental report of the Committee mentions the need of National aid to reclamation by direct appropriations from the Federal coffers for public works for irrigation—this in addition to the present Reclamation Fund. The precedents of Federal aid for navigable rivers, highways, aviation, flood control, and inland waterways are cited as the arguments for such National aid for future water utilization.

If such procedure is imminent, and it so appears, then a new phase of financing arid reclamation is in the offing, and Federal reclamation will be more than a term; it will be a fact, and the relations of Federal and State activities in water matters will assume a matter of extreme importance to the Western States in view of past experience with Federal reclamation.

The desire for "Federal aid at any price" (which has been so rampant in recent years), and at the price of local government, is not believed to be advantageous to the West.

Federal and State relations and co-operation in water matters are specifically referred to in Items (3) and (7) of the Committee's report, and one page of the supporting statement is devoted to discussion thereof. The writer desires to direct attention to an unenviable feature of past reclamation and water utilization with the hope that future Western reclamation may be devoid of a repetition of such offenses, especially if National funds are to be the backbone of such development.

The ownership and control of Western rivers lie in the Western States as announced in constitutional provisions and enabling acts of the various States, and as sustained in the Kansas *vs.* Colorado, U. S. Supreme Court decision. Paragraph 8 of the Federal Reclamation Act specifically states that Federal reclamation shall conform to and be subservient to State water laws. The history of National reclamation does not chronicle complete acquiescence to State laws in such matters.

The National Reclamation Act was scarcely passed before the U. S. Reclamation Service intervened in the U. S. Supreme Court water suit between Kansas and Colorado concerning the Arkansas River, claiming National title to and right of control of the waters in non-navigable streams of the Western

[59] Cons. Engr., Denver, Colo.

States. Furthermore, the Reclamation Service asked the Court to announce a doctrine of priority in water matters regardless of State lines and irrespective of whether the riparian or appropriative doctrine obtained in adjacent States. The Supreme Court held adversely to the Reclamation Service and confirmed the rights of the States as to complete jurisdiction over their rivers.

The entry of the Federal Government on river systems of the West immediately chronicled the commencement of Federal interference in State water matters and opposition to proposed private power and irrigation projects even where the rights of such projects in many instances were anterior to the rights of Government projects. Illegal and injurious embargoes by the Federal Government were imposed on some of the river systems for the so-called protection of Government projects. Canal and reservoir rights of way were denied by the Department of the Interior at the instigation of the Reclamation Service on the grounds that the construction of such projects would jeopardize the water supplies of the Federal projects, despite the protection under State laws of their rights by the doctrine of priority. Not satisfied with priority dates of Government projects, the Reclamation Service blocked and "killed" power and irrigation projects, especially reservoir features thereof, within river systems where Government projects were located. Trans-mountain diversions through the Continental Divide were opposed and defeated by denials of rights of way by the Department of the Interior on the flimsy ground of injury to the Yuma Project on the Lower Colorado River, etc. Hence, while the Reclamation Service and affiliated Federal bureaus had no direct control over Western rivers, they maintained indirect control of parts of river basins and water supplies through control of Government land, giving preferential status to Federal projects.

International disputes were unfairly invoked to the detriment of the development in river basins in the United States. A list of private projects blocked and "killed," with the means resorted to in "killing" them, would not grace the present Federal accomplishments.

Even at this late date Federal reclamation officials are claiming ownership of return flow and drainage water from Federal projects with sales of the water to other projects lower down on river systems. The U. S. District Courts have become a refuge for Federal projects in return-flow disputes, and a line of U. S. District Court decisions is being forged favorable to Government ownership of return-flow waters.

Federal bureaucracy has left an unnecessary trail of blighted hopes, blocked and "dead" power and irrigation projects, now submerged in the rainbow of accomplishment. Section 6 of the National Reclamation Act specifies that ultimately the management and operation of Federal irrigation works shall pass to the water users served thereunder. This local management is gradually coming to pass, but all too slowly. Early local management and operation of Federal projects will go a long way toward the elimination of Federal interference in water administration. The assumed preferential status of Federal projects in water matters will then collide with State laws, and it is hoped that such assumed preferential status will be effaced.

Item (15) of the Committee report, *in re* turning of reclamation projects over to local management at an early date, is highly desirable in order to get away from a part of Federal interference and opposition to State water laws and river administration.

The writer realizes that the encroachments of Federal reclamation on State water control and the special privileges assumed by Federal projects have been made possible partly as a result of local encouragement by politicians and water users under some of the projects, and even State legislators who were willing to go the limit in getting Federal monies expended on their river systems. This situation still persists as to proposed Federal projects. The expenditure of large sums of money from the National Treasury on reclamation and water utilization in the arid West should not be looked upon with favor unless State and Federal relations are clearly defined, and abuses of the past are avoided.

The August, 1929, proposal of President Hoover authorizing the transfer of the remaining public lands to the Western States, and voicing a hope that a line of action might be followed that would "check the growth of Federal interference in affairs of essentially local interest, and thereby increase the opportunity of the States to govern themselves," is a consummation devoutly to be wished in water matters of the arid West.

The writer heartily concurs in Item (8) of the Committee report to the effect that future stream regulation shall give preference to supplemental water supplies for existing Federal or private projects before new projects are considered.

E. B. DEBLER,[60] M. AM. SOC. C. E. (by letter).—The Committee proposals, briefly stated, comprise:

(*a*) Stream development in accordance with general plans formulated by the Federal and State Governments with basic data obtained by them.

(*b*) Change in Federal aid from that of waiving of interest to the assumption of part of the cost with low rate of interest to be charged on the remainder.

(*c*) Finding of feasibility and recommendation by experts on all phases to be a prerequisite to the approval of new projects for construction, with the States to share the responsibility for the selection of projects; the elimination of State lines and local interest in such selection.

(*d*) Construction preference to be extended to projects providing supplemental water supplies, and the reclamation of new lands to be delayed.

(*e*) Construction repayments to commence promptly upon the completion of each unit of the project, to be initially light, and to extend over a long term, with forfeiture of land upon delinquency.

(*f*) Aid in settlement to be provided by States and local interests.

The lack of an official discussion by the Committee, as a whole, of the annunciated principles leaves a wide latitude of interpretation for the reader. The writer has necessarily relied largely on Mr. Lippincott's discussion for guidance in this situation.

[60] Hydr. Engr., U. S. Bureau of Reclamation, Denver, Colo.

The desirability of planned stream development needs no defense; but acceptance thereof by States will not always be readily obtainable, as witness the wrangling over the Boulder Canyon (Colorado River) and the St. Lawrence River developments.

*Change in Federal Aid.*—The proposed change in form of subsidy from a waiver of interest on construction cost to one of outright donation of a part of the necessary works, provided the remainder of the works are constructed by other agencies, has one very decided advantage over present conditions. It obviates the always unpleasant task of collections which, in the nature of things, is always difficult when anything is bought under the instalment plan, whether it be a radio or a water right. Mr. Lippincott at one place advocates that Federal aid take the form of reservoir construction on navigable and interstate streams, with similar aid on non-navigable streams to be provided by the States. Such a course would discriminate heavily against the inter-mountain States having no navigable waters. On the other hand, States fortunate enough to be possessed of navigable waters would receive a double benefit of subsidized water supply and subsidized transportation. If such a plan were enacted, navigation on mountain streams might suddenly be found to have surprising possibilities. Mr. Lippincott appears to recognize the exceptions that would be necessary in that he considers it only fair that a Federal appropriation be made for the construction of the All-American Canal. While storage construction would go far toward solving Sacramento Valley problems, it would be only an insignificant aid to the Columbia Basin Project. In justice to the Committee as a whole it must be noted that the report is not specific on the development features to be donated by the Federal Government or the basis on which appropriations for such work are to be secured. No doubt, a plan can be evolved which will not favor particular sections. Success will be greatly enhanced by general applicability.

Viewed in the light of the situation which would arise in the event that the public lands and minerals are ceded to the States, with elimination thereby of the original source of the Reclamation Fund, the Committee proposal merits careful consideration, especially by the Rocky Mountain States. Agriculture in the Lower Mississippi Valley is receiving a heavy subsidy in flood protection and cheapened water transportation. The Panama Canal gave Pacific Coast agriculture a decided advantage over the mountain region in reduced freight rates, while greater advantage is being sought under the guise of local aid to navigation.

*Finding of Feasibility.*—Careful investigation of new projects, as recommended by the Committee, will not mark a new departure for the Bureau of Reclamation. In earlier years, more stress was laid on engineering than land classification and economics, and rightly so, as works of a new magnitude and difficulty of construction were necessary. Agriculture was not then, nor for many years afterward, in a depressed state. With few exceptions the lands served with water could, at moderate cost, be placed on a profitable production basis.

The most unsatisfactory feature then was the inability to compel participation in costs by privately owned lands, the holders of which needed to pay only

when using water. Irrigation districts with their powers of general assessment were introduced to meet this situation.

The agricultural situation of recent years and the less desirable quality of much of the land remaining to be irrigated have necessitated greater attention to matters of soil, land classification, and economics, so that these factors are now given consideration on a par with engineering. Considering the magnitude of the works undertaken and the human difficulties encountered, the results on Government projects compare very favorably with those obtained under private activity.

If projects had been accepted purely on their relative merits, the results to date would no doubt have been more favorable and the prospect of successful future development much brighter. The Bureau of Reclamation has not endorsed some projects undertaken in the past, and Congress has seen fit to modify the adopted 10-year program. Agitation for construction of projects without regard to their prospect of success has never been more pressing.

The proposal to have States assume responsibility in project selection has been tried by the Bureau through representation of the States on boards that reported on projects, often with disappointing results. Lack of training and, in some cases, exertion of political pressure and business influences precluded intelligent and unbiased consideration.

*Construction Preference.*—The suggestion by the Committee of favoring projects that will provide for supplemental water supplies for existing developments is, in fact, already the policy of the Bureau, and with this policy Congress appears to be in harmony. Projects of this kind, when planned with due regard to proper stream utilization, will often result in the development of new lands.

The Gooding or Minidoka Gravity Extension Project is of this type. It was started as a Carey Act project more than twenty years ago, when a reservoir was constructed on Big Wood River and canal systems were built to irrigate the greater part of an area of 200 000 acres. Lack of water led to gradual shrinkage of the district area to 76 000 acres, of which about one-half is cultivated in scattered tracts, with a water supply inadequate for profitable farming. The only practical solution is to bring a supplemental supply from Snake River by means of a long, expensive canal to deliver stored water from American Falls Reservoir and, incidentally, provide the means of irrigating an area of new land as large as the old. While it is generally desirable to delay settlement of new lands (in this case largely public in character), the result is to load present settlers with the operation and maintenance cost of works intended for a much larger area, construction to less than full capacity being impracticable.

*Suspension of Construction.*—The agricultural depression of recent years has so seriously undermined the financial stability of innumerable privately constructed developments, especially those with inadequate water supply or expensive operation, that wholesale abandonment can only be averted by reconstruction which they can not finance themselves and in the course of which some new lands will almost invariably be supplied with water. A general

policy of discouraging, temporarily, construction that tends to increase crop production, is advocated by some as desirable. If adopted, the policy should not be limited to the arid states, but should be extended to all activities that tend to increase production, such as flood protection for overflowed lands in the Mississippi and Sacramento Valleys, drainage of swamp lands in all non-arid States, development of cut-over lands, and the rehabilitation of exhausted or eroded lands of the Eastern States. Such a policy requires careful consideration of the speed with which serious shortages in food supply can develop, while the preparation of new areas for production consumes much more time, especially in the case of irrigated lands; neither should a purely altruistic attitude of "the greatest good to the greatest number" be adopted in preparing the policy; the relative needs of various localities for development to maintain and improve their existence should be given careful consideration.

The continuation of development with the Reclamation Fund can hardly be considered a tax on other communities since two-thirds of the funds now used are derived from repayments by constructed projects, and this proportion is on the increase.

*Construction Payments.*—The Reclamation Bureau policy on the whole has never been other than that proposed by the Committee, although individuals within the Bureau, and possibly department heads, have wavered at times while certain members of Congress have publicly fostered resistance to such a policy and by every means at their command have aided and abetted evasion and reduction in payment of monies due the Government.

The crisis of 1921 and the subsequent years of agricultural depression were even more severe on irrigated than on humid lands, as they were still in progress of development with credit resources strained to the limit. The most vulnerable creditor was the Federal Government. Relief in an acute situation, no doubt often well deserved, was found so easy to obtain, that a drive was then successfully made for more general relief. Although the relief granted may not have been justified in its entirety in all cases, the result has been such as to improve the morale of the settlers and to increase the revenue from these projects.

Much will be accomplished if the efforts by the Committee will aid in a new set-up that will remove the ever-present danger of a recurrence of these incidents.

*Aided Settlement.*—The Committee evidently has recognized that all is not well with the settlement of projects after water becomes available. It suggests stimulation by prevention of land speculation and recommends that financial aid should be a concern of the State and locality rather than the United States. The reference in the Committee report to aid extended by the Federal Land Bank is not pertinent, because the bank makes no loans on undeveloped farms.

In his discussion Mr. Mead describes the gap between completion of construction and the use of water. The turning point, however, is not reached until water has been used a sufficient length of time and to a degree corre-

sponding with farm development to that point where the operating income exceeds the annual costs and leaves a surplus for retirement of debt.

In earlier years, this gap was bridged by moderate amounts of hardship extending over a few years. A far different situation now exists, due, in part, to: (*a*) Lower quality of new lands left for reclamation; (*b*) increase of farm equipment required; (*c*) changes in living standards; and (*d*) decline in farming profits compared with other industries.

The first two items are promptly reflected in an enormous increase in the cash capital, or its equivalent, required at the outset. The latter two have resulted in an extremely low net income even on fully developed lands and have forced out marginal lands. The margin of profit is wholly lost under conditions of incomplete development, and, if such conditions extend over a series of years, failure is inevitable. Lack of adequate capital is the most common cause for failure.

To meet the situation, the Interior Department has adopted and is practising certain measures of general application that require no investment, such as: (1) Prevention of entries on public lands by unqualified settlers; (2) curbing of land speculation; (3) compulsory district organization to stimulate development of private holdings; (4) dissemination of information to attract qualified settlers; and (5) assistance in the sale of private lands to "dirt" farmers.

These measures have contributed notably to improvement in settlement, but they do not wholly meet the need of adequate capital. The present requisite of $2 000 liquid capital, or its equivalent in stock and equipment, for the settler on public lands is generally too small to permit a proper start. Analyses indicate the need for fully twice that amount. Further increase in the required capital would rapidly reduce the ranks of eligibles and would introduce resentment by untold numbers who still cling to time-worn ideas of carving a homestead out of public lands with little more than their bare hands for assets. On developments that provide supplemental water, lands are largely privately owned, but there is at present no means to compel selection of buyers when large holdings are broken up, and, apparently, there is no firm legal foundation that will permit imposition of such requirement. It must be said, however, that local interests have had marked success in endeavoring to eliminate unworthy purchasers. While these measures have been effective, they are far from adequate. Unsuccessful efforts have been made to obtain settlement funds from Congress for a trial demonstration. Support for this proposal is not strong in or out of Congress, due, no doubt, to a general conviction that the Federal Government has done enough in constructing the irrigation works and because of a misgiving as to the possibility of maintaining a proper business relation where one party has so little at stake.

More than one effort has been made to obtain active and financial co-operation by States in settlement problems. In some cases no interest can be kindled, and nowhere has financial aid been forthcoming. In many quarters there is a decided tendency to consider the projects strictly a Government affair with all responsibility on the part of the State terminating when its representatives have brought about a start on construction.

The problem of settlement has not been solved; it warrants further serious study, because it will inevitably be a major factor in determining future reclamation policies.

Summing up the situation, the increasing difficulty of operations under the present plan and the growing criticism of the interest-waiver form of subsidy make it advisable to consider a change. The Committee's proposal of gratuitous construction of a part of the works has much merit and should be given further consideration. Settlement after completion of the engineering works is far from satisfactory and merits much more attention by those dealing with proposed changes in the Federal reclamation policy. State participation in construction and even more in settlement has been suggested, but all efforts to enlist the States in such work have been unsuccessful. If curtailment of development to reduce farm surplus is desirable and is adopted, it should be general and should be directed not only at irrigation activities, but impartially at irrigation, flood control, drainage, and all other activities throughout the country which either directly or indirectly result in increased production of those crops the overproduction of which is held to be responsible for depressed prices.

JOHN E. FIELD,[61] M. AM. SOC. C. E. (by letter).—As a member of the Committee, the writer considered the question referred to in Section (9) more from the viewpoint of its effect on the settler than on the market for farm products, the competition with existing farms, or the needs of the Nation for farm products. The question of first importance is: Can the settler succeed? If he succeeds in his enterprise and if, in consequence, some other farmer finds it necessary to give up farming, that is competition, the "survival of the fittest," or the evolution of the industry.

The increasing cost of transportation and distribution has tended to revive or sustain agriculture in the more densely populated areas, and such revival from a National viewpoint is more desirable than the reclamation of new and isolated areas, and will tend to supply any future deficiency in area cultivated.

The evolution in menus, the rapidly increasing area of crops grown under glass and canvas, the artificial stimuli of fertilizers and light rays, the development of better seeds and better methods, all indicate that, even without additional areas being brought under cultivation, there is no prospect of a food shortage for a long time to come.

This condition, supplemented by the tendency toward urban employment and habitation and the lack of demand for land for farming, justifies the principle stated in Section (9).

The movement of people in the United States has been westward since the founding of the Government; but in the decade, 1920-1930, there has been a general trend toward the South. With this movement southward of large numbers of people, although predominantly commercial and industrial, development will create a demand for land in that region. This local demand will be met with increased cultivable areas or more intensive cultivation.

[61] Denver, Colo.

The South is in strenuous competition with the West for new citizens, more capital, and more enterprises. One section of the West is the rival of another section of the West. The same is true of the South and of the Pacific Slope. Thus, reclamation of land is primarily a local, not a National, need; it should, therefore, be promoted and financed locally. The Federal Government, in so far as the Nation is benefited directly or indirectly, should aid these enterprises, but any other body, section, or region benefited should contribute in proportion to the benefits to be received. This principle is reflected in Sections (3) and (4) of the report.

"What's the hurry?" Many Governments have found it necessary to enter upon programs of large public undertakings involving the seeking of new territory and the founding of colonies, on account of the pressure of population, the necessity for more room, more work, and more revenue. Often, without such relief, the durations of government and even nations themselves have been threatened. Such conditions do not exist in the United States; nor will they for many years to come. It is all but certain, however, that, in time, this country will have like conditions to face and similar questions to answer. When that time comes it can be easily imagined that the people will deplore the too rapid growth of their country; they may wonder why the people of the present day were so desperately anxious to populate the country that aliens and undesirables were imported; that Americans had preferred to hand over their inheritance to strangers and to deprive their own descendants of opportunity. Coming back to the present, one may well ask, "What's the hurry?"

Every section has the right to grow and expand, and to do its utmost to develop its resources. This is a commendable characteristic, but the problem is local and not National, and it must be judged by its effect on posterity as well as on prosperity.

The explanatory statement by Mr. Lippincott is from the National rather than from the local viewpoint. As the membership of the Society is nation-wide and as the subject is a "National" reclamation policy, the Committee strove to view the question Nationally, although of necessity the illustrations, discussions, and citations given in Committee meetings were local. Nevertheless, they covered quite one-half the area of the forty-eight States.

Throughout the report the principle is maintained that the States or local enterprise should be permitted to develop the natural resources, and that the Government should do only those things the States cannot do—such as the gathering of data over wide areas and long periods of time; but the report also holds that where the Government acts it should be in co-operation with the State—with the State's consent, and at its request. It is also stated in the report that projects not now feasible should not be undertaken at this time.

With reference to Section (1) of the report, it was suggested by some members of the Committee that the proposed program for the expenditure of $100 000 000 should be held in abeyance and subjected to the same rules of feasibility as new enterprises; this is expressed in Sections (10) and (11) of the report. It was agreed that the Government should limit the expenditures of this fund and "fulfill its assumed obligations" only.

In proposing a reclamation policy the desire to prevent foolish, excessive, or premature expenditures of money—whether Federal, State, or private—should be expressed. Some of the proposals for the expenditure of the $100 000 000 Reclamation Fund were foolish; others excessive in cost; and many were premature. One project likely to be built has all these three faults. If the States in which these projects are located had been required to share the financial responsibility, and the localities had been required to guarantee repayment, some, at least, of the projects never would have been suggested. In the future, localities and States should be required to guarantee, in part at least, the interest and repayment of principal, in accordance with the terms of a contract and schedule of repayment, before any project is undertaken.

The writer approves of applying a test question, "Can the project be made to pay?" It should be applied in such a way as to discourage inopportune construction; to deter those who could not or would not pay a reasonable interest on the advance made to them; to discourage speculation; to banish the thought that Government funds were free; and to impress on the settlers a sense of entire responsibility.

In analyzing the differences in attitude of the Government and of private enterprise as applied to the ownership of water, the writer believes that attachment of the water to the land is a mistake. In Colorado, titles to land and water are separate, and water may be transferred and its use extended to cover greater areas. This flexibility of use of water accounts in large measure for Colorado's marked progress in irrigation and her position as second of the arid States in the area of land irrigated. Similarly, the limitation of the area which one person could own on a Federal reclamation project was not entirely wise as it assumed that all settlers were equal in ability, enterprise, and resources; it assumed even that the number of children would be the same. A man of real executive and managerial ability would scarcely be content with an 80-acre tract in Colorado, Wyoming, or Nebraska, where only a living was in prospect, and where ultimate independence and the hope of providing advantages for his children were absent. The lack of experience and sufficient funds among the settlers was due, in part at least, to this limitation of the activities and prospects of the more experienced and able farmers.

*State vs. Federal Control.*—In Colorado the control and the responsibility for the distribution of water rests in appropriate State officials. Dual or joint control of the water by State and Nation would lead to confusion. The Enabling Acts of the States of the West give them the same standing as the original thirteen States. The public lands are held by the Government in trust for those who desire to use them. Except for this condition of trustee, all the land within its boundaries is owned by the State and has the same status as lands in private ownership. It is not possible, therefore, for the Government to assume the original ownership and control of the natural resource of water. That the Government has called State ownership into question is true; but the Western States are on equal footing with the original thirteen States. Can the Government, therefore, claim control and ownership of the water of New York, Connecticut, and Pennsylvania? This is a

form of bureaucratic aggression which the original thirteen States may consider with profit to themselves.

The writer does not advocate nationalization of the rivers. He believes the province of the Government should be limited to investigation and research, to the gathering of data, and to aiding in the preparation of comprehensive plans for the ultimate maximum utilization of available water. He hesitates to advocate even the construction of large reservoirs unless it is distinctly provided that the control and distribution of the stored water remains in the State water officials.

The writer does not subscribe to Mr. Lippincott's explanatory statement that control of reservoirs should remain in the Federal Government if that means control of the water distribution. In Colorado there is an efficient organization for the distribution of the waters of the State. This control should, and of necessity will, remain in the State and under the State Engineer. A change from State to Federal or joint control can lead only to confusion because all canals and reservoirs now built are operated under State laws. Even the two Government projects (Uncompahgre and Grand Junction) receive their water (in accordance with the Reclamation Act) through the State water officials. Rather than submit to Federal distribution of water it would be better to forego Federal aid.

Considerable money has been spent in Colorado by the Government on these two projects. They are, or at least may yet be, advantageous to the State, but when one remembers the restrictions imposed on enterprises desiring to build irrigation works on the Rio Grande and North Platte Rivers, he is impressed with the fact that Colorado has gained nothing through Government aid; on the other hand, a question has been raised as to her right to administer and control the waters within her own boundaries. Interstate questions have been and can be settled by Court procedure or by compact. The writer consented to the recommendation in Section (2) that "the conservation of the water in the rivers and lakes of the country should be under public control," only because "public control" means generally State control. It means Federal control only where the States cannot function alone or by compact. This thought is stated in Section (3), as follows: "utilization of the waters should be undertaken by the States," or, as an alternative, "jointly by the United States and the States."

The thought lying back of Sections (1) and (10), as the writer sees it, is that it is better to fix definitely and irrevocably what the settler is to pay and when and how he is to pay it. Indefiniteness in this regard has led in the past to many of the evils now recognized. If the obligations are fixed and irrevocable before construction begins the unwise projects would be dropped; speculation largely eliminated; the incompetent deterred; and the experienced farmer encouraged to settle. It is a species of fraud not to tell a settler the cost of his land and water, and especially is it fraud to tell him what it will cost at the time he enters the contract and then increase it later without his consent. Similarly, it is a deception to obtain public funds under promise of repayment and then to pay no interest and to ask for the cancellation of part of the indebtedness. The contract, once made, should be

carried out to the letter, just as contracts are carried out in the business world; some losses are inevitable in all business and some will be suffered in Federal reclamation, resulting in losses for the Government and bankruptcy for the individual. The one will charge it off to poor judgment in building the project and the other will charge it to his own foolishness, inexperience, or "hard luck." In addition, it is fraud to construct a project and induce settlement where the settler cannot achieve independence in his old age. It is a fraud to treat public money as "easy money."

Generally speaking, the cost of reclamation is in excess of what the settler can pay. Recognizing this condition the Government, the State, and the locality desiring to build a project should make up the difference under the assumption that either the direct or indirect benefits, immediate or remote, justify the necessary aid. The probable benefits to Nation, State, and locality can be determined in advance, and the settler, knowing that the amounts due from him must be paid, will put his mind and labor on his farm work rather than in devising ways and means to obtain remissions from the Government. Also, in the knowledge that he must pay for the operation, maintenance, and improvements, he will weigh the necessity before demanding expenditures.

Even if it were true that original capital costs the Government nothing, this would not excuse the undertaking of projects that were not feasible or for which the settler would require heavy subsidy in the form of no interest payments or the remission of the original cost.

The only basis for any other policy is the theory that every locality is equally entitled to its share in the contents of the "pork barrel." The fact that the Reclamation Fund is derived from the sale of lands in certain States is scarcely sufficient reason for undertaking projects that will not pay the costs; nor does the fact that the money comes from sales of lands or revenues from a certain State justify the theory that, "the money comes from our State, we want it spent here, it will give our people employment; we do not care whether the project is feasible or not."

To some this may be surprising, but as early as 1903 and as late as 1929, the writer has heard this sentiment expressed by eminent "native sons" advocating a project in their States.

A five-year period would be sufficient to develop a reclamation project, when the improvements are opportune and when a demand for land exists. However, where improvements are premature or where postponed payments encourage the holding of land without cultivation, twenty-five years for development would probably be required; in that time, however, prematureness would probably have disappeared.

The Colorado River Project with its Boulder Canyon Dam has been specifically mentioned as an enterprise which the Government alone can handle. This probably is true at present, but one can imagine either the seven Basin States, or the three lower ones, entering a partnership and compact to develop the basin. To declare (as some have done) that projects could not have been built without Government financing and Government contributions, is in the writer's judgment, an over-statement. There are projects which could not be built without Government aid. International questions might be such that

the Government alone could function but, except that time is an essential element, the writer finds it difficult to imagine a project which a State, such as California, for instance, could not build. California is certainly equipped with engineers and scientists capable of undertaking the very largest projects. However, as long as Government financing will furnish the funds with the least expenditure of effort on the part of the States; as long as it will assume the risk and do the work, and will do these things in the shortest space of time, the line of least resistance will be followed. It is very easy to acquire the habit of being waited upon and relieved of work, worry, and responsibility. If hope of Government aid were not present one can imagine the States or even local enterprise and private capital undertaking the work—not at this time, perhaps, but at some future time.

It appears to the writer that the megalomania that is so characteristic of the United States is the real moving force back of most promotions, rather than any National or even State necessity. If there is a State necessity, then the State should assume the responsibility, and the part of the financial burdens needed to supplement the amounts that the settler can afford to pay. If such a rule prevailed the "log-rolling, pork-barrel" manifestations would abate, and loud shouts of "necessity" would sink to mere whispers.

Although the writer recognizes that extraordinary or supplemental aid is desirable from the settlers' point of view, and is often necessary on projects unwisely undertaken, he cannot subscribe to the universality of the need. In 1902, the Government examined the South Platte Project in Northeastern Colorado; it built the interstate North Platte Project less than 100 miles north. These projects were similar in elevation, soil, climate, markets, crops, and potential settlers. The supply of water in the South Platte was questionable, that of the North Platte, unquestionable. Several years later portions of the land in Colorado were provided with canals and storage reservoirs through the irrigation district plan. The districts have been successful. The cost of construction, including expenses of promotion, discount on bonds, interest during construction, and costs of investigations, was not greatly different from the costs on the North Platte Project, exclusive of drainage and costs of maintenance and operation. The difference is even less if the character and the permanence of the irrigation works built by the two agencies are taken into consideration. Nearly all the bonds of the districts have now (1930) been paid off. In the Colorado projects, the settlement was less rapid at first than on the Federal project, but the general character of the settlers was better in that they were more experienced and that the projects met local demands for land. Time, place, and cost corresponded with desire, demand, and necessity. A part of the indebtedness of the largest district was written off, in amount about equal to the promotion cost, and since then, in the knowledge of the futility of demanding further reductions or concessions, such demands have not been made and the district's credit is "A1." This illustrates, also, that land settlement can be taken care of locally. Had this been a Federal project less competent settlers would have rushed in; speculation based on the hope of avoiding repayment of costs would have been present; large maintenance, operation, and improvement costs would have been incurred on money advanced

by the Government; and, probably, a demand for houses and leveling would have been made. As stated in Section (14) of the report, "Land settlement * * * or any other kind of assistance * * * should be treated as a local matter." If the locality and the State are unwilling to assume this duty and responsibility, construction should be postponed until demand and feasibility induce it to do so.

Referring to Sections (1) and (11), the contributions by the Federal Government should be based upon the estimated benefits to the country as a whole and nothing more. As a maximum, the contribution should not reduce the settler's obligations to less than what he can reasonably be expected to pay. The interest-payment rate should approximate the interest rate paid by the Government on its indebtedness. Such limitations and rates would undoubtedly leave obligations greater than the amount the settler could pay, and, in such cases, the project would be classed as premature and its construction postponed.

The proper desire of the U. S. Bureau of Reclamation has been to build projects so as to include all the lands possible. Often it was found that the earlier private enterprises took in only the choice areas, leaving the less desirable ones in such a condition that they could not be reclaimed feasibly. This suggests the popular expression, "they took the heart from the melon and left the rest." Carrying the simile further, the service in some cases undertook to "save the rind as well as the seed zone," and the results were unsatisfactory in that considerable areas were put under canal at great expense, but were later abandoned. A portion of the amounts written off by the Government were chargeable to this condition. Thus, reclamation went from the one extreme of private enterprise to the other by National expenditure. It is now proposed to construct a project in which only a very small percentage of the land to be irrigated can support a settler, even if both land and water, leveling, and fencing were given him at one-fourth the cost. The advisability of imposing the conditions of Section (10) is under such conditions apparent.

In Sections (8) and (9), the Committee's report indicates a preference for completing and bringing to perfection existing projects, and that great caution be exercised in attempting new projects. On existing projects much necessary expense has been met; facilities, such as roads, schools, and telephones, have been provided; small business centers have been built; and markets have been established. On a new project these facilities will have to be provided. It is obvious that the bringing of existing projects to a higher state of efficiency is the more economical and promises quicker results than undertaking new projects.

One of the primary purposes of the irrigation congresses, and of individuals proposing Federal aid, before the passage of the National Reclamation Act, was to furnish supplemental water supplies to existing projects and the extension of those projects. About the time the Reclamation Act was passed, the scope was enlarged to include construction of main canals. The writer does not remember that the construction of laterals, administrations of systems, building of drains, colonization, or aids to settlers, were proposed until after the passage of the Act, and some of these activities were not suggested

for some years thereafter. It was when the activities undertaken were broadened in scope that needs for new contracts with increased cost over original estimates appeared. In the "pre-Act period," it was assumed that the settlers would be drawn from experienced communities and that they would be capable of self-government, would have initiative and ability, and would be able to cope with all the problems except that of the supply of water. The present tendency is to revert to the original conceptions of the irrigation congresses, and this thought is expressed in Section (8) of the report.

The writer believes that criticisms and distrust of Federal reclamation activities are decreasing, due, first, to the withdrawal by former Secretary Work, of the Department of the Interior, of restrictions of the rights of private enterprise to build reservoirs in Colorado on the Rio Grande and North Platte Rivers. While this reversal of previous rulings came too late to be of great benefit to that State, because the time when funds could be secured had passed, this saner and more equitable attitude of the Department of the Interior is appreciated. Second, the general conduct of the engineers of the Reclamation Service is winning ever greater popular approval. The present-day opposition and criticism is due to the attitude of the Government's legal advisers who claim that the title to water is in the hands of the Government and thus deny any weight to the article of the Enabling Act to the effect that all States are equal and are admitted on the same terms as the original thirteen States. Criticism is now more outspoken than formerly against the growth of bureaucracy, of which President Hoover, President Coolidge, and others have warned the Nation.

In the writer's experience the management of projects by the water users who pay the bills (Section 15), is more economical than that by either Government or corporations. In time, through experience, the water users become as efficient as and more conservative and less technical and theoretical than either.

Mr. Mead states it to be his conviction that "one of two things should be done: (1) Either provide aid in carrying out the second stage of reclamation; or (2) quit building canals to irrigate unimproved land." The writer agrees with this statement, but chooses the second alternative, because he believes that—except for local ambition, a megalomania, and the desire for local expenditures—there is no demand for such construction; and that, as indicated in Section (8) of the report, the construction of storage reservoirs for supplemental supplies and flood protection for existing projects meets the present need and also that for a very long time in the future. This need is aptly illustrated under the head of "Achievements of Federal Reclamation in Completing Private Development," in Mr. Mead's paper. The Salt River, the Weber Valley, and the Snake River are mentioned; the Uncompahgre Project, where a supplemental supply for existing canals was secured through a tunnel, and the North Platte Project, where many existing canals were supplied with a supplemental supply from Pathfinder Reservoir, are other examples. In the latter case a community of interest was created and conflicts of water rights were eliminated. On that

project priority of right has now little meaning; but the matter of control and distribution remains a source of conflict and litigation in a three-cornered fight—in which Wyoming, Nebraska, and the Federal Government are concerned. Allocation of the water between the States and joint control by compact would solve the problem.

The explanatory statement by Mr. Mead is particularly worthy of study as it presents many facts pertinent to the question of reclamation by irrigation in general, and not to Federal reclamation alone. While the Committee's report was prepared by engineers, several of them were raised on irrigated farms; some now (1930) own and operate such farms; and all, probably, have had to deal with irrigation economics and with settlers.

It is probably impossible (outside the group of irrigation engineers) to secure a committee more familiar with all three phases that Mr. Mead mentions, namely, engineering, economics, and the settlement problem. Such being the case, it is vital that the subject be thoroughly discussed by engineers other than those of the Committee, and the fact that so many have entered the discussion and that ample time has been given for the discussions, is a matter for congratulations. While the discussions have been local in view application, taken in their entirety they have a National viewpoint. Out of them a correct conclusion will doubtless be reached that will be to the credit of the Engineering Profession in that it will demonstrate that engineers do not have as narrow an outlook as they are sometimes accused of having.

The subject discussed herein may be summarized as follows:

(*a*) There is no hurry; the Government should beware of camouflaged frauds in considering requests for Federal aid.

(*b*) Reclamation is at present a local and not a National question.

(*c*) Under present (1930) National conditions of market and crops the settler is likely not to succeed even with local, State, and Federal aid.

(*d*) To complete and perfect existing projects is desirable from a local viewpoint, although it is not necessary nationally.

(*e*) Willingness on the part of the State and locality to assume responsibility and a part of the cost should be the test of necessity and feasibility.

(*f*) Most projects that are feasible, desirable, and opportune can be built without Federal aid.

(*g*) The control and distribution of water should remain in the State.

COMMITTEE OF THE IRRIGATION DIVISION ON "A NATIONAL RECLAMATION POLICY" (by letter).—On November 1, 1926, the Irrigation Division appointed a committee composed of eleven Western irrigation engineers to consider and report upon "A National Reclamation Policy". After much correspondence two meetings of the Committee were held, and a unanimous report was finally adopted in San Francisco, Calif., in July, 1928. The report of the Committee was presented to the Division at San Diego, Calif., in October, 1928, and discussed in two statements by Elwood Mead, M. Am. Soc. C. E., and by the Chairman of the Committee, J. B. Lippincott, M. Am. Soc. C. E.

Twenty-four discussions have been presented during the two years after the publication of this report in September, 1928, by engineers of the United

States, Canada, Australia, and India. The Committee devoted more than a year's time to a consideration of its report which was unanimously signed before its presentation to the Irrigation Division. The Committee now has reviewed its original report, and the discussions, and does not find occasion to modify or amend its judgment of July, 1928.

President Hoover presented a letter, under date of August 21, 1929, to the Conference of Western Governors and Representatives, held in Salt Lake City, Utah, on August 27, 1929, relative to the control of public lands, minerals, and reclamation in the West. The parts of this letter that bear on the policy of Federal Reclamation are, as follows:

"It may be stated at once that our Western States have long since passed from their swaddling clothes and are to-day more competent to manage much of these affairs than is the Federal Government. Moreover, we must seek every opportunity to retard the expansion of Federal bureaucracy and to place our communities in control of their own destinies. The problems are in large degree administrative in character, both as they affect the Federal Government and the Government of the States."

As to the Reclamation Service, President Hoover continued:

"It seems to me that the vital questions here are to re-orient the direction of the Reclamation Service primarily to the storage of water and to simplify its administration.

* * * * * * * *

"The present Reclamation Act is based fundamentally on the reclamation of Government-owned lands. Possible areas available for reclamation have now passed almost wholly into private ownership and the use of the Reclamation Fund for further projects may be legally criticized owing to the fact that the land is no longer part of the public domain and circumlocution by voluntary agreements may not always be possible.

"Moreover, the application of the fund under the present organization results in very large Federal administrative activities within the States of a character which was never originally contemplated and which could be much better administered by the local State Governments themselves. In many ways it duplicates the State water administrations."

The position of President Hoover in connection with the policy of Federal Reclamation is of particular interest because of the many respects in which he presents similar opinions to those of the Committee.

The Committee calls attention to Principle (6) of its original report, which reads:

"(6) The output of power and of water at Federal or State works should be disposed of at wholesale and not at retail."

The intention of the Committee was to express its opposition to either the State or Federal Government entering into the distribution of either water or power to individual consumers thereof. Its belief was that the actual contact with such consumers should be through local organizations, such as districts, mutual water companies, or private corporations. The Committee recognizes that, as provided in the Reclamation Act, the control and distribution of the water are vested in the respective States.

The Committee endorses as a fundamental policy the proposal that the Federal Government should expend the money derived from the sale of public lands and the natural resources derived therefrom, in the arid land States, in the improvement and development of those States by the conservation and utilization of their water supplies. The Federal and State Governments should co-operate in the construction particularly of storage reservoirs for irrigation, flood control, and other water supply projects. The province of these reservoirs is to regulate the stream flow in such a manner as to make them of public benefit to all classes of water users irrespective of whether they are on Federal Reclamation Projects, or otherwise. This policy of development of the West is of great public importance not only to the Western States themselves, but to the Nation as a whole.

# MEMOIRS OF DECEASED MEMBERS

## CLEMENS HERSCHEL, Past-President and Hon. M. Am. Soc. C. E.[1]

DIED MARCH 1, 1930

Clemens Herschel was born on March 23, 1842. He passed his boyhood in Davenport, Iowa, and, after studying with a tutor, he entered the Lawrence Scientific School of Harvard University at the early age of 16. Graduating in 1860 with distinction (*summa cum laude*), he took an advanced course in chemistry for one term, and then went to Europe to study French and prepare to enter the Ecole des Ponts et Chaussées, in Paris. As the number of foreigners was limited, and the quota was complete, he was unable to obtain admission, and went, as a consequence, to the Technical School at Karlsruhe, Germany, to complete his education. Long afterward, in 1925, the Karlsruhe Technical School bestowed upon him the honorary title of Doctor of Engineering.

In 1864, Mr. Herschel returned to the United States and opened an office as Consulting Engineer, in Boston, Mass., doing such work as came to hand. He was Engineer of the Albany Street Bridge, built by the City of Boston in 1867, and at one time was connected with the Boston Sewer Department. The variety of his work is indicated by a letter-head of 1871 which reads, "Civil Engineering in all its branches, Iron and other Bridges and Roofs, Hydraulic Engineering, Roads, River and Harbor Improvements, etc., etc." In 1872, he was appointed Superintendent of Streets of West Roxbury, Mass. (now part of Boston), and from 1881 to 1883 he was one of the three Railroad Commissioners of Massachusetts.

Mr. Herschel was Engineer of the Quinnipiac Drawbridge, New Haven, Conn., erected 1874-1878, and this led to the publication, in 1875, of his book on "Continuous Revolving Drawbridges." A bridge of minor importance, but which is of interest because it is still standing and readily accessible, is that across the Public Garden Pond in Boston. The design, prepared in cooperation with an architect named William G. Preston, was accepted as the result of a prize competition.

To one of Mr. Herschel's independence of thought, it was disappointing to note that "bridges and roofs" did not offer any future for a Consulting Engineer since their design was falling entirely into the hands of large bridge companies, where a designer became, as he expressed it, merely a "cog in a wheel". He had at one time worked under the late James B. Francis, Past-President and Hon. M. Am. Soc. C. E., a hydraulic engineer whom he greatly admired, and this, as well as the lack of a future in bridge work, naturally turned his attention especially to hydraulics.

In 1879, Mr. Herschel was appointed Hydraulic Engineer of the Holyoke (Mass.) Water Power Company. It should be remembered that power at

[1] Memoir prepared by J. Waldo Smith, Hon. M. Am. Soc. C. E., and William H. Burr, M. Am. Soc. C. E.

Holyoke was developed before the days of electrical transmission, and the Power Company not only controlled the dam, but had also to operate the canals which supplied water for power to the various mills. During the ten years that Mr. Herschel held this position he built and operated the Holyoke Testing Flume, then one of the few places in the country for measuring the efficiency of hydraulic turbines. All the turbines in use in the Holyoke mills were tested, and the discharge was determined for different gate-openings. Thus, every turbine became its own water meter, and by reading the gate-openings twice a day, an accurate record of the use of water for power purposes was obtained. This system was of great help in securing an equitable distribution of water among the different mills, supplied from the canals of the Holyoke Water Power Company, and in preventing waste.

This was not enough. The many paper mills used large quantities of wash water that did not pass through the turbines and was not measured. Mr. Herschel gazed on those wash-water pipes and pondered. He wondered how they could be made to tell how much water was passing through them. The Venturi meter was the answer, but it came too late to be used for measuring wash water. As he was wont to remark, the Venturi meter has been used for a great variety of purposes, but never for the purpose for which it was invented.

It had been observed by Venturi in 1791, that, if a liquid flows first through a converging and then through a diverging cone, the pressure at the narrow section where the two cones join is less than the initial pressure. To Venturi, the philosopher, this was merely an interesting phenomenon of Nature; to Herschel, it was a suggestion of a practical and much needed device, and, in 1887, he conducted a series of tests to determine whether the rate of flow could be calculated from this difference in pressure. Here, again, his training under Mr. Francis was of great assistance, as the latter had determined in tests on diverging cones, the small taper necessary for the down-stream cone of the meter, if the permanent or over-all loss of head should be a minimum.

The Holyoke tests were so satisfactory that the device was patented and was named the Venturi meter. Thus, Clemens Herschel became "the man who made Venturi famous". He was presented with the Rowland Prize by the Society for his paper describing his tests,[2] and was awarded the Elliott Cresson Gold Medal by the Franklin Institute for his invention.[3]

Another piece of important work at Holyoke was in practically rebuilding the wooden dam across the Connecticut River. This had become unsafe and threatened to give way, but when repaired and filled with gravel, it lasted as long as necessary, that is, until it was replaced after Mr. Herschel left Holyoke, by a stone dam built below it. In connection with the work on the dam Mr. Herschel added to the diversity of his accomplishments by going down in a diving suit, because he did not believe what the divers told him and he wanted to see for himself.

In 1889, Mr. Herschel was made Chief Engineer and Superintendent of the East Jersey Water Company, and gave up his position with the Holyoke

[2] *Transactions*, Am. Soc. C. E., Vol. XVII (July–December, 1887), p. 228.
[3] *Proceedings*, Franklin Inst., February, 1899.

Water Power Company. The East Jersey Water Company was organized to build works to provide a large additional water supply to Newark and other New Jersey communities. These works included dams and reservoirs on the Pequannock River, and a riveted, steel pipe line which was one of the first of that type to be built in the East. A contract was made on September 24, 1889, with the City of Newark, to build works to supply 50 000 000 gal. of water per day to that city, the works to be finished by May 1, 1892. Eventually, two pipe lines were laid and the capacity was increased to 80 000 000 gal.

It was on the works of the East Jersey Water Company that the Venturi meter had its first practical application. About thirteen meters were used and a daily record was kept of all water entering the pipes and of water delivered. From this beginning, the use of the Venturi meter has spread over the entire world, not only for water, but also for measuring gas and steam and other fluids. Noteworthy on account of their great size are the meters of the Catskill Aqueduct which measure the water consumption of New York City.

It was during Mr. Herschel's service with the East Jersey Water Company that he published, in 1897, "115 Hydraulic Experiments", on the flow of water in pipes and conduits. He left that Company in 1900, after the works for the City of Newark had been finished and turned over to the city.

Since 1884 Mr. Herschel had been Consulting Engineer of the largest power developments at Niagara Falls, including the work of the Cataract Construction Company and the Niagara Falls Power Company. In earlier developments at Niagara Falls, the head was subdivided or part wasted, and power was distributed by shafting. The ready-made turbines available at that time in the United States could not be used for the high heads and the large volumes of water available at Niagara Falls, and electrical transmission of power seemed desirable. To consider these questions, an International Commission of five members was appointed, Mr. Herschel being the only American member.

This work brought him into contact with European and especially with Swiss builders of hydraulic turbines, and the decision was reached to obtain from Europe, turbines built to order for the head and discharge available, and with a speed suitable for driving electric generators.

Turbines were first imported from Switzerland about 1904, but later the building of large power hydraulic turbines designed for predetermined conditions, was established in the United States, largely as a result of the experience of the Niagara Falls Power Company with Swiss turbines. Mr. Herschel was the first Manager of the Hydraulic Engineering Department of the Allis-Chalmers Company, but resigned when the Company's office was moved from New York to Milwaukee, Wis. With his intense love for Boston, he considered even New York as "too far West", and Milwaukee was unthinkable.

Mr. Herschel devised an application of the Venturi meter, which he called a "fall increaser", to increase the power of hydraulic turbines when low head was experienced in times of flood. This, however, was never put into practice, and conical draft-tubes, and other features of more recent turbine design, have rendered it unnecessary.

Mr. Herschel continued to act as Consulting Engineer with his office at 2 Wall Street, New York. He was one of a Commission of three engineers who examined the plans for the New York City Aqueduct in 1910 before they were approved by the Board of Estimate and Apportionment. In 1920, he read a paper before the American Society of Mechanical Engineers on "An Improved Form of Weir for Gaging in Open Channels", in which he described a method of reading pressures in a perforated pipe placed at the crest of the weir, and of calculating the flow from these readings.

He was a frequent contributor to the technical journals, and was always ready to champion the Venturi meter with vigor. Although he had written "A Farewell Word on the Venturi Meter", in April, 1929, at the age of 87, we find him back again on the firing line with a letter[4] to the Editor of *Engineering News-Record* written when confined to his home, and dated, Glen Ridge, N. J., August 28, 1929.

Among the obviously professional parts of Mr. Herschel's engineering career there is none more prominent than his contributions to what may be called Engineering Science. It was fundamental with him in seeking the solution of any important engineering problem to make a searching general analysis of all its features leading to results constituting a marked advance in engineering practice. His professional work from its beginning to its end exhibited such marked advances, as in his papers on drawbridges and other continuous trusses and on the Venturi meter, and in other cases of similar character. The same desire to give intellectual quality and finish to his professional work is gracefully shown in his translation of Frontinus on the water supply of Ancient Rome.

These characteristics of his practice as a civil engineer just at the time when Civil Engineering was taking its place as a profession in the United States made him one of its marked pioneers, especially in Hydraulic Engineering. His excellent educational equipment combined with a trained analytic mind was well timed to act upon the opportunities offered by the profession of Civil Engineering then coming into being. In fact, it is due to him and a few others associated with him that Hydraulic Engineering has been developed to its present status in this country.

His most remarkable literary achievement, and the culmination of years of study, was the publication, in 1899, of a translation from the Latin into English, of the "Two Books on the Water Supply of the City of Rome", by Sextus Julius Frontinus. Like many another, Mr. Herschel had forgotten the Latin learned in his youth, but, nothing daunted, he undertook the task with the help of a French and a German translation, and produced the first translation to appear in English.

Mr. Herschel enjoyed unusually good health until the last year of his life, and commuted daily from Glen Ridge, N. J., to his office in New York.

He was married, in 1869, to Grace D. Hobart, of Boston, who died in 1898; he was married a second time in 1910 to Jeanette B. Hunter, of Thompsonville, Conn. His children, all of whom survive, are Arthur H., Winslow H., and

[4] *Engineering News-Record*, September 12, 1929.

Clementine (Mrs. Hobart Rawson), by his first wife, and one son, Clemens, by his second wife.

Mr. Herschel was Treasurer of the Boston Society of Civil Engineers from 1874 to 1880, and was President of that Society in 1890–1891. At the time of his death he was Past-President and Honorary Member both of the American and of the Boston Society of Civil Engineers. He always loved Boston and the Boston Society, and directed in his will that his engineering books should be given to the Boston Society and to the Boston Public Library. His correspondence of many years has been given to the Engineering School of Harvard University.

In addition to the memberships mentioned, Mr. Herschel was a member of the Union Club of Boston, the Century and Engineers' Clubs, of New York City, and a Life Member of the Institution of Civil Engineers of London, England.

Mr. Herschel was elected a Member of the American Society of Civil Engineers on April 21, 1869, and an Honorary Member on June 19, 1922. He served as Director of the Society in 1891; as Vice-President in 1915 and 1916; and as President in 1916.

## GEORGE SMEDLEY WEBSTER, Past-President, Am. Soc. C. E.[1]

DIED JANUARY 23, 1931

George Smedley Webster was born at "Stouton Farm", now McPherson Square, Philadelphia, Pa., on October 19, 1855, the son of John Hambleton and Lydia (Smedley) Webster. On his father's side he was a direct descendant of Nicholas Waln who came to America in the ship *Welcome* with William Penn, and on his mother's side, of George Smedley who settled in Middletown, Pa., about 1682. Both families were members of the Society of Friends. His father and grandfather were farmers, the latter having moved to "Stouton Farm" in 1805. Mr. Webster attended the Friends' Select School in Philadelphia, and later entered the University of Pennsylvania, from which he was graduated in 1875 with a Certificate of Proficiency in Civil Engineering. In 1909, he received the degree of Bachelor of Science and, in 1910, the honorary degree of Doctor of Science from this institution.

During the summer following his graduation, Mr. Webster was engaged as Transitman on surveys for a proposed gravity railroad around Fairmount Park, Philadelphia, and in the fall of that year became Assistant Engineer on the survey for the layout of the buildings and grounds for the Centennial Exposition held in Philadelphia the following year. This work being completed, he spent the fall of 1876 as an Assistant with the United States Coast and Geodetic Survey on primary triangulation in Eastern Pennsylvania.

In 1877, Mr. Webster entered the employ of the City of Philadelphia and continued to serve with the municipality for forty-four years. Starting as Draftsman in what was then the Department of Surveys, he became, succes-

[1] Memoir prepared by Samuel Tobias Wagner, Henry H. Quimby, and Charles H. Stevens, Members, Am. Soc. C. E.

sively, Inspector and Assistant Engineer. In 1880, he was made Surveyor and Regulator (Assistant Engineer) of the Tenth Survey District which comprised about one-third the total area of the city, having charge of the design and construction of sewerage systems, bridges, street systems, parks, and other engineering work for this large District. The position made him a member of the Board of Surveyors, a body charged with street and park planning and the approval of plans for major engineering works throughout the city. In the early part of 1892, he became Principal Assistant Engineer of the Bureau of Surveys, and, later that year, was promoted to the position of Acting Chief Engineer and Surveyor, and, in 1893, to that of Chief Engineer and Surveyor of the Bureau, which position he held until 1916 and, again, in 1920. During the interval from 1916 to 1920, he was Director of the Department of Wharves, Docks, and Ferries.

As Chief Engineer and Surveyor of the Bureau of Surveys, Department of Public Works, Mr. Webster was in charge of the extensive engineering work undertaken by the City. This covered all phases of municipal engineering, including the construction of bridges, elimination of grade crossings, sewerage, water purification, port development, and city planning. Any history of his accomplishments is practically a history of the development of Philadelphia during this period.

The more important bridge work undertaken by him includes the completion of the Walnut Street Bridge over the Schuylkill River, and the construction of the steel truss bridge, at the Falls of the Schuylkill, the electrically operated drawbridge over the Schuylkill River, at Grays Ferry, the bascule bridge over the Schuylkill River, at Passyunk Avenue, and the concrete arch bridge over Wissahickon Creek, at Walnut Lane. At the time of its construction, the Walnut Lane Bridge, with a main span of 233 ft., was the longest masonry arch in the United States and the longest concrete arch in the world. In 1915, Mr. Webster reported to the City Council on the feasibility of a bridge over the Delaware River connecting Philadelphia with Camden, N. J. The location and type of bridge recommended by him at this time were essentially the same as those finally adopted in 1921.

The elimination of grade crossings of the steam railroads was an important branch of the work of the Bureau of Surveys, which extended throughout Mr. Webster's entire term of office. This involved negotiations with the railroad officials, and, in conjunction with the railroad engineers, the design and construction of many highway and railroad bridges and structures. The more important projects include: The removal of twenty-nine crossings on the New York Division of the Pennsylvania Railroad by the construction of four-track and six-track bridges; the removal of thirty crossings on the Trenton Branch of the Pennsylvania Railroad by the construction of a two-track elevated railroad in Trenton Avenue, with bridges over cross streets; the removal of seventeen crossings on the main line of the Philadelphia and Reading Railroad by the construction of the Pennsylvania Avenue Subway, involving a four-track to six-track open subway, four-track tunnel, elevated railway, and nine bridges; the removal of twenty-eight crossings on the line of

the Philadelphia and Reading Railroad between Greene Street and Wayne Junction, by the construction of a four-track elevated structure; the removal of eight important crossings of from eleven to thirty tracks on the Richmond Branch of the Philadelphia and Reading Railroad, by the elevation of the line and the construction of bridges; and the preparation of plans for the removal of fifty-six crossings of the Pennsylvania and Baltimore and Ohio Railroads, in South Philadelphia.

More than 800 miles of sewers were constructed in the city during Mr. Webster's term as Chief Engineer of the Bureau of Surveys. He inaugurated and carried on research work for more than twenty years on the relation between storm-water run-off and rainfall in various parts of the city, which proved of great importance in the design of storm-water sewers. After visiting sewage treatment plants in Europe in 1908, he established a station for testing various methods of the treatment of sewage in Philadelphia, and, in the light of these experiments, he designed and built the first sewage treatment plant in the city. In 1914, he prepared, with two Assistant Engineers, a complete report on the collection and treatment of the sewage for the entire city, which was adopted and, in principle, is now being followed. The Governor of Pennsylvania appointed Mr. Webster a member of the State Sanitary Water Board, the duty of which is to administer the statutes relative to sewerage and the discharge of sewage into streams, and to pass upon all plans for sewers and sewage treatment works throughout the State.

The filtration of city water was inaugurated early in 1900, and Mr. Webster designed, built, and had charge of the operation of, the Spring Garden Water Testing Station. He also supervised the design of the Torresdale, Belmont, and Roxborough slow sand filter plants. From 1905 to 1906, in addition to his other duties, Mr. Webster was Acting Chief of the Bureau of Filtration.

One of his main interests was the establishment of the Municipal Testing Laboratory, one of the first of its kind in America. It was used at first to test the cement and concrete for city work, but its use was soon extended to include the testing of other materials entering into construction work and paving. Later, this was still further extended to include the testing of practically all materials purchased by contract for the city.

From 1892 until the establishment of the Department of Wharves, Docks, and Ferries in 1907, Mr. Webster was a member of the Board of Harbor Commissioners, having charge of the engineering work in connection with the improvement of the Port of Philadelphia. This included the widening of Delaware Avenue from Vine Street to South Street, the construction of municipal piers at Chestnut, Arch, and Race Streets, and the dredging of the Delaware River and Schuylkill River channels. When Mr. Webster was appointed Director of the Department of Wharves, Docks, and Ferries in 1916, he again had charge of the harbor improvement work. During the four years that he held this position the municipal piers at McKean, Kenilworth, and Cherry Streets, and numerous smaller piers were constructed.

From 1880 until 1916, Mr. Webster was a member of the Board of Surveyors and served as its President for twenty-four years. As mentioned previously, this Board was responsible for the planning of the city. Under his direction the first City Planning Division in America was established in the Bureau of Surveys, and some of the results of this can be seen in the development of the Parkway, Roosevelt Boulevard, Delaware Avenue, Lincoln Drive, Torresdale Avenue, and other important highways. At the time of his death, he was Vice-President and Chairman of the Technical Advisory Committee of the Regional Planning Federation of the Philadelphia Tri-State District, which is engaged in the preparation of plans for the co-ordinated development of the territory for thirty-five miles around Philadelphia.

While Chief Engineer of the Bureau of Surveys from 1892 to 1916, Mr. Webster was an *ex officio* member of the Fairmount Park Commission, a member of its Committee on Improvements, and, for many years, Chairman of the Committee on Land Purchases and Damages. During this period he was also a member of the Board of Highway Supervisors, and, for more than twenty years, was its Presiding Officer. When the Transit Commission was formed in 1912 to make a study of the transit situation, Mr. Webster was appointed Acting Transit Commissioner during the illness of Transit Commissioner A. Merritt Taylor. The preliminary studies made and the work done by the Commission led to the formation of the Department of City Transit.

Mr. Webster resigned from the Bureau of Surveys in 1920 when selected by the Delaware River Bridge Joint Commission, together with Ralph Modjeski and Lawrence A. Ball, Members, Am. Soc. C. E., as a member of the Board of Engineers to consider sites and prepare plans and estimates for the Delaware River Bridge. The report of the Board was submitted to the Committee the following year, and the Board of Engineers was retained for the construction of the bridge. At the time of its completion in 1926, the Delaware River Bridge was the longest suspension bridge ever built, the length of the main span being 1 750 ft., and the total length, including approaches, 9 570 ft. In 1928, Mr. Webster was engaged as a Consulting Engineer, with Mr. Modjeski and C. E. Chase, M. Am. Soc. C. E., on the Henry Avenue Bridge, over Wissahickon Creek.

President Roosevelt appointed Mr. Webster a member of the Advisory Board on Structural Materials. On nomination by the American Society of Civil Engineers, he also became a member of the Engineering Division of the National Research Council.

Mr. Webster was especially interested in the American Society for Testing Materials, of which he was elected a member in 1900, and of which he was Vice-President in 1918 and 1919, and President in 1920. In addition, he served on various committees, as follows: The Committee on Cement (C-1), from 1903 to 1931, being Vice-Chairman from 1903 to 1915; the Committee on Reinforced Concrete (C-2), from 1904 to 1931; and the Committee on Clay and Concrete Sewer Pipe (C-4), from 1910 to 1922. He also presented a paper before that Society in 1902 on the "Advantages of Uniformity in

Specifications for Cement and Methods of Testing." From 1906 until its activities were suspended at the beginning of the World War, Mr. Webster was also a member of the International Association for Testing Materials.

He was the first to be elected to membership in the Engineers Club of Philadelphia after its organization in 1878. He served as Director of the Club in 1891 and as President in 1895, and was always actively interested in it. From time to time, he presented papers before the Club covering municipal projects under his charge, the most notable being the report of his investigations of sewage works in Europe.

He was a member of the Engineering Alumni Society of the University of Pennsylvania and its President in 1911; the Society of Municipal Engineers of the City of Philadelphia, of which he served as President in 1914; Past-President of the Sanitary Engineering Section of the American Public Health Association; member of the Franklin Institute; National Conference on City Planning; Chamber of Commerce of Philadelphia; Union League of Philadelphia; Honorary Member of the Rotary Club; Honorary Member of the T Square Club; Honorary Member of the City Parks Association; member of the Fairmount Park Art Association; Pennsylvania Forestry Association; Historical Society of Pennsylvania; Historical Society of Frankford; Frankford-Torresdale Country Club; and of the Board of Managers of the Pocono Manor Association. He was a member of the Society of Friends and, at the time of his death, was President of the Board of Managers of the Friends' Hospital in Philadelphia.

The following papers were presented to the Society from time to time by Mr. Webster: Final Report of the Special Committee on Uniform Tests of Cement[2]; "History of the Pennsylvania Avenue Subway, Philadelphia, and Sewer Construction Connected Therewith"[3] (joint paper with Samuel Tobias Wagner, M. Am. Soc. C. E.); "Specifications and Methods of Tests for Portland Cement"[4]; "The Pennsylvania Avenue Subway and Tunnel, Philadelphia, Pa."[5] (joint paper with Mr. Wagner); and "Walnut Lane Bridge, Philadelphia"[6] (joint paper with Henry H. Quimby, M. Am. Soc. C. E.).

Mr. Webster was a man who commanded the admiration of all who came in contact with him. He devoted his entire life to the planning and development of public works for the betterment of his native city and in the service of its citizens. His knowledge of conditions in Philadelphia and his breadth of vision in planning for its future growth were outstanding. Serving under eleven Mayors in succession, he was retained in important executive positions until he resigned from the City service on his appointment to the Board of Engineers of the Delaware River Bridge Joint Commission. An indefatigable worker, he demanded similar service from those who worked for him. He watched after the interests of the City as if they were his own. Straightforward, upright, positive in his convictions, a real diplomat in the public

service, he gave to the citizens of Philadelphia an engineering service that will be hard to equal.

He was married on December 5, 1883, to Mary H. Anderson, of Philadelphia, who, with their son, Maurice A. Webster, survives him.

Mr. Webster was elected an Associate Member of the American Society of Civil Engineers on September 7, 1892, and a Member on October 4, 1893. He served as a Director of the Society from 1904 to 1906; as Vice-President in 1917 and 1918; as President in 1920; and on the Board of Direction as Past-President from 1921 to 1922. He also served as President of the Philadelphia Association of Members (now the Philadelphia Section), of the American Society of Civil Engineers.

## GEORGE DAVIDSON, Hon. M. Am. Soc. C. E.[1]

DIED DECEMBER 1, 1911

George Davidson was born at Nottingham, England, on May 9, 1825. He came to the United States with his parents in 1832, and his early education was obtained in the Central High School, at Philadelphia, Pa. He was employed as Magnetic Observer at Girard College, in Philadelphia, from 1843 to 1845, and on June 1, 1845, he entered the service of the United States Coast and Geodetic Survey, as a Computer and Secretary to Superintendent Bache. He was appointed an Aid in 1846, and during the last twenty-seven years of his service was in charge of all Coast Survey operations on the Pacific Coast of the United States, until his resignation on June 30, 1895.

From 1846 to 1848, while serving as an Aid, Mr. Davidson was a member of survey parties engaged in making astronomical and meteorological observations, and, from that time, his interest in astronomy never flagged.

The necessity for an accurate knowledge of the Pacific Coast in the interests of navigation was recognized by the Federal authorities in Washington, D. C., and, in the summer of 1850, Mr. Davidson was appointed Chief of a party for making the needed surveys. The first requirements were the determination of the geographical positions of the prominent capes and headlands, the hydrographic surveys of the principal harbors, and the topographic surveys of the shore line adjacent to the harbors. Mr. Davidson's first observing station on the Pacific Coast was at Point Conception, California, one of the most prominent and dangerous on the coast. Here, he determined the latitude and longitude of the station, the variation and dip of the magnetic needle, and also reported on the best location for a lighthouse in that neighborhood. During the next four years, stations were occupied in California, successively, at Monterey, San Diego, Cape Disappointment, Port Orford, Neah Bay, the Presidio of San Francisco, and at approximately twenty minor points.

At that time only two methods were available for obtaining longitude, one by moon culminations and the other by the observed times of occultations

[1] Memoir prepared by Fremont Morse, Esq., Berkeley, Calif., and presented by Paul C. Whitney, M. Am. Soc. C. E.

of stars by the moon. Both these methods were used by Mr. Davidson. Travel along the coast in those days was by sailing vessels, and dangerous landings through the surf were often unavoidable. Sometimes there was danger from hostile natives, as at Neah Bay, where the observations were made behind breastworks, with men fully armed and ready to shoot.

A report by Mr. Davidson, entitled "Directory for the Pacific Coast", giving the results of his accumulated observations, was issued in 1855 as a guide to mariners. In the Coast Survey report for 1858, the Superintendent refers to this Directory as follows:

"This useful work has been compiled by George Davidson, Assistant in the Coast Survey, from Coast Survey and other authentic data, embodying also the results of his own experience on the coast, and topographical parties since the commencement of the survey in 1850. Having thoroughly and peculiarly identified himself with the survey of the western coast from its beginning, and having occasion himself to know the necessities, facilities and dangers of its navigation, he has been in a position to prepare a particularly valuable directory for the use of mariners and navigators."

This Directory was later known as the "Coast Pilot of California, Oregon, and Washington," and has passed through many revised editions.

Early in 1867, Mr. Davidson was appointed as Engineer of the exploration party dispatched by the Government to the Isthmus of Darien for the purpose of finding a practicable location for an Isthmian Canal. Immediately following the purchase of Alaska from Russia, he was ordered to make a preliminary geographical survey of that Territory, and, in 1868, the results of these accumulated observations were published in the "Coast Pilot of Alaska", of which he was the author.

The partial eclipse of May 26, 1854, was observed by Mr. Davidson at Humboldt Bay, California, chiefly for times of contact of solar and lunar images. He observed the occultations of twenty-two stars of the Pleiades group on March 1, 1857, and, to strengthen the longitude determination of the San Francisco Station, he observed at San Francisco the partial solar eclipse of March 25, 1857. He observed occultations of the Pleiades on March 25, 1860, at Ross Mountain, and the partial solar eclipse of July 18, 1860, on Sonoma Mountain.

Because of his intensive work on the astronomical foundation of the Pacific Coast surveys, any weak point in the instruments used was brought to his attention, and many improvements were suggested because of his inventive genius. A description of his meridian instrument for determining time, longitude, and latitude, which is used extensively by the Survey throughout the United States, was published in the report for 1867.

The construction of the Union and Central Pacific Railways, and the establishment of telegraphic connection between the Atlantic and Pacific Coasts enabled the longitudinal determinations of the West Coast to be placed on an accurate basis for the first time. The Pacific end of the longitudinal comparison with Harvard College Observatory was conducted by Mr. Davidson in a temporary observatory set up for the purpose in Washington Square, San Francisco. Telegraphic signals were exchanged with Cambridge, Mass.,

on twelve nights between February 15 and April 4, 1869, through the courtesy of the Western Union Telegraph Company. Mr. Davidson had already taken part in the transatlantic longitudinal determination in 1866, conducted by means of the new Atlantic cable.

The total solar eclipse of August 7, 1869, was observed by Mr. Davidson on the Chilkat River, Alaska, and, in 1870, he recorded the flight of 556 meteors at the San Buena Ventura Station, and made a special report on the subject.

In 1873, his party surveyed and permanently marked the eastern boundary line of California, north of Lake Tahoe, fixing the position of the 120th meridian west of Greenwich, and from 1893 to 1899, the diagonal boundary line from Lake Tahoe southeasterly to the Colorado River, was run.

The transit of Venus had been observed in 1769 by M. Chappe de l'Auteroche, at San José del Cabo, in Lower California, but this observer had not determined, or at least had not published, the exact position of his observing station. On account of the interest attached to the transits of Venus which occurred in 1874 and 1882, Mr. Davidson, in 1873, searched for the exact spot occupied by de l'Auteroche. Although no evidence of the latter's occupation remained, the description of the station enabled Mr. Davidson to locate it within a space of 20 sq. ft., and the co-ordinates of the observing station were accordingly determined.

Mr. Davidson was appointed by the United States Government Commission to observe the transit of Venus, in Japan, on December 8, 1874. On that occasion he determined the difference of longitude between Nagasaki and Tokyo, telegraphically, at his own expense.

He was a Delegate from the Federal Government to the Paris Exposition of 1878, with instructions to examine and report upon the instruments applicable to geodesy and astronomy. He was elected President of the Jury on Machinery by the French and foreign jurors. This Jury examined 3 800 pieces of machinery and awarded 850 prizes. Mr. Davidson was awarded a diploma and a medal for this service by the French Government.

The total solar eclipse of January 11, 1880, was carefully observed from the summit of Santa Lucia Mountain, California, by a Coast Survey party under his direction. He also directed the United States Government party for the observations of the transit of Venus, at Cerro Roblado, New Mexico, in 1882.

In the late Eighties, the question of the variation of terrestrial latitudes was prominent, and observations at widely separated stations were urgently requested. Mr. Davidson undertook the observation of latitude pairs, by the Talcot-Horrebow method, at his observatory in San Francisco, between May, 1891, and August, 1893. An additional series was made by him in 1893 and 1894. The results confirmed those secured at European, Atlantic Coast, and Hawaiian stations, establishing the fact that the astronomical latitudes of points on the surface of the earth are constantly changing by minute amounts.

Mr. Davidson's programs of observation, whether for the determination of latitude, time, azimuth, magnetic declination and dip, refraction constants,

or for research in theoretical astronomy on his own account, were characterized by the great number of observations planned for and acquired as well as by the observance of precautions for ensuring that the individual observations be as accurate as possible.

It is a remarkable fact that the first investigating astronomical observatory planned for the western half of the United States—the Lick Observatory—was on a large scale for its time. The first research observatory completed, however, was that of Mr. Davidson. This was established in Lafayette Park, San Francisco, about 1879. It contained a 6.4-in. equatorial telescope (by Mr. Alvan Clark) and auxiliary apparatus. Here, Mr. Davidson made drawings of the principal planets and observed star occultations and comets. The instruments were transported to stations occupied for the various eclipse observations.

Mr. Davidson was one of the three Commissioners sent by the United States Government in 1875 to East Asia, India, Egypt, and Europe, to report on the methods and state of irrigation in those countries. He was also a delegate from the United States to the Conference of the International Geodetic Association held in Paris, France, in 1889, and was commissioned to bring to Washington the international prototypes of the stardard meter and kilogramme.

His life was devoted with untiring energy and complete unselfishness to the interests of science on the Pacific Coast. It is no exaggeration to say that during sixty years his name was more familiar to the scientifically inclined of that region than that of any other resident. His services were not confined to the requirements of the Coast Survey work, and his efficient help was always available for the advancement of any department of science.

Professor Davidson was an authority on the voyages of the early explorers of the Pacific Coast and on its early history. The subject of astronomy, theoretical and practical, seemed to make a special appeal to him. He was well versed in the geodetic applications of astronomy, and the reports of the Coast Survey show that he never failed to grasp opportunities for making observations promising to be useful in any department of theoretical astronomy. The list of his published contributions contains many titles relating to eclipses, occultations, meteors, comets, and to atmospheric conditions affecting astronomical observations. His influence with James Lick, while Mr. Lick was formulating plans for erecting the most powerful telescope in existence, was wise and potent, and perhaps even vital to a practical solution of Mr. Lick's problem. In fact, it is entirely possible that without Professor Davidson's guidance at a critical period the plans for the construction of a useful telescope and observatory might have come to grief.

He was President of the California Academy of Sciences for sixteen years, and of the Pacific Geographical Society for thirty years. At various times and during periods of different length, he served on the Federal Commission for Irrigation, in California, the United States Advisory Harbor Commission of San Francisco, the Mississippi River Commission, and the United States Assay Commission, as Regent of the University of California, and, during

the last ten years of his life, as Professor of Geography in the University of California.

The high merit of Professor Davidson's work was recognized by the conferring of honorary degrees and election to membership in many learned societies. He received the degree of Master of Arts from the Central High School of Philadelphia, in 1850; the honorary degree of Doctor of Philosophy from Santa Clara College, California, in 1876; the honorary degree of Doctor of Sciences from the University of Pennsylvania, in 1889; and the degree of Doctor of Laws from the University of California, in 1910. He was made a Life Member of the Academy of Natural Science of Philadelphia, in 1885. He was elected a member of the American Philosophical Society in 1886; a member of the National Academy of Sciences in 1874; a Fellow of the American Association for the Advancement of Science in 1880; an Associate Member of the American Academy of Arts and Sciences in 1887; a Corresponding Member of the Bureau of Longitude of France in 1894; and a Foreign Correspondent of the Academy of Sciences of France in 1901. He held Honorary Membership in the American Geographical Society, of New York, the Royal Geographical Society of London; the Swedish Society of Anthropology and Geography; and the Berlin Geographical Society. He was a member of the Seismological Society of America (President, in 1907), the California Academy of Sciences, the Pacific Geographical Society, and the Washington Academy of Sciences. He was created a Knight of the Royal Order of St. Olaf of Norway in 1907, and he received the Charles P. Daly Medal of the American Geographical Society in 1898.

On October 8, 1858, he was married to Elinor Fauntleroy, of Virginia, and made his home in San Francisco until his death on December 1, 1911. He is survived by a son, Thomas Davidson, and a daughter, Elinor Davidson, both of San Francisco.

Fremont Morse, Hydrographic and Geodetic Engineer (*Retired*), U. S. Coast and Geodetic Survey, one of the few officers still living (1931), who served with Professor Davidson, writes of him as follows:

"He was a man of strong likes and dislikes. As a chief of party, he was the finest I have ever served under. If he had confidence in you and knew you could handle any situation that might arise, he would never give you any detailed instructions when assigning you to perform a piece of work; but if at any time you felt you needed some help, he was never too busy to interrupt anything he might have in hand and would willingly give you the benefit of his great experience."

Professor Davidson was elected an Honorary Member of the American Society of Civil Engineers on May 5, 1897.

## GRENVILLE MELLEN DODGE, Hon. M. Am. Soc. C. E.[1]

DIED JANUARY 3, 1916

Grenville Mellen Dodge was born on April 12, 1831, at Danvers, Mass. His parents were Sylvanus and Julia Phillips Dodge, people of gentle birth

[1] Memoir prepared by George H. Pegram, Past-President, Am. Soc. C. E.

whose progenitors had come from England early in the Seventeenth Century, and had settled in the vicinity of Rowley, near Boston, Mass. His parents were poor, his father in later life becoming Postmaster of Danvers.

When the boy was thirteen years of age he went to work on the large farm of Mrs. Lander on the outskirts of Danvers, where he also assisted in his first surveying work. Through contact in this work with the son, Frederick Lander, the boy was fired with the ambition to prepare himself for college. He matriculated at Norwich University, Northfield, Vt., in the autumn of 1848, from which he was graduated in 1851, with the degree of Military and Civil Engineer. In 1892 he was further honored by the degrees of Master of Arts, Master of Military Science, and Doctor of Laws from Norwich University, and, later, the degree of Doctor of Laws which was conferred on him by Cornell College, Iowa, in 1904.

Immediately after his graduation Mr. Dodge went to Illinois, where he entered railroad work. In 1852, he served as Assistant Engineer on the Illinois Central Railroad, on the survey of the line from LaSalle to Dixon, Ill. In 1853, Chief Engineer Peter A. Dey, of the Chicago and Rock Island Railway Company, gave him charge, as Principal Assistant Engineer, of a survey of the Mississippi and Missouri River Railroad (now a part of the Chicago, Rock Island and Pacific Railway System), across Iowa, from Davenport to Council Bluffs, and he determined the latter point as the proper crossing of the Missouri River for a transcontinental line.

At various times between 1853 and 1861 Mr. Dodge made explorations west of the Missouri River and in the Rocky Mountains for the purpose of finding the best route for a transcontinental railroad.

He was employed on the construction of the Mississippi and Missouri Railroad until 1857, when with the cessation of railroad activities, he became a member of the firm of Baldwin, Pegram and Company, engaged in banking and mercantile interests, and freighting across the plains to Denver, Colo. He continued with this firm until the opening of the Civil War in 1861.

Mr. Dodge had always been interested in military training and was Captain of the Council Bluffs Guard when he was offered an appointment as Captain in the Regular Army, which he declined in order to accept a commission as Colonel in the 4th Iowa Infantry, which entered service at Rolla, Mo., on August 24, 1861. He was assigned to a post at Rolla on October 9, and commanded expeditions to Houston and Salem, Mo., on November 1. The enemy was defeated in both engagements.

Some of Colonel Dodge's further engagements were as follows: Assigned to command of 1st Brigade, 4th Division, Army of the Southwest, January 21, 1862; advanced to and occupied Springfield, February 13; in engagement at Sugar Creek, Mo., February 17, and Cane Creek, Mo., February 20; defeated Gates' command at Blackburn's Mills, February 27; Battle of Pea Ridge, March 6 to 8, during which he was wounded in the right side; commissioned Brigadier General of Volunteers, March 31; reported to Major-General Halleck at Corinth, Miss., June 6, and ordered by him to report to Major-General Quimby commanding the District of Columbus, Kentucky, to re-build the

Mobile and Ohio Railroad; assigned to the command of the Central Division, Army of Tennessee, with headquarters at Trenton, Tenn., June 28; organized and mustered into service, 1st Tennessee Cavalry; finished re-building Mobile and Ohio Railroad, in August, and built stockades and earthworks at all its important bridges and stations.

During the time General Dodge was in command at Trenton, the captures of Dyersburg, Huntington, and O'Brien, Tenn., were made, and Villepigue was defeated on the Hatchie River.

On September 29, 1862, by order of Maj.-Gen. U. S. Grant, General Dodge was assigned to the command of the District of Columbus, Kentucky. Extensive fortifications and important works in and around Corinth were finished while he held that command.

On December 1, 1862, a combined movement was made from Holly Springs and Corinth during which the troops of General Dodge captured Tupelo and Okolona, Miss., defeating the enemy and taking the stores at those places. During the same month, by order of General Grant, he moved to Lexington and Spring Creek, Tenn., driving Forrest across the Tennessee River. In February, 1863, he attacked Van Dorn's column at Tuscumbia, Ala., and captured the place with its stores, artillery, etc.

In April, 1863, while in command of the 2d part of the 5th and a part of the Cavalry Divisions of the 16th Army Corps, he conducted an expedition in Northern Alabama, defeating the forces of the enemy in the Tuscumbia Valley. During the movement, the fights at Bear Creek, Cherokee, Burton Station, Leighton, and Town Creek occurred. Immense quantities of stores for Bragg's Army were captured and destroyed. During the same month, Chalmers and Ruggles were attacked and defeated at Tupelo. In June, General Dodge crossed the Tennessee River at Savannah, Tenn., and moving into Van Dorn's rear, captured the Town of Florence, Ala., defeating its garrison. On June 19, he attacked Ferguson's command on Big Muddy and stopped the raid on the Memphis and Charlestown Railroad. The fighting was severe and the loss considerable. On July 5, after the capture of Vicksburg, Miss., General Dodge was recommended by General Grant as first for promotion to the rank of Major-General. On July 8, he was assigned to the command of the left wing of the 16th Army Corps, with headquarters at Corinth. On the 14th of that month he defeated a part of Roddy's command at Jackson, Tenn., and captured many prisoners. On August 15, he made a raid on Granada, Miss., captured a large number of locomotives, cars, railroad stock, stores, etc., and defeated the enemy at Water Valley and Granada.

While at Corinth, General Dodge organized and mustered into service the 1st Alabama Cavalry, the 1st Alabama Colored Infantry, and several companies of colored troops for siege artillery. On October 30, his command was attached to that of Major-General Sherman, then moving into Middle Tennessee.

During November and December, 1863, he rebuilt the Nashville and Decatur Railroad, also pontoon bridges across the Tennessee River at Decatur, Ala., and the Duck and Elk Rivers, and constructed good and substantial

earthworks and stockades at all the important bridges and points. During this time the command had several engagements with the enemy, and captured and fortified Decatur.

In January, 1864, General Dodge organized and mustered into service the 2d and 3d Regiments of the Alabama Colored Infantry. In May, he was in command of the 16th Army Corps in the field in the Atlanta Campaign, and took part in the battles and engagements at Ship's Gap, on May 6; Snake Creek, on May 9; Resaca, on May 11; Estonula River, on May 12; Kenesaw Mountain, Roswell, Dallas, and Decatur, on July 21; Atlanta on July 22; and Ezra Church on July 28. On June 7, 1864, he was commissioned Major-General.

He was wounded in the head on August 19, and, on October 14, was ordered to City Point, Va., to visit General Grant. On November 3, General Dodge was assigned to the command of the District of Vicksburg and of the left wing of the 16th Army Corps. On December 2, he was assigned to the command of the Department and Army of Missouri, and on the 9th of that month was commissioned Major-General of the Missouri State Militia.

On January 30, 1865, the Department of Kansas was added to the Department of Missouri. Gen. Jefferson C. Thompson surrendered the Confederate forces in Arkansas. During January, February, and March, General Dodge made Indian campaigns on the plains, opening up the stage lines, and rebuilding telegraph lines destroyed by the Indians.

During 1865 and 1866, in his Indian campaigns, extending from the Arkansas River on the south to the Yellowstone on the north, many severe battles were fought. Treaties of peace were made with the Comanches, Apaches, Southern Cheyennes, and other Southern tribes, and a Council with the Northern Cheyennes, Arapahoes, and Sioux at Fort Laramie established the basis for a treaty. For service in this campaign, General Dodge received the thanks of the Legislature of Iowa.

In his "Memoirs" General Grant states, in part: "General Dodge besides being a most capable soldier, was an experienced railroad builder," and, referring to the re-construction of the railway between Nashville and Stevenson, he says further:

"General Dodge had the work assigned to him finished within forty days after receiving orders. The number of bridges to re-build was one hundred and eighty-two, many of them over deep and wide chasms. The length of the road repaired was one hundred and two miles."

On May 30, 1866, General Dodge resigned from the Army and immediately took charge, as Chief Engineer, of the construction of the Union Pacific Railroad. The transportation of supplies was one of the serious difficulties. No railroad had yet reached Council Bluffs, the initial point, and supplies had to be shipped from St. Louis and St. Joseph, Mo., by boats, then across the plains through a hostile Indian country, by teams.

The road was completed to a connection with the Central Pacific at Promontory Point, Utah, on May 10, 1869, 556 miles having been built in the last year—the most rapid railroad construction of record.

General Dodge realized the importance of intensive preliminary study of the ground. In the location of the Union Pacific Railroad, 25 000 miles of reconnaissance were made, and 15 000 miles of instrument lines were run. As a result the Union Pacific was originally so well located that subsequent improvements have shortened the road but thirty miles.

General Dodge was America's greatest railroad builder. He constructed the Union Pacific from Council Bluffs, Iowa, to Ogden, Utah; the Texas and Pacific from New Orleans, La., to El Paso, Tex.; the Fort Worth and Denver City, from Fort Worth, Tex., to Trinidad, Colo.; the Missouri, Kansas and Texas, from Fort Worth to Taylor, Tex.; the International Railroad of Texas from San Antonio to Laredo, Tex.; and the Des Moines and Northern (now part of the Chicago, Milwaukee and St. Paul Railway System). He was engaged as well in an advisory capacity on the construction of other lines. As President of the Mexican and Southern Railroad, he supervised the surveys from the City of Mexico through the State of Oaxaca, to the Pacific Ocean.

General Dodge at times was President of the following Railroad Companies: St. Louis, Des Moines, and Northern Railway; Des Moines Union Railway; Denver, Texas, and Fort Worth Railroad; Des Moines and Northern Railroad; and Union Pacific, Denver, and Gulf Railway. He was a Director of the Union Pacific Railway Company, and of the Wichita Valley Railway and Iron Steamboat Company.

General Dodge also had served, either as President, Director, or Chief Engineer, of the following companies: The Pacific Railway Improvement Company; the American Railway Improvement Company; the International Railway Improvement Company; the Texas and Colorado Railway Construction Company; the Oriental Construction Company; and the Colorado and Texas Construction Company, and the Western Industrial Company.

On the death of General Sherman in 1892, General Dodge became President of the Society of the Army of the Tennessee, which office he held until his death. He was Vice-President of the Grant Monument Association and Grand Marshal of the parade at the dedication of Grant's Tomb in New York, N. Y. He was also one of the organizers of the Loyal Legion and served as its Commander-in-Chief from 1907 to 1909.

In 1886-88, he represented the First Iowa District in Congress, declining re-nomination on account of the demands of his railroad work. In 1898, he was appointed by the President as Chairman of the Commission, known as the "Dodge Commission," to inquire into the management of the war with Spain.

In addition to his frequent contributions to periodicals, General Dodge published "How We Built the Union Pacific Railway, and Other Railroad Papers and Addresses" (1911), and, also, "The Battle of Atlanta."

He was married on May 29, 1854, to Annie Brown, of Peru, Ill., who, with their three children, Lettie (Mrs. Robert E. Montgomery), Ella (Mrs. Frank S. Pusey), and Annie, survives him.

General Dodge was patient in planning, but prompt to decide and act. His keen glance and quick movements expressed the energy he possessed in an unusual degree. He was direct and frank. As an illustration of these characteristics, he organized and conducted the Spy System for Grant and Sherman's Armies on the basis that spies should give correct information to the enemy, if any. A personality that made friends and a loyalty that bound them contributed in no small measure to his success.

Of modest and retiring disposition, he was dragged forward or pushed ahead by his friends, as his intimate history reveals, and this, of course, was the reaction of a loyalty that knew no bounds. It illustrates Emerson's maxim: "If you want a friend, be one." If a friend asked assistance, it was not "I will see what I can do," but "What can I do *now*?"

The history of General Dodge shows in a unique manner the value of preparedness. Educated in a military school at a time when war was not contemplated, and persisting in military training until the outbreak of the Civil War, he was fitted for military service at the start. His training in railroad and bridge building fitted him for the remarkable work of that character which he accomplished during the Civil War. His experience in freighting through an Indian country across the plains fitted him for the Indian campaign at the close of the war. His surveys west of the Missouri River and his wide knowledge of conditions in the West enabled him to advise President Lincoln on the selection from several routes proposed for the first transcontinental line.

All these experiences peculiarly fitted General Dodge to build the Union Pacific Railroad through a hostile Indian country with the necessity of transporting all materials for construction and supplies over long distances by boats and teams.

He died on January 3, 1916, in his eighty-fourth year, at his home in Council Bluffs, where he is buried.

General Dodge was elected Honorary Member of the American Society of Civil Engineers on March 2, 1915.

## KENNETH ALLEN, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 7, 1930

Kenneth Allen was born at New Bedford, Mass., on April 6, 1857, the oldest child of Edward A. H. and Eugenia (Teulon) Allen.

His father, Edward A. H. Allen, was graduated from the Rensselaer Polytechnic Institute, Troy, N. Y., in 1850, and from 1851 to 1855 was Professor there, in geology, physics, and chemistry. His ancestor, James Allen, came from England in 1639 and settled in a part of Dedham, Mass., which afterward was incorporated separately as the Town of Medfield. The Reverend

[1] Memoir prepared by George W. Fuller, William H. Breithaupt, and Arthur W. Tidd, Members, Am. Soc. C. E.

Jonas Clarke, of Lexington, Mass., prominent during the Revolutionary War, and whose house is now a museum, was his great-grandfather. Mr. Allen's mother, Eugenia Teulon Allen, was a daughter of Dr. William F. Teulon, Oxford graduate and descendant of a refugee Huguenot family which came to England in the first years of the Eighteenth Century. Dr. Teulon was married in London and, later, settled in Massachusetts.

After preliminary education at New Bedford, at Madison, Wis., where he spent a year (1872-73), at the preparatory school of the University of Wisconsin, and after a year at the West Newton, Mass., English and Classical School, Kenneth Allen entered Rensselaer Polytechnic Institute in the fall of 1874. He was graduated in the Class of 1879 with the degree of Civil Engineer.

Previous to his graduation Mr. Allen had been with the Boston Water-Works for more than a year. From 1879, he was engaged on railway work for three or more years, first on Western railways and then with the Pittsburg, McKeesport, and Youghiogheny Railway Company. In 1883, he was employed on surveys for the Water Department of Philadelphia, Pa., after which he again went West, on railway work, on branches of the Kansas City, St. Joseph, and Council Bluffs Railway Company and of the Missouri Pacific Railway Company, with both of which he had worked before.

From 1886 to 1890, Mr. Allen had an engineering office in Kansas City, Mo., in partnership with William H. Breithaupt, M. Am. Soc. C. E., with whom he was engaged on railway, general structural and bridge work, etc. On his return East in 1891, he was employed for a number of years with the Frick Coke Company, of Scottdale, Pa., largely on surveys.

He later served as Assistant Engineer to the Commissioner of Public Works, Yonkers, N. Y.; Assistant Engineer on the sewerage system of Williamsbridge, N. Y.; and, in 1895, he was in charge of studies for the sewerage system and sewage disposal of Baltimore, Md. From this time, his work was mainly on sewerage, in which branch of engineering he became prominent, and an authority. His Baltimore work was interrupted from 1900 to 1902 when he was in consulting practice with N. S. Hill and A. M. Quick, Members, Am. Soc. C. E., under the firm name of Hill, Quick, and Allen, of Baltimore and New York, N. Y., reporting on sundry water supply and sewerage projects. There was an interval also from 1902 to 1906 when he was Engineer and Superintendent of the Water Department of Atlantic City, N. J., but he returned to Baltimore in 1906 and until 1908 served as Engineer in Charge of the Low-Level Division of the Sewerage System.

In 1908, Mr. Allen was appointed Engineer of the Metropolitan Sewerage Commission of New York and, until 1913, was engaged in studies of New York Harbor phenomena and investigations of sewers and sewage disposal in the Metropolitan District. At various times during this period he was granted leave of absence for special consulting work, such as reporting on the sewage disposal of Hyndman and Bellwood, Pa., and on the East Orange-Newark (N. J.), storm-water, trunk sewer. During 1913, he inspected sewerage systems and sewage disposal works abroad, visiting England, Scotland,

Holland, France, and Germany; some of his observations are incorporated in his book on "Sewage Sludge". On his return he resumed his investigations with the Metropolitan Sewerage Commission culminating in the development of a plan for the main drainage and sewage disposal of New York City. The work of the Commission was terminated in 1914, subsequent to which date the studies were continued by Mr. Allen as Sanitary Engineer on the staff of the Chief Engineer of the Board of Estimate and Apportionment, which position he held until, shortly before his illness, he was drafted for similar work in the newly-created Department of Sanitation of the City. Granted leave of absence during the World War, he served as District Engineer, United States Housing Corporation, in charge of seven housing projects in the Middle West.

Mr. Allen was employed as expert in the case of the "State of New York *vs.* State of New Jersey and Passaic Valley Sewerage Commission", involving the alleged pollution of New York Harbor by New Jersey sewage. He also gave expert testimony in several cases involving oyster pollution and garbage disposal and, from time to time, investigated and reported on numerous drainage, sewerage, and garbage problems in and about New York City.

Mr. Allen was the author of many papers and discussions in the scientific societies to which he belonged, and was a frequent contributor to the technical press. He had unusually wide contacts in the sanitary field both at home and abroad.

An operation in February, 1930, left him in impaired health from which he did not recover. A pathetic feature is that he had decided to retire from active work on October 1, 1930, and his friends had arranged to give him a formal testimonial of appreciation. He had, however, the satisfaction of seeing, shortly before he passed away, appropriations made for contracts for the construction of the 180 000 000-gal. daily activated sludge plant on Wards Island, the installation of which he had for years advocated and urged as constituting the key plant in the disposal of the sewage of New York City.

Mr. Allen was a member of Sigma Xi, the only one of his class at Rensselaer to receive such membership. He was a member of the American Society for Municipal Improvements, of the American Public Health Association, and of the Municipal Engineers of the City of New York. He was a member and first President of the New York State Sewage Works Association which he was largely instrumental in organizing. He served for several years as Chairman of the Society's Special Committee on Rainfall and Run-Off. He was also a member of the Unitarian Laymen's League, a Charter and Honorary Member of the Tramp and Trail Club of New York, in which he was very active, and a member of the Westchester Trails Association, and of the University Club of White Plains, N. Y.

Kenneth Allen, in 1886, was married to Rose Whitmore Switzer, of Philadelphia, Pa., who, with their two sons, Edward S. and Harold A., and their daughter, Mrs. Frances Allen Dorsey, survives him.

Of kindly and amiable disposition, which made him many friends, ever serene and unruffled, he was nevertheless a man of strong character, persistent in the accomplishment of a set purpose. Always interested in others,

he was ever ready to give freely of his time and experience to help them in their troubles or problems. He retained his youthful enthusiasm and vigor to a quite unusual degree, and up to the time of his operation was a steady and welcome member on the regular trips of the hiking clubs to which he belonged.

Mr. Allen was elected a Member of the American Society of Civil Engineers on May 2, 1888.

## WILLIAM FRANKLIN ALLISON, M. Am. Soc. C. E.[1]

### Died July 7, 1927

William Franklin Allison was born in Elgin, Minn., on March 31, 1870, the eldest child of William and Kezia (Culbertson) Allison. His parents moved with their family to South Dakota in 1877, where they encountered the usual hardships and difficulties of pioneer life in the Middle West. Here, Mr. Allison attended the rural schools during his early life, and, later, the grade and high schools in the villages adjoining the family farm.

He taught a number of terms in the district schools in order to provide the means for his attendance at the State College of Agriculture and Mechanic Arts, at Brookings, S. Dak. from which institution he was graduated with honors in 1895. In 1897, he received the degree of Bachelor of Science in Civil Engineering from Purdue University.

From Purdue Mr. Allison went back to his home where he was engaged in the practice of general surveying until the outbreak of the war with Spain, at which time he organized a company of infantry and was commissioned its Captain in the First South Dakota Volunteer Infantry Regiment. Soon afterward he was promoted to the rank of Major. His regiment was sent to the Philippine Islands early in the summer of 1898 and remained there for the duration of the war and during the Philippine Insurrection. Major Allison was the Engineer Officer of the Regiment (May, 1898, to October 1899), detailed for road and bridge building and for the laying out of earthworks—winning signal merit for his services. He was recommended for the Brevet Rank of Lieutenant-Colonel of Volunteers for distinguished gallantry.

After his return from the Philippines in October, 1899, Major Allison spent some time in general engineering in South Dakota and worked for a time for the Chicago and Northwestern Railway Company. Later, he took graduate work at the South Dakota State College and at Purdue University and spent a year in Cornell University. From Cornell he received the degree of Civil Engineer in 1904.

In September, 1904, he became an Instructor in Civil Engineering in the Colorado School of Mines, at Golden, Colo., and, in 1905, was advanced to the rank of Professor of Civil Engineering, and Director of the Department of Civil Engineering at this school, which position he filled for the ensuing seven years. During this period he was also engaged in considerable private prac-

[1] Memoir prepared by C. Edward Magnusson, M. Am. Soc. C. E.

tice, including municipal, highway, water-works, sewers, and irrigation projects involving an expenditure of approximately $1 500 000, besides the design and supervision of construction of a large testing plant for the School of Mines. He also served as City Engineer for Golden, from 1908 to 1911.

In 1912, Professor Allison resigned his position at the School of Mines and entered private practice as Consulting Civil and Sanitary Engineer, in Portland, Ore. where he remained until September, 1913, when he was appointed Professor of Hydraulics and Sanitary Engineering at the University of Oregon. In 1914, he left Oregon to accept the position of Professor of Municipal and Highway Engineering at the University of Washington, Seattle, Wash., which position he held until his death on July 7, 1927. From August, 1914 to May, 1917, he also served as Consulting Engineer for the State Board of Health of Washington.

From his early boyhood he was interested in military affairs. He enlisted in the National Guard of Dakota Territory at the age of sixteen, and served continuously until the outbreak of the Spanish-American War when he entered service with the Volunteers. At the beginning of the World War in 1914, he was intensely interested and felt that all who had been trained in military affairs should be ready to serve if the need presented itself. It was with this idea in mind that he offered his services to the Government and received the rank of Major in the Reserve Officers Engineering Corps of the United States Army. On the entrance of the United States into the war, he was called into service (May, 1917), and was granted a leave of absence from the University of Washington.

As Major he went to France with the American Expeditionary Forces in September, 1917, and from November, 1917, to April, 1918, he was assigned to duty with the Sixteenth Engineers on general construction work. From April to November, 1918, he was Chief of the Construction Staff at Is-sur-Tille, France, and during November and part of December, he was Consulting Engineer on water supply at Liffol-le-Grande. During the remainder of December and through January, 1919, he was Engineer with the Peace Commission in Paris, France. He was discharged from service in Washington, D. C., February 17, 1919, and returned to his duties at the University of Washington in March of that year.

Professor Allison took an active part in his profession as well as in church, business, and civic affairs. He served as President of the Western Washington Section of the American Society of Civil Engineers in 1923, and was a member of the Special Committee of the Society on Irrigation Hydraulics from 1922 to 1927. He was the author of a number of papers and bulletins on various phases of Irrigation and Sanitary Engineering. He was a member of the American Public Health Association; the Society for the Promotion of Engineering Education; the University Faculty Men's Club; the American Association of University Professors; the American Legion; and the Presbyterian Church.

On August 25, 1904, he was married to Mabel Hegeman, the daughter of Mr. and Mrs. P. J. Hegeman, of Brookings, S. Dak. He is survived by

his widow; three children, Katherine, William, and Muriel; his mother, Mrs. Emma Allison, all of Seattle, and two brothers, Dr. H. T. Allison, of Stanwood, Wash., and A. C. Allison, of Lake Stevens, Wash., and a sister, Mrs. C. E. Winegar, of Sequim, Wash.

He was a peace-loving, genial, whole-souled man, loved and respected by all who were privileged to know him.

Professor Allison was elected an Associate Member of the American Society of Civil Engineers on October 4, 1910, and a Member on October 1, 1913.

## JUSTIN KENDERDINE ANDERSON, M. Am. Soc. C. E.[1]

DIED FEBRUARY 15, 1930

Justin Kenderdine Anderson was born in Sheffield, Pa., on September 26, 1869, the son of David Fort and Elizabeth (Kenderdine) Anderson. After graduating from the public schools, he received the degree of Bachelor of Science in Civil Engineering from Swarthmore College in 1889. He was a member of Delta Upsilon Fraternity.

Following his graduation, from 1889 to 1892, Mr. Anderson was engaged in construction work on the Clinch Valley Division of the Norfolk and Western Railroad, and, later, on the survey of lands, in Wayne, Mingo, and Logan Counties, West Virginia, for various coal companies. As a member of the firm of Forman and Anderson, his practice took him permanently to West Virginia where he held his first public office, from 1895 to 1896, as a member of the first Board of County Commissioners of Mingo County. During the next year he was Commissioner of School Lands in this County.

From 1899 to 1902, Mr. Anderson was Superintendent and Chief Engineer of the Guyandot Land Association holdings, covering more than 200 000 acres of coal, timber, oil and gas lands in Mingo, Wayne, Logan, and Lincoln Counties in West Virginia. He served as Assistant to the Chief Engineer of the Pocahontas Coal and Coke Company from 1902 to 1904, and during the following six years he was Superintendent and General Manager, as well as Chief Engineer and Director of several coal companies in the Pocahontas field. From 1911 to 1913, he was engaged in general engineering practice, with an office in Williamson, W. Va., and in the latter year was made the first Chief Engineer for the Public Service Commission of West Virginia, in which capacity he organized the Engineering and Inspection Department of the Commission. He retired from active service with the Public Service Commission, in 1919, but was frequently engaged by this body in a consulting capacity.

In 1913, Mr. Anderson established his home in Charleston, W. Va., where, in 1919, he opened an office as Consulting Engineer, specializing in public utility valuations and rate cases before the Public Service Commission. In 1920, he became senior member of the firm of Anderson and Taylor, Consulting Engineers. He frequently testified before the United States Supreme Court in interstate water power cases, and at the time of his fatal illness from heart

[1] Memoir prepared from information on file at the Headquarters of the Society.

disease, was at work on an investigation, for the Public Service Commission, of plans filed by the West Penn Power and Transmission Company in December, 1929, for an extensive water-power development program along Cheat River. In making that investigation he was aided by previous experience gained as one of a Commission of five members appointed by former Governor Morgan to study proposed water power legislation. He also investigated for the Commission, plans for water power projects in New River.

In recognition of his interest in military training Mr. Anderson was appointed a Civilian Aide to the Secretary of War in 1923, re-appointed in 1927, and was designated by former Governor Gore as a Colonel on the Governor's Staff. He was intensively interested in boys' activities and was a prominent figure at the first public investiture of the West Virginia Order of De Molay held at Clarksburg, W. Va. In addition, he was Chairman of the Advisory Board of the Charleston Chapter, Order of De Molay.

Mr. Anderson was a member of the American Institute of Mining and Metallurgical Engineers, President of the West Virginia Engineers Association, a member of the American Association of Engineers (Charleston Chapter), also a member of the Natural Gas Association of America, the West Virginia Oil and Natural Gas Association, and the Charleston Chamber of Commerce.

He was a Scottish Rite and a Thirty-second Degree Mason, and a member of the Beni-Kedem Shrine Temple. He was a charter member of Thacker Lodge 119, A. F. and A. M., and a member of the Clinch Valley Commandery, Knights Templars, at Tazewell Courthouse, Va. He held membership in the Edgewood Country Club, the National Advisory Board of Old Colony Club, the National League of Masonic Clubs, and the Rotary Club. He attended the Presbyterian Church.

He was married to Fannie Taliaferro Tinsley on February 26, 1895, and is survived by his widow and two children, Seaton Tinsley and Frances Gaines Anderson. The oldest son, Lane Schofield, was killed while serving overseas during the World War and posthumously received the Distinguished Service Cross for bravery in action.

Mr. Anderson was elected a Member of the American Society of Civil Engineers on September 2, 1914.

## HENRY CLARKE ASH, M. Am. Soc. C. E.[1]

DIED JUNE 20, 1929

Henry Clarke Ash, the son of John and Sarah (Clarke) Ash, was born on October 27, 1864, at Preemption, Ill. He was of Scotch-Irish ancestry.

He attended Cornell College, at Mount Vernon, Iowa, where he received the degrees of Bachelor of Civil Engineering, in 1890, and Civil Engineer in 1897.

On the completion of his studies in 1890, Mr. Ash went to work with the Chicago and Northwestern Railway Company in the capacity of Rodman and

[1] Memoir prepared by a Committee of the Duluth Section consisting of W. A. Clark, M. Am. Soc. C. E., and G. H. Butler, Sr., and Sheldon B. Shepard, Assoc. Members, Am. Soc. C. E.

Leveler, but left this Company in 1891 to become Assistant City Engineer, of Duluth, Minn. While serving in this position, he was in charge of the office and field work in the West End Branch of the City Engineering Department, from which he supervised the customary engineering work necessary to such an office. He carried on the construction of about nine miles of street paving, six miles of sewers, two pile and timber trestles, two miles of rubble masonry retaining walls, and a great deal of ordinary minor city construction, such as sidewalks and curb and gutter installation.

In 1896, Mr. Ash joined the engineering forces of the Duluth and Iron Range Railroad Company, and was in charge of the field party at Two Harbors, Minn. He laid out the new yard system for handling and classifying the ore trains for the docks and located the "Loop Line" from the yards to the main line. He also re-surveyed and placed monuments for North Two Harbors and, later, made a complete survey of all the property owned by the Railroad Company in Duluth. In addition, he located the piers for the construction of the Duluth-Superior Interstate Bridge and inspected the foundation work for this structure.

In 1896 he returned to Cornell College and for a year was an Instructor in "Adjustment, Use, and Care of Instruments", and in "Field Practice". During this period Mr. Ash carried on the necessary post-graduate work to receive his Civil Engineer degree which was presented to him in June, 1897.

On examination he became eligible for appointment to the grade of United States Junior Engineer, and in June, 1897, received his assignment as United States Inspector in the Chicago District under Maj. W. L. Marshall, Corps of Engineers, U. S. A. From June, 1897, to the fall of 1898, Mr. Ash was engaged as Inspector of Dredging in the vicinity of Chicago, Ill. He was then transferred to Sterling, Ill., for work on the Illinois and Mississippi Canal. He carried on the office work and surveys for about one year and then became Resident Engineer on the Canal in charge of the Tampico Office and Receiving Station. During this time, approximately eleven miles of the Feeder Canal were completed, including foundations for siphon culverts, iron and concrete culverts, bridges, and bridge approaches.

In 1902, Mr. Ash became associated with the Great Northern Power Company (now the Minnesota Power and Light Company of Duluth) for which he made an examination and report on a water power proposition in Michigan. Following this work he made the topographical surveys, current meter and weir measurements of the St. Louis and Cloquet Rivers, and the necessary calculations of flow in rivers, canals, and pipes with the fluctuations of head incidental to preparations for the design of the Thompson Dam and Reservoir at Thompson, Minn. Mr. Ash designed the dam for this Company and it was his privilege to supervise the construction work on the Thompson Reservoir consisting of: An earth dam, ½ mile in length, faced with rip-rap; a 700-ft. rock-fill dam with a concrete core wall; a concrete arch dam, 55 ft. high, with a 100-ft. radius; a concrete over-fall dam, 370 ft. long, which was 45 ft. high; 1 000 lin. ft. of concrete retaining dams ranging from 10 to 50 ft. in height; reinforced concrete sluice-gate house and head-gate house; 1 mile of canal;

concrete and steel wagon bridges; an 80-ft. steel girder railroad bridge; and supervision of a complete laboratory for testing materials for the entire development.

In 1928, Mr. Ash prepared a paper,[2] for the Twenty-fifth Convention of the American Concrete Institute held in Detroit, Mich., February 12 to 14, 1929, covering this work. Mr. M. B. Lagaard, of the Portland Cement Association, made an examination of this concrete work during 1928, and presented a discussion[3] on the paper by Mr. Ash, pointing out the fact that the thoroughness of the methods used by him as Resident Engineer was accountable for the excellent condition of all the concrete structures.

From 1907 to 1910, Mr. Ash was with the Minnesota and Ontario Power Company, following which he was Consultant on the Rice Lake Dam. In the winter of 1910 and 1911, he was in Beaudette, Minn., in charge of relief work following the disastrous forest fires. From 1915 to 1921, he was engaged as Assistant Engineer with the Duluth, Missabe and Northern Railway Company on valuation work. He then became Executive Secretary for the City Planning Commission of Duluth.

Mr. Ash had an unfailing sense of humor, which made him a delightful companion and associate. He was in very poor health during the last two years of his life, and while suffering and sick, as he knew himself to be, his usual cheerful smile gave an outward sign of content and happiness. His life was a continuous portrayal of that which man should be toward his fellows—considerate of others even to the neglect of self. It may be compared with that in which it was most useful, a piece of construction in which all success depends upon the foundation. The life of Mr. Ash on this earth constitutes the foundation upon which the superstructure of the most marvelous future may be erected without fear of deterioration due to faulty substructure.

Mr. Ash was a member of the Glen Avon Masonic Lodge, and of the Scottish Rite Fraternity. He was also a member of the Glenn Avon Presbyterian Church, in which he took an active interest.

On January 11, 1899, he was married to Frances C. Hoadley, of Boston, Mass., who, with a son, James H., and a daughter, Katherine C., survives him.

Mr. Ash was elected a Member of the American Society of Civil Engineers on October 3, 1906.

---

## FRANK MILLIGAN ASHMEAD, M. Am. Soc. C. E.[4]

---

DIED DECEMBER 7, 1925

---

Frank Milligan Ashmead was born at Germantown, Pa., on February 23, 1853, the son of Samuel B. and Mary (Milligan) Ashmead. His father, Samuel B. Ashmead, a leather merchant in the City of Philadelphia, Pa., traced his

[2] "The Thompson Dam and Reservoir" (Minnesota), *Proceedings*, Am. Concrete Inst., Vol. XXV, 1929, p. 29.

[3] *Loc. cit.*, p. 39.

[4] Memoir prepared by James H. Herron, M. Am. Soc. C. E.

American ancestry back to John Ashmead who came to Germantown, from Cheltenham, England, in 1682.

Mr. Ashmead received his early education in the public schools of Germantown and Philadelphia, afterward attending the Philadelphia Polytechnic Institute from which he was graduated in 1875.

His first professional engagements were in construction work on the Dutchess and Columbia Railroad, in New York State, and the Columbia and Port Deposit Railroad in Pennsylvania. He afterward went to the Allegheny Valley Railroad Company with which road, its branches, and successors, he remained during his professional life. He first served as Assistant Engineer on the low-grade division, after which he was, successively, Engineer, Department of Bridges, Resident Engineer, and Chief Engineer, with headquarters in Pittsburgh, Pa.

In 1901, when the Pennsylvania Railroad Company took over the Allegheny Valley Railroad and merged it with the Western New York and Pennsylvania Railroad, designating them the Buffalo and Allegheny Valley Division, Pennsylvania Railroad, Mr. Ashmead became Engineer, Right of Way, and Assistant Engineer of the Division. He remained in Pittsburgh until 1903, when he was transferred to Buffalo, N. Y., as Assistant to the Principal Assistant Engineer.

In 1918, Mr. Ashmead's health began to fail, and by request he was transferred to Pittsburgh (to be near his children), where he continued to serve as Assistant to the Principal Assistant Engineer intermittently on problems of right of way, etc., until he retired in 1921. After this time he lived, successively, in Atlantic City, N. J., and Cleveland, Ohio, in which latter city he died on December 7, 1925.

Frank Ashmead was a man of sterling integrity, retiring in disposition and much respected and beloved by his subordinates and associates. He was well informed, not only in regard to his profession, but upon many other subjects of a philosophical and economic character. While he spent practically all his professional life with one organization, he was well and favorably known on many of the Eastern railroads.

He was married on December 22, 1881, to Mary Lillian Herron, of Oil City, Pa., who with a son, Charles B. Ashmead, and a daughter, Edith (Ashmead) Hutchinson, survives him.

Mr. Ashmead was elected a Member of the American Society of Civil Engineers on July 6, 1887.

## FRANK FOY AXTELL, M. Am. Soc. C. E.[1]

DIED AUGUST 14, 1929

Frank Foy Axtell, the son of Thomas Jefferson and Edna Ann Axtell, was born at Washington, Ind., on August 18, 1867. His father was a successful business man, having come to Indiana from his native State, Pennsylvania,

[1] Memoir prepared by Charles Warren Hughes, Assoc. M. Am. Soc. C. E.

as a young man. The mother was from one of the Indiana pioneer families long resident in that part of the State and their son grew up with many early advantages in a material and social way.

Following his graduation from the local High School, Mr. Axtell entered Indiana State University, from which institution he received his degree in 1891. In September following, he was temporarily employed as Rodman on a precise level survey of the Missouri River. He left that work in the spring of 1892 to go as Recorder on a topographical survey of the Mississippi River, under the Mississippi River Commission, at St. Louis, Mo., becoming Field Draftsman in 1894. In that same year he left the work of the Commission for a time, engaging in the survey of suburban property and on an interurban railway in St. Louis, with F. B. Maltby, M. Am. Soc. C. E.; in 1895 he went with Mr. Maltby to Uvalde and Eagle Pass, Tex., on an irrigation project. On returning to the Mississippi River Commission in 1896, he was, successively, Recorder, Draftsman, Leveler, and Surveyor. He was promoted to the grade of United States Surveyor in 1897, and given charge of a Topographical Party.

As early as 1899, however, it became so advisable for Mr. Axtell to seek a milder climate on account of his health, that January, 1900, found him in New Orleans, La., attached to the United States Engineer Department, under the late Lt.-Col. H. M. Adams, Corps of Engineers. He was sent to Calcasieu Pass, La., to supervise the reconstruction and extension of the jetties at that place, covering mattress foundation and rip-rap stone work, which involved considerable expense. On the completion of this work, he was for a time Assistant to the late Mr. C. Donovan, at Port Eads, La., at the mouth of the Mississippi River. In the fall of that year Mr. Axtell transferred to Pilot Town, La., where he supervised the construction of a submerged dam across Pass á Loutre, one of the mouths of the Mississippi River, a work of many difficulties requiring the expenditure of $175 000.

On the completion of this work, Mr. Axtell was transferred back to the U. S. Engineer Office, at New Orleans, and advanced to the grade of U. S. Junior Engineer. He was placed in charge of the improvement of a number of small streams, including the dragging and dredging of these and the planning of improvements of a permanent nature. Then, for a time, pending the passing of the River and Harbor Bill, he was employed in the Division Engineer's Office of the Louisville and Nashville Railroad Company, at Montgomery, Ala. Following the passage of the River and Harbor Bill in June, 1902, Mr. Axtell returned to New Orleans and in December, 1902, he was transferred to Sabine, Tex., where he was given local supervision of the improvement of Sabine Pass Harbor and Jetties, Sabine Lake, and the Sabine and Neches Rivers. In 1906, the U. S. Government acquired title to the Port Arthur Ship Canal and Harbor, and the supervision of those works was turned over to Mr. Axtell. In 1908, the office maintained by him at Sabine was moved to Port Arthur, Tex.

From 1902 to 1912 his duties included the following: (1) Complete triangulation, topographic and hydrographic surveys of Sabine Pass, Sabine

Lake, and Sabine and Neches Rivers; (2) the preparation of plans and specifications and the supervision of jetty work at Sabine Pass, in 1903, 1905, 1908, and 1910, to the amount of $716 000, the work including rip-rap stone work foundation, and the granite and concrete capping; (3) the surveys for, the preparation of plans and specifications, and the supervision of the work of excavating, a canal connecting the Port Arthur Ship Canal and the mouths of the Sabine and Neches Rivers, known as the Sabine-Neches Canal (this canal had a depth of 10 ft., was 100 ft. wide on the bottom, and 16 miles long when first completed, but it has been widened and deepened several times since as appropriations became available); (4) the supervision of the dredging and the repairing of the U. S. hopper, sea-going dredge, *Sabine*, and the U. S. hydraulic dredge, *Port Arthur;* and (5) the supervision of the surveys for the Intracoastal Canal from (*a*) Calcasieu River, Louisiana, to Sabine River, Texas; and (*b*) Sabine Pass, Louisiana and Texas, to Galveston Bay.

In 1912, Mr. Axtell went with the Texas Company at Port Arthur, as Construction Engineer, in which position he supervised the construction of concrete retaining walls, docks, warehouses, and oil pipe lines. In 1913, he was sent to Tampico, Mexico, where as Chief Engineer for the Panuco Transportation Company he was engaged in land surveys, hydraulic dredging, and the construction of docks, warehouses, and dwellings. When the Panuco Transportation Company was merged into the Texas Company of Mexico, he was made Chief Engineer for the construction of oil pipe lines, boiler and pump houses, docks and dwellings, hydraulic dredging, and filling—a total of more than $1 500 000. He remained in Mexico seven years and returned in 1920, as at this time his two sons were of an age to need the educational opportunities of the United States.

In 1921 Mr. Axtell became allied with the Gulf Refining Company, of Port Arthur, reputedly the largest in the world. Dredging, the filling in of a bayou, a large expansion and construction program carried on by the Gulf Company, were projects in which he had a part; later, the land maps and records were handled. In spite of his failing health, for more than a year, he kept actively engaged with whatever came in his line of duty until July 19, 1929, when it became impossible for him to continue. He went home a sick man, indeed, and was unable to leave his bed from that time. Four weeks from that day, on August 16, he was laid to rest in Greenlawn Cemetery, Port Arthur, the city which had been his home for more than 20 years, except the 7-year period he spent in Mexico.

Mr. Axtell was a man of rare personality, loyal to his friends, yet in his judgment charitable toward all. He was a devoted family man—a man of high ideals. He was married on September 15, 1904, to Harriet Duncan, of Washington, Ind., who, with their two sons, Edwin Duncan and Frank F., survives him. He is also survived by one sister, Mrs. George Kramer.

He became a member of the Presbyterian Church in early manhood and continued in that faith to the end of his life. He took great interest in civic affairs as long as his health permitted, having served as a member of the local Chamber of Commerce and other organizations.

His technical training made him accurate in his methods, and he was unsparing of himself as an Engineer. He was generous, to a fault, toward those with whom he was associated in various engineering projects, and this to such an extent that often others reaped where he had sown.

Mr. Axtell was elected an Associate Member of the American Society of Civil Engineers on June 6, 1911, and a Member on November 26, 1918.

## MORTIMER GRANT BARNES, M. Am. Soc. C. E.[1]

DIED OCTOBER 7, 1930

Mortimer Grant Barnes was born on a farm near Reedsburg, Wis., on January 17, 1867. His parents were James B. and Alice Randall Barnes, who, when the boy was very young, moved to Nebraska, where he grew up and received his early education. In 1888 and 1889 he attended a business college at Holton, Kans., where he also took a course in higher mathematics. He then entered engineering work, and, in 1891, was elected County Surveyor of Boone County, Nebraska.

In 1892, Mr. Barnes entered the Engineering Department at the University of Michigan. During the next four years, he spent about half his time in the employ of the Corps of Engineers, U. S. Army, on the construction of the Poe Lock of the Sault Ste. Marie Canal, Michigan, and the other half in study at the University, from which he was graduated in 1896 with the degree of Bachelor of Science. After his graduation, he pursued the advanced course in mathematics, majoring in hydraulics and masonry; he received the degree of Civil Engineer in 1901. In 1922, the University of Michigan conferred upon Mr. Barnes the degree of Master of Engineering.

In 1896 and 1897 he was Assistant Chief Engineer of the Lake Superior Power Company, at Sault Ste. Marie, Mich., on the construction of a power plant at that place. For the next three years he was making surveys and preliminary plans for a canal in Alabama and was engaged on the survey and study of the United States Deep Waterway Survey in New York State and Canada. From 1900 to 1905, he was in charge of the design and construction of the Hennepin Canal in Western Illinois. In 1905, he was transferred to Rock Island, Ill., to take charge of the design and construction of the lock on the Mississippi River at Moline, Ill.

In 1906, Mr. Barnes was placed in charge of the design of locks and other structures of the Panama Canal, but resigned in 1907 when the U. S. Army Engineers were given charge of the work there. He then entered the employ of the Board of Water Supply, New York City, studying the design and foundation in connection with the construction of the Catskill Water Supply, but in a few weeks he was appointed by Governor Hughes as Consulting Engineer

[1] Memoir prepared by Walter M. Smith, M. Am. Soc. C. E.

on the New York State Barge Canal. He remained on that work for about eight years. During a part of that time, he also had a private office in Albany, N. Y., where he carried on a general engineering practice, having been engaged principally in problems of navigation, terminals, and the design and construction of water-power plants.

During the major part of 1914 he was associated with Walter M. Smith, M. Am. Soc. C. E., in the general practice of hydraulic engineering, under the firm name of Barnes and Smith, with offices in Albany. During this time, preliminary designs were made for power plants at various places and plans were completed for locks for the Brazos and Trinity Rivers, in Texas, and for a hydro-electric plant at Waterloo, N. Y. This partnership was dissolved in the fall of 1914 on account of the exigencies of the World War. Mr. Barnes continued in general practice, constructing the plant at Waterloo, and designing and building another at Seneca Falls, N. Y.

In 1917, Mr. Barnes was called to Illinois by Governor Frank O. Lowden to take charge of the design and construction of the Illinois Waterway as Chief Engineer of the Illinois State Division of Waterways. A $20 000 000 bond issue had been voted for the undertaking several years before this time. The waterway was to extend from the west end of the Sanitary District Canal, at Lockport, to the head of navigation on the Illinois River, at Starved Rock, Ill. Several attempts had been made by previous State Administrations to design a waterway acceptable to the United States War Department by which it had to be approved, but all such plans had failed. Mr. Barnes, however, designed a waterway that was approved by the Department, and work was started in 1919. He continued to be Chief Engineer until May, 1928, when he had to relinquish the arduous duties of that office on account of declining health, but he was retained by the State in a consulting capacity. After a long rest, his health was sufficiently improved to allow him to do consulting work, and he was engaged by the States of New Jersey and Pennsylvania to assist in opposing New York City in diverting water from the Delaware River for its own use. His strenuous work in this suit again caused a steady decline in health, from which he was not able to rally.

In addition to the work herein outlined, Mr. Barnes was consulted by various municipalities and other bodies at various times. He also owned and had most of the managerial cares of a large cattle ranch in Nebraska.

He suffered greatly from ill health for many years before his death, due largely to his intense interest in his work and his unwillingness to take rest or allow himself to rest while engaged on important tasks.

In 1898, Mr. Barnes was married to Mina M. Wood. They had three children, Alice E., Florence L. (now Mrs. Oscar C. Strom), and James M., all of whom survive him.

Mr. Barnes was elected an Associate Member of the American Society of Civil Engineers on November 2, 1898, and a Member on May 31, 1904. He was also a member of the Western Society of Engineers.

# AXEL SAMUEL FREDERICK BERQUIST, M. Am. Soc. C. E.[1]

DIED OCTOBER 6, 1915

Axel Samuel Frederick Berquist was born on February 1, 1863, in Smaland, Sweden. In 1882, he entered the University of Lund, Sweden, from which he was graduated in 1886.

Subsequent to his graduation, Mr. Berquist came to the United States and was engaged with the Baldwin Locomotive Works until 1892 in the capacities of Machinist, Draftsman in the Highway Department, Tool Designer, and Erection Superintendent.

From 1892 until 1897, he acted as Chief Draftsman and Engineer in the Construction Department of the Spreckels Sugar Refining Company, in Philadelphia, Pa. Among the principal structures which Mr. Berquist erected are the following: A new raw sugar wash house, complete with machinery; Pier 61 on the Delaware River, with sheds for this pier and also for Pier 60; a sugar warehouse, 500 by 175 ft., with 2 miles of over-head track for trolley operations; a new style of furnace for burning sugar baskets and mats; ten bridges, from 50 to 98 ft. in span, for various purposes; and, finally, he assisted in remodeling the entire plant of the Spreckels Company.

In 1897, Mr. Berquist entered the service of the American Coffee Company with which he remained as Engineer until 1900. He was instrumental in designing and erecting the Company's plant in Brooklyn, N. Y., and in connection with a power house for this plant, he invented the "Berquist Suspension Bunker" for storing coal, ore, and similar materials.[2]

From 1900 until a short time prior to his death, Mr. Berquist was associated with the Rapid Transit Subway Construction Company of New York, N. Y. As Engineer he was in charge of metal structures and the steel erection, including the new Harlem Ship Canal Bridge, at Kingsbridge, N. Y. His work likewise included all revisions and alterations of steel work at the time of, and during, erection and the financial adjustments relating thereto. It was a conspicuous fact that in his dealings representing the Contractor with the several sub-contractors, his decisions were uniformly fair and diplomatic. After severing his connection with subway work, Mr. Berquist was engaged in consulting practice and in some contracting. He was associated with the work of track elevation of the New York Central Railroad through the City of Yonkers, N. Y., and, at this time, he also continued to be actively engaged in the development and improvement of his "suspension bunker."

His untimely death removed from the ranks of the Engineering Profession an able and an experienced engineer. He was of a quiet but sociable disposition, agreeable, patient, and ever ready to help solve the mathematical and engineering problems which his co-workers might bring to him. Early

[1] Memoir compiled from information furnished by the late William J. Boucher, M. Am. Soc. C. E., and Theodore Belzner, Affiliate, Am. Soc. C. E., and from data on file at the Headquarters of the Society.

[2] *Engineering News*, July 27, 1899, p. 54, and *Engineering News-Record*, August 31, 1922, p. 346.

in the introduction of reinforced concrete, he devised some very workable and simple formulas for practical application.

Mr. Berquist was elected a Member of the American Society of Civil Engineers on June 6, 1906.

## ALEXANDER LESLIE BLACK, M. Am. Soc. C. E.[1]

DIED MARCH 3, 1930

Alexander Leslie Black was born in New Orleans, La., on January 4, 1871. He attended private preparatory schools in New Orleans and in New York, N. Y., and was graduated from the School of Mines, Columbia College, in 1890. He then engaged in mining work in the West and in Mexico for three years, subsequently acting as Assistant Engineer on the topographical survey of New Orleans.

In 1894 and 1895, Mr. Black had charge of the reconstruction for electric operation of the St. Charles Street Railroad in New Orleans, and remained with that Company supervising operation and construction extensions for this and other local companies until 1901, when the New Orleans properties were consolidated. He then became Engineer for the New Orleans Railway and Light Company and its predecessors controlling the New Orleans street railways and lighting companies.

In 1910, he became identified with the firm of Ford, Bacon, and Davis, Incorporated, as Engineer in charge of Southern Properties, supervising the reconstruction, maintenance, and operation of street railway, electric light and power, and water and gas properties in New Orleans, Birmingham, Ala., Memphis, and Knoxville, Tenn., Little Rock, and Pine Bluff, Ark., and Houston, Tex. These activities engaged Mr. Black's time until 1914, when he became Chief Engineer of Design and Construction of public cotton warehouses and terminals in New Orleans. This work was highly diversified in character, including the construction not only of warehouses, but of power plants, cotton compresses, wharves, tracks, cotton-handling equipment, and land reclamation.

Two years later, Mr. Black was made Chief Engineer on Design and Construction of the New Orleans Public Grain Elevator. This project included a warehouse, grain dryer, million bushel storage bins, with wharves, conveyors, galleries, trackage, and land reclamation. During the eight years following this engagement (which in itself consumed only one year), Mr. Black was occupied with valuation and rate negotiations for the Market Street Railway Company, Sierra and San Francisco Power Company, Coast Valleys Gas and Electric Company, in San Francisco, Calif., and as Consulting Engineer, Way and Structures, for the Market Street Railway Company. From 1924 to 1925, he was Vice-President in Charge of Market Street Railways in San Francisco. The two years following he was Chief Engineer of the New Orleans-Pontchar-

[1] Memoir prepared by William von Phul, M. Am. Soc. C. E.

train Bridge, conducting investigations for the foundations, design, and construction of a bridge, with highway approaches, over Lake Pontchartrain.

Failing health caused Mr. Black to curtail his activities considerably during the three years before his death, and he alternated between the Corporation's New York and Birmingham Offices. His last assignment was as Consultant during the construction of the transportation system of the Southern Natural Gas Company.

He was a member of the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, the American Association of Engineers, and the Louisiana Engineering Society.

He is survived by his widow, the former Virginia Bullitt Grant, and two sons, William Grant and Alexander Leslie Black.

Mr. Black was elected a Member of the American Society of Civil Engineers on December 4, 1907.

## JOHN CARLISLE BLAND, M. Am. Soc. C. E.[1]

### Died July 16, 1927

Champion of riveted against pin-connected bridges, successful constructor of many bold and difficult works, and a leading figure in the art during more than thirty years, John C. Bland, long the Bridge Engineer of the Pennsylvania Lines West, left a lasting impress on bridge engineering. His death in 1927 deprived railroad bridge construction of one of its most original and creative minds.

John Carlisle Bland was born in Philadelphia, Pa., on January 22, 1853, of British West Indies parentage. After an education in Mathematics at Johns Hopkins University, he began practical work with the Pennsylvania Railroad Company in 1871, first as member of a survey party and later as Assistant Engineer in charge of a bridge under construction. After three years, however, he was engaged as Engineer by the bridge building firm of J. H. Cofrode and Company, Philadelphia. He remained with this firm for six years, and then spent three years (1879-1882) as Engineer in the office of the Supervising Architect of the United States Treasury. He then returned to the firm, which had become Cofrode and Saylor, Philadelphia Bridge Works, and remained with it until 1888. In the latter year ill health, which had for some time troubled him, compelled him to move permanently to Colorado, where until 1894 he practiced as Consulting Engineer in Colorado Springs, serving, during this period, the Colorado Midland Railway and the Denver and Rio Grande Western Railroad Companies.

Mr. Bland's second and permanent connection with the Pennsylvania Railroad Company began in 1895. A year earlier he had taken charge for the late Thomas Rodd, M. Am. Soc. C. E., of the construction of the East Pittsburgh Plant of the Westinghouse Electric and Manufacturing Company, but soon he was called by the late M. J. Becker, M. Am. Soc. C. E., Chief Engineer of

[1] Memoir compiled from information on file at the Headquarters of the Society.

the Southwest System, Pennsylvania Lines West, to design and supervise the construction of the Company's Ohio River Bridge, at Cincinnati, Ohio. Upon completion of this work he was placed in charge of all bridge work on the Southwest System. This was the beginning of an unbroken career of important bridge construction for the Pennsylvania System, which continued until his retirement for age in 1923. He held, successively, the positions of Principal Assistant Engineer of the Southwest System (1896 to 1900); Engineer of Bridges of both the Northwest and Southwest Systems (1901-1920); and Engineer of Bridges and Buildings. After his retirement he lived in Atlantic City, N. J., where he died.

Mr. Bland's first great contribution to railroad bridge practice was the reform of designing and contracting methods prevalent in the Eighties and early Nineties. It was usual for the railroad companies to prepare a general specification and a plan of span lengths, and to require bidders to prepare designs and submit lump-sum bids. This practice, while it stimulated the ingenuity of bidders and resulted in low first cost, also produced many poor bridges. Mr. Bland strongly opposed this practice, and for the first time at Cincinnati prepared a complete general design as the basis for bids. This innovation led ultimately, through his own influence as well as through the precedent of good practice which it set, to the progressive abandonment of the old method by all railroad companies. The change cleared the way for the great advance in the art which growing railroad requirements demanded.

In the same period, Mr. Bland did much to extend the use of steel in place of wrought iron to all railroad bridge work. The Cincinnati Bridge was built wholly of steel, but the Northwest System of the Pennsylvania Lines West continued to restrict steel to eye-bars, rods, and pins. When Mr. Bland became Bridge Engineer of both Systems he prepared a new specification which permitted the use of steel throughout.

Much more important, however, was his influence in turning railroad bridge practice away from pin-connected construction toward full riveted-truss construction, now the established standard in the railroad bridge field. In the first large structures which Mr. Bland designed and built for the Pennsylvania Lines West, he adopted pin-connected trusses, the last important one being the Panhandle Bridge, over the Monongahela River at Pittsburgh, Pa. (1903), comprising spans from 183 to 363 ft. long. The 230-ft. riveted spans of the Ohio River Bridge, at Steubenville, Ohio, were his first important riveted trusses. Soon it was shown that riveted construction could so thoroughly meet the requirements of modern engineering, and was so well adapted to the improved facilities of fabrication and erection, that in a relatively short time it was generally adopted. Nevertheless, Mr. Bland's own works still remain among the largest and heaviest riveted spans, notably the 416-ft. and 525-ft. channel spans of the Ohio Connecting Railroad over the Ohio River at Pittsburgh (1913-14), and the 644-ft. channel span of the Louisville, Ky., Bridge (1916-18).

Because of their place in the record of heavy railroad bridge construction, a few of Mr. Bland's larger undertakings for the Pennsylvania Lines West claim mention here: The Allegheny River Bridge, at Pittsburgh (1902), a

most difficult replacement undertaking, involving what is still the heaviest bridge of its size; it has a 333-ft. channel span, and four lines of trusses, carrying five tracks on two decks; not only was it built under traffic, but in 1917 it was raised, also under traffic, about 13 ft. to give greater under-clearance for river traffic; both the original construction and the raising were operations of utmost complexity and delicacy, and both were carried out with complete success, free from all untoward incident: The Monongahela River Bridge, at Pittsburgh (1903), channel span, 363 ft.: The Ohio River Bridge, at Steubenville (1909), the replacement of an old pin-connected bridge under traffic, with change of span lengths to give a wider channel; the channel bridge, a three-span, continuous-riveted structure of 353, 568, 353 ft., respectively, was not built until 1926-1927; the 230-ft. spans of this bridge (1909) were Mr. Bland's first large riveted trusses: The Ohio Connecting Railroad Bridge, at Pittsburgh (1913-14), through channel spans of 416 and 525 ft., and eleven deck spans of 171 ft., the longer channel span being erected without falsework, by cantilever construction using parts of the other channel span as counterbalance: The Muskingum River Bridge, at Tyndall, Ohio (1914), one of the early examples of rolling a series of spans into place laterally between trains without delay to traffic; the previous bridge had been washed out in the great 1913 Central States flood: The Calumet River and South Branch (vertical lift) Bridges, at Chicago, Ill. (1914-15); two double-track lift spans of 210 ft. over the Calumet, and one double-track lift span of 273 ft. over the South Branch, probably the heaviest railroad lift span attempted up to this time; the Miami River Bridge, at Dayton, Ohio (1916); three double-track spans of 221 ft., rolled laterally to place in two successive operations because of complicated approach-track conditions; the Ohio River Bridge at Louisville (1916-18); this structure comprises twenty-two spans, ranging from 110 ft. to 644 ft. long, and replaced a historic bridge built by the late Albert Fink, Past-President, Am. Soc. C. E., in 1868-70; Mr. Bland's 644-ft. channel span is the longest riveted simple truss for railway use yet constructed.

Outside of bridge work, Mr. Bland was consulted by the Pennsylvania Lines West on many problems of railroad construction and maintenance, chiefly because of his mathematical insight. He made many investigations and reports on such questions. He was also called upon to act as Consulting Engineer to the Terminal Railroad Association of St. Louis on the Eads and Merchants Bridges. In this service he made a thorough investigation of the old Eads Bridge, built in 1874, and strengthened it for modern traffic. He later similarly investigated and reinforced the near-by Merchants Bridge.

His published works include one of the early handbooks for engineers and architects, that of the Pottsville Iron and Steel Company, of Pottsville, Pa. (1887). He contributed discussions on "Train Loadings for Railroad Bridges"[2] and on "Some Disputed Points in Railway Bridge Designing,"[3] two papers published by the Society, as well as similar articles to other scientific societies.

[2] *Transactions*, Am. Soc. C. E. Vol. XXXI (1894), p. 194.
[3] *Loc. cit.*, Vol. XXVI (1892), p. 232.

His interests, however, were not limited to the field of bridges. He was a man of broad general culture and studied deeply many scientific subjects as well as cultivating philosophy, literature, and humanistic studies. In particular, he was a brilliant mathematician, and both pure and applied mathematical investigations were his principal hobby.

Mr. Bland was married to Emma Virginia Long, of Philadelphia, in 1874. He is survived by one son, Arthur Stanley Bland, of St. Louis, Mo.

Mr. Bland was elected a Junior of the American Society of Civil Engineers on May 12, 1875, and a Member on June 4, 1879.

## GEORGE BOWERS, M. Am. Soc. C. E.[1]

DIED FEBRUARY 28, 1930

George Bowers was born on October 30, 1848, in Middlesex Village, then a part of Chelmsford, Mass., the son of Sewall and Sylvia (Fisher) Bowers. He was of English ancestry; his earliest known paternal ancestor was Michael de Bures who was seated in Dorset, England, in 1075. His earliest paternal ancestor in America was George Bowers, whose son, Jerathmell Bowers, built the Bowers homestead in 1695 on land granted from the King of England. Mr. Bowers lived in this same house many years, the home still remaining in the Bowers family, having been passed down from generation to generation.

George Bowers spent his early life in Middlesex Village and Lowell, Mass., where he attended the local schools. He started his engineering work in the City Engineer's Office in Lowell, remaining for two years before entering the Massachusetts Institute of Technology with the Class of 1875. After leaving the Institute he was employed as First Assistant Engineer on the construction of the Waltham, Mass., Water-Works. Returning to Lowell, he became First Assistant Engineer and, later, City Engineer.

In addition to his regular work as City Engineer, Mr. Bowers carried on an extensive series of experiments with driven wells to determine whether it would be possible to supply Lowell with driven-well water. He was convinced that this could be done, and his judgment proved to be correct, for since the wells were put into operation, Lowell has used no other water supply. He was the author of a number of papers on his driven-well experiments.

After leaving the City Engineer's Office, Mr. Bowers took up consulting work, which he followed until his last illness. He planned, and was Engineer during the construction of, a new driven-well water supply for Chelmsford, Mass., and acted as Consulting Engineer for The Nashua Manufacturing Company, and The American Hide and Leather Company in connection with water supply problems and the disposal of wastes. During the World War, Mr. Bowers was Engineer for a development for the United States Housing Board.

At a special meeting of the Board of Trustees of the Lowell Institution for Savings, of which Mr. Bowers was First Vice-President, the following memorial was placed on the records:

[1] Memoir prepared by E. B. Carney, Treas., Lowell Inst. for Savings, Lowell, Mass.

"George Bowers, our First Vice-President and Chairman of our Board of Investment, died Friday morning, February 28, 1930, at a few minutes after midnight. He was born October 30, 1848, in Middlesex Village, and afterwards lived in the old Bowers Homestead on Wood Street, built in 1695. This is supposed to be the oldest house now in Lowell.

"He was elected Corporator, Trustee, Vice-President, and member of the Board of Investment in 1904. Mr. Bowers had been City Engineer for over twenty years, but in 1911 was defeated for re-election.

"No ruler ever had his subjects more at heart, nor has a great general looked after his soldiers one bit more than Mr. Bowers did when he fought almost single-handed to have the polluted water system of Lowell changed to one of purity, and thereby saving many lives. This was his Victory of Peace.

"He was faithful to all the duties imposed upon him of whatever nature, and this bank will turn back its pages to his record and say with pride, 'Well done Thou Good and Faithful Servant'."

A life-long Unitarian, George Bowers devoted time and money to help his church. He was a member of the Boston Society of Civil Engineers, the New England Water Works Association, the Engineers Club of Boston, the Vesper Country Club, and a number of historical and philanthropical societies.

On October 24, 1878, Mr. Bowers was married to Estelle L. Wilkins, who survives him. He also leaves a daughter, Helen E. Bowers, and two sons, George W. Bowers, Assoc. M. Am. Soc. C. E., and Alton R. Bowers.

Mr. Bowers was elected a Member of the American Society of Civil Engineers on October 1, 1902.

## STOERK JOHAN BRATAGER, M. Am. Soc. C. E.[1]

### Died August 29, 1930

Stoerk Johan Bratager was born in Bergen, Norway, on June 7, 1860, a son of Lars and Cecelia (Lohn) Bratager, who came to Bergen from Voss, Norway.

He received his primary education in his native city, and was graduated from the Bergen Technical School in June, 1880. A short time later he left for Hanover, Germany, where he attended the Technical High School during 1881 and 1882. On his return to Norway he found the prospects for a position very poor. He continued his search, however, during the following winter, but finally decided to emigrate to the United States and arrived in New York, N. Y., in the spring of 1883.

From New York Mr. Bratager followed the route of his countrymen, finally reaching St. Paul, Minn. He quickly obtained temporary work with the St. Paul and Pacific Railway Company, now a part of the Northern Pacific System. As it happened, this "temporary job" in all its different manifestations continued for forty-two years, at the end of which time he retired at his own request because of ill health.

The positions held by Mr. Bratager during that period were, successively, as follows: 1883 to 1893, Draftsman and Chief Draftsman, the St. Paul and Pacific Railway Company; 1893 to 1898, Chief Draftsman; 1898 to 1901,

[1] Memoir prepared by Martin S. Grytbak, M. Am. Soc. C. E.

Assistant Engineer; 1901 and 1902, Division Engineer; 1902 to 1904, Office Engineer; January, 1904, to December 1922, Principal Assistant Engineer; and January 1923 to June 1, 1925, Assistant Chief Engineer, Northern Pacific Railway Company.

During his forty-two years of service Mr. Bratager was engaged in bringing the records and the physical condition of the railroad up to the high state of development which was required for taking care of the heavy traffic of 1925 as compared with the light traffic requirements of 1883. With a few assistants, he established the early distance schedules and records of the line, which, due to the rapid growth of the System, had become an important and difficult problem. Later, when valuation work started, he made the first complete valuation of the railroad.

While Mr. Bratager's service was generally devoted to the design of engineering undertakings and office administration, he was greatly interested in the application of these designs. He was in charge of the construction of fifteen miles of the Sykeston Branch during 1899. His design of the steel rollers and screws used in the moving of the east pier of Bismarck Bridge proved very successful. This pier, with load, weighed 4 700 tons, and was moved under traffic. On the completion of the work, it was found that 90% of the rollers had practically complete bearing after moving the pier 5 ft. easterly and 4 in. northerly, the rollers working between parallel planes.

During his long service with the Railway Company, Mr. Bratager gained the sympathy and confidence of his superiors, as well as the love and respect of his employees. All the engineers who received their early training under his direction will long remember him for his fair and correct dealings and his thorough investigation of the subjects at hand. His sympathy and help were of the greatest importance to all young engineers who, during his time with the Engineering Department of the Northern Pacific Railway Company, were looking for advice or a "start" with the Company.

Mr. Bratager disliked publicity. He was a friendly, quiet man of high principles and stern character, loved and respected by all who knew him. He enjoyed his work most of all, and his spare time was spent in working in his garden and around his home. In his earlier days he enjoyed traveling around in the "Twin Cities" and vicinity, alone, or in the company of a friend, generally winding up at some of the Company's track improvements or bridges. He was very interested in baseball and attended the games as long as he was able. He enjoyed the company of his family and friends, and they appreciated his keen humor and valued his friendship. He was a member of the Christ Lutheran Church of St. Paul.

On October 5, 1895, he was married to Synneva Bugge, the daughter of Mr. and Mrs. Ludvig Daae Bugge, of Valders, Norway. He is survived by his widow and his sister, Miss Carrie Bratager, of St. Paul, and one brother, Lars Bratager, of Minneapolis, Minn.

Mr. Bratager was elected a Member of the American Society of Civil Engineers, on June 3, 1915. He was also a member of the American Railway Engineering Association.

# PETER FRANKLIN BRENDLINGER, M. Am. Soc. C. E.[1]

DIED DECEMBER 16, 1929

Peter Franklin Brendlinger was born on January 18, 1850, in New Hanover, Pa. He was the son of Frederick Brendlinger, a land owner and farmer, storekeeper, and Postmaster for many years, and, at one time, County Treasurer. His mother was Mary (Hill) Brendlinger who, like her husband, was of sturdy Pennsylvania German stock. His immediate forebears had never moved from this location since his great-grandfather had settled there in 1751, having emigrated from Getzigen in Wurtemburg, Germany.

Mr. Brendlinger prepared for a college education in the country schools of his home district near Pottstown, Pa., and at the Tremont Academy, at Norristown, Pa. He was graduated as a Civil Engineer in June, 1870, from the Polytechnic College of the State of Pennsylvania, in Philadelphia.

From August, 1870, to August, 1871, he was an Assistant Engineer on the location and construction of the St. Louis, Council Bluffs, and Omaha Railroad, from St. Louis, Mo., to Omaha, Nebr. Between October, 1871, and November, 1874, he served as Assistant Engineer on the Pittsburgh, Virginia, and Charleston Railroad, from Pittsburgh, up the Monongahela River, to Brownsville, Pa.; and in March and April, 1875, he was in charge of the Right-of-Way Department of the Allegheny Valley Railroad Company.

From April, 1875, to June, 1877, Mr. Brendlinger was Chief Engineer of Construction of the Point Bridge across the Monongahela River at Pittsburgh, surveys for which were started in 1875. The City Engineer of Allegheny, Pa., was the Consulting Engineer, and Mr. Brendlinger was Engineer in charge of the work, while the late Samuel Rea, Hon. M. Am. Soc. C. E., was an Assistant Engineer. The contract was awarded to the American Bridge Company, of Chicago, Ill. At that time the Point Bridge was the longest span chain bridge in the world. Designed by Edward Hemberle, an Austrian by birth, it had a span of 800 ft. In 1904, it was generally rebuilt and, in 1921, was replaced by a heavier and more modern structure.

From June until July 4, 1877, Mr. Brendlinger was in charge of testing American iron and steel for the United States Commission, headed by the late Q. A. Gillmore and Alexander L. Holley, Members, Am. Soc. C. E., and W. Leroy Smith. Between July 4, 1877, and November, 1878, he served as Assistant Engineer on the location of the Pittsburgh and Lake Erie Railroad from Pittsburgh to Youngstown, Ohio; later, he became Resident Engineer of Construction in charge of the Ohio River Division.

From November, 1878, to July, 1881, Mr. Brendlinger was Chief Civil Engineer for the Edgar Thompson Steel Works, at Braddock, Pa., which work included surveys for locating iron mines in Center County, with headquarters at Bellefonte, Pa. He resigned from the Steel Company in 1881 to become Assistant Chief Engineer of an important railroad project. In this connection,

[1] Memoir prepared by Clark Dillenbeck and Charles S. Churchill, Members, Am. Soc. C. E.

he was the recipient of a short autographed letter from Andrew Carnegie, reading in part as follows:

"Cresson, Sept. 21, 1881

"My dear Mr. Brendlinger,

"Yours duly rec'd. It is always painful to me when one of the corps leaves the service but I can scarcely wonder that you longed to get back to Railroading.

"That is a great line you are building—a great property—I hope it will give Pittsburgh fair rates upon Coke. * * *

"With best wishes for your success,

"I am truly yours,

"Andrew Carnegie."

From July 1, 1881, to January, 1884, Mr. Brendlinger was Assistant Chief Engineer for the Pittsburgh, McKeesport, and Youghiogheny Railroad during its location and construction from Pittsburgh to Connellsville, Pa., a distance of 60 miles. Between 1878 and 1881, the mileage of railroad construction in the United States was comparatively small, due to heavy mortgages and many receiverships on existing railroads. This undertaking in 1881 was the first of considerable moment in Western Pennsylvania. It was planned to be constructed on a relatively high standard as to roadbed, masonry, bridges, and track; and Mr. Brendlinger was selected to carry out these plans. He took great care in selecting the entire Engineering Department and energetically followed up every detail necessary to bring about the desired results. The line was opened for traffic on November 19, 1883, at a cost of about $5 000 000 and was in such good condition that, during 1884, it earned 6% interest on its cost, together with a surplus, and thereafter continued this good record.

From January 1, 1884, to April, 1888, Mr. Brendlinger was Chief Engineer of the Pennsylvania, Schuylkill Valley Railroad Company and of all Pennsylvania Railroad Lines between Hamburg and Nescopeck, Pa., on what is now the Sunbury Division of the Pennsylvania Railroad, on the North Branch of the Susquehanna River. Surveys were started on January 15, 1884, on that part of the line north of Hamburg, covering a section where there were difficult questions to be settled between the new line and both the Reading Railroad and the Schuylkill Canal; also, difficult questions arose from the necessity of crossing Broad Mountain. Many miles of preliminary lines were run, and topographical maps made, covering a large area between Hamburg and Hazleton, Pa., before the best route could be determined.

The final location, which included an approximately right-angle crossing of the outcrop of the Mamouth Coal Measure of the Mahanoy Valley, within the Stephen Girard Estate, where the coal has a thickness of 40 ft., involved the purchase of a pillar of coal as a support of the railroad with a depth of about 300 ft. The line was located in the spring of 1885 and contracts were awarded by Mr. Brendlinger in April of that year for a railroad with roadbed, masonry bridges, and track in accord with the standards of the Pennsylvania Railroad Company. The same characteristic expedition which he had practiced in Pittsburgh was used by Mr. Brendlinger, with the result that the line

was completed and operated between Philadelphia and Pottsville, Pa., in November, 1886; and through to Nescopeck on the Pennsylvania Railroad, and thence, to Wilkes-Barre, Pa., in April, 1887, the new lines constructed north of Hamburg, covering 71 miles. Mr. Brendlinger received great credit for the completeness of the construction records and plans which were acclaimed as a great aid to the Operating Department of the Pennsylvania Railroad Company.

From April, 1888, to April, 1892, Mr. Brendlinger was General Superintendent of Construction for Brown, Howard, and Company of New York, N. Y., on the New Croton Aqueduct, with headquarters at Tarrytown, N. Y.

In 1892 he organized the firm of Brendlinger and Nearing, which was engaged in general contracting, doing work, until 1896, for the City of Yonkers, N. Y., for the Buffalo, Rochester and Pittsburgh Railroad Company, and for the Long Island Railroad Company. He also was associated with Pennell and O'Hearn, Contractors, on railroad construction for the Pennsylvania Railroad Company.

From 1896, until he retired from active business in 1914, Mr. Brendlinger was a General Contractor engaged on work for the Pennsylvania Railroad Company, the Pittsburgh, Cincinnati, Chicago, and St. Louis Railway Company, and the Philadelphia and Reading Railway Company, completing the following works: For the Pennsylvania Railroad Company, change of line, Pomeroy, Pa., and Oxford, Pa., at Milbourne Mills, League Island, and Lewistown Narrows, and on the Gallitzin Tunnels; for the Pittsburgh and Erie Railroad Company, Renovo to Keating, Pa.; for the Susquehanna Coal Company, at Millersburg, Pa.; for the Philadelphia and Reading Railroad Company, at Bowmansdale, Shippensburg, and Barnitz, Pa., and Hopewell, N. J.; for the Baltimore and Ohio Railroad, the Baltimore and Ohio Southwest Yard, at Philadelphia; for the Cleveland Short Line Railroad Company, at Cleveland, Ohio; and for the Pittsburgh, Cincinnati, Chicago, and St. Louis Railroad at Cambridge City, Ind.

Mr. Brendlinger was an easily approached, helpful man and a good friend. He exercised an uplifting influence on those with whom he was associated. His thoroughness and care in his engineering practice were, after 1888, followed in his contract work. The high standards of his entire life work were followed in all business and social dealings with others.

He died in Philadelphia, Pa., on December 16, 1929, from heart failure, caused by shock and exhaustion resulting from a fractured hip, due to a fall five weeks previous. He was within a month of completing his eightieth year, and prior to the accident had retained the keen and alert mental faculties which had always been his.

He was married to Hannah Emily Brown, on October 24, 1872, who died on April 27, 1924. There survive him four children: Margaret R. Brendlinger, George F. Brendlinger, William B. Brendlinger, and Mary B. Olmsted.

Mr. Brendlinger was elected a Member of the American Society of Civil Engineers on September 7, 1887.

## ROBERT BROWN, M. Am. Soc. C. E.[1]

DIED OCTOBER 20, 1929

Robert Brown was born in Gatehouse of Fleet, Kirkcudbright Shire, Scotland, on September 23, 1860. He was educated at Borgue Academy and came to the United States in 1883.

Prior to his moving to this country and up until early in 1885, Mr. Brown was an Engineer in the British Army, engaged on surveying, bridging, submarine mining, and other engineering work. He served during the Egyptian War of 1882, for which he was awarded a medal and star for exceptional service in behalf of the British Government. He was then transferred to military engineering work in Bermuda, being assigned to fortification design.

From 1885 to 1917, he was engaged in engineering construction in many places throughout the United States, among which may be briefly noted the following: From 1885 to 1889, with Filbert and Porter, Philadelphia, Pa., on the construction of conduits and manholes; from 1889 to 1893, with the Bell Telephone Company, on conduit work; from 1893 to 1897 with the National Conduit Company, New York, N. Y., on a sub-contract for conduit and manholes; from 1897 to 1900 with Holbrook, Cabot, and Daley, on the Fourth Avenue Subway, New York, maintaining the Fourth Avenue track to 34th Street during construction, and building rubble stone from the roof of the tunnel and forming a conduit for the underground trolley; from 1900 to 1907 with Horgan and Slattery, Architects, as Inspector on the construction of the Hall of Records, the Tombs, an abattoir at 39th Street and Eleventh Avenue, the Butterick Building, the Harlem Hospital, the Irving National Bank, the First Battery Armory, as well as other buildings, in New York; during 1907, for eight months on expert insulation for a cold storage plant, at Cristobal, Canal Zone; and from 1907 to 1910, as sub-contractor on brick work for private houses.

In 1910 Mr. Brown went to Texas. Until 1915 he served with the American Construction Company, of Houston, in full charge of construction (acting as Engineer), for this Company on the Littlefield Building, at Austin; the Southwestern Life Building, at Dallas; the Union Belt and Terminal Station, at Houston; the Gulf, Colorado, and Santa Fé Station, the Nurses' Home and Women's Building ($3 000 000), and, from 1915 to 1917, on the reconstruction of the John Sealy Hospital, the State Medical College, and the Galveston Wharf Company's Piers 16 to 18 ($450 000), all at Galveston.

In 1917, he spent eight months as Superintendent of Construction, at Camp Travis, Division F, San Antonio, Tex.; in 1917 and 1918 he served as Construction Engineer for Stone and Webster, in France, on the erection of steel, ordnance machine shops, etc.; and from 1918 to 1921, he was Superintendent of Construction, for the Magnolia Petroleum Company, of a 28-story building, and on the design of other structures.

In March, 1922, Mr. Brown was commissioned as Major of Engineers of the United States Reserves, 8th Corps Area. He was a member of the City

[1] Memoir prepared by E. N. Noyes, M. Am. Soc. C. E.

Temple (Presbyterian Church), at Dallas, and served on its Board of Deacons. He was also actively interested in the construction and operation of the Reynolds Orphanage at Dallas.

Major Brown was a typical Scotchman in manner and speech and in the thoroughness with which he carried out the various projects with which he was connected. Starting in the building construction business in New York in 1885, when steel construction was in its infancy, and reinforced concrete was scarcely thought of, he saw and took part in the development of these materials, and during his life time handled them in some of the most important construction work in the United States.

He was always interested in matters pertaining to the Local Sections of the Society and made it a point to attend Section meetings whenever possible. He made friends easily and, being always extremely interested in the engineering work carried on by his friends in the profession, he took occasion to visit their projects and discuss details with them whenever possible. Major Brown was uniformly loved and esteemed by his engineer friends in Texas, and he will be missed greatly.

He is survived by his widow and a daughter, Scotia B. Brown, of Dallas, and by two sons, Preston W. and Robert C., of New York.

Major Brown was elected a Member of the American Society of Civil Engineers on November 21, 1921.

## HENRY AMSDEN BURR, M. Am. Soc. C. E.[1]

DIED JUNE 20, 1930

Henry Amsden Burr, the son of Clarence and Blanche (Amsden) Burr, was born on December 11, 1890, in Granby, Que., Canada. Mr. Burr's parents were natives of Framingham, Mass., which was also their home, but were traveling in Canada when their son, Henry Amsden Burr, was born. The boy received his early education in Framingham. He enrolled in the Massachusetts Institute of Technology during 1909, and was graduated therefrom in 1913 with the degree of Bachelor of Science in Civil Engineering.

Following his graduation, Mr. Burr was employed by the Pennsylvania Steel Company at Steelton, Pa., as Draftsman and Structural Steel Detailer. He remained with this Company until April, 1914, when he was engaged by Stone and Webster, with offices at Cambridge, Mass., as Draftsman and Reinforced Concrete Detailer. This position was of short duration, due to a general reduction in forces in July, 1914.

He spent the remainder of 1914 and the first half of 1915 at his home in Massachusetts and in the West, most of this time being devoted to the study of his profession. He went to Nashville, Tenn., in August, 1915, and entered the employ of the Nashville, Chattanooga, and St. Louis Railway as Draftsman. During his connection with this Company, which lasted approximately five years, he served as both Draftsman and Designer.

[1] Memoir prepared by C. W. Butts, M. Am. Soc. C. E.

Mr. Burr resigned his position with the Nashville, Chattanooga, and St. Louis Railway in May, 1920, to enter the employ of the J. N. Chester Engineers on work in connection with the water supply of Nashville. He resigned this position, however, after about a month's service and accepted an appointment with the Tennessee Department of Highways and Public Works with headquarters at Nashville. He held this position from June, 1920, until June, 1930, during which time he served as Designer and Assistant Bridge Engineer. While he was connected with this Department, many bridges were designed and constructed, a number of which were large river crossings that were designated as Special Toll Bridges and authorized by Acts of the Legislature. These toll bridges span some of the larger streams of the State.

Mr. Burr's hobby, if it can be said that he had a hobby, was work. During his period of employment with the Department of Highways and Public Works he found time outside his regular working hours to design the structural steel work for the Nashville Trust Building and the Bennie Dillon Building, both of which are large office buildings in Nashville. Also, during this time, he was appointed by Davidson County, Tennessee, to check the plans and exercise general supervision of the construction of a bridge spanning the Cumberland River near Old Hickory, Tenn. All his work was done in a most satisfactory manner. Between 1915 and 1930, Mr. Burr found time to study commercial law and general business as well as more advanced work in engineering. He accomplished this through night school and correspondence schools.

Mr. Burr possessed a sterling character, indisputable integrity, and unquestioned reliability. He was an indefatigable worker, and had the confidence of his employers.

He was a Deacon of the Moore Memorial Presbyterian Church of Nashville, and was affiliated with the Masonic bodies, holding membership in Doric Lodge, F. and A. M., No. 732; Edgefield Chapter, No. 197, Royal Arch Masons; Nashville Council No. 1, Royal and Select Masters; Nashville Commandery No. 1; Trinity Consistory No. 2 (Thirty-second degree), and Al Menah Temple, A. A. O. N. M. S.; also, Doric Chapter No. 321, Eastern Star, all these lodges being in Nashville. He had served as Excellent High Priest of Edgefield Chapter No. 197, Royal Arch Masons; as Worthy Patron of Doric Chapter No. 321, Eastern Star, and, at the time of his death, was Junior Warden of Doric Lodge, F. and A. M., No. 732.

Mr. Burr was a member of the American Concrete Institute, the American Society for Testing Materials, and the Nashville Engineering Association, the last-mentioned body passing the following resolution, which also conveys the sentiment of his co-workers and acquaintances:

"*Whereas,* our valued friend and co-worker, Henry Amsden Burr, was lost through death, on June 20, 1930, to the membership of the Engineering Association of Nashville; be it

"*Resolved,* that this organization go on record as deeply deploring his untimely death and that we hereby give expression to our regard for his sterling qualities, both personal and professional.

"A native of Massachusetts and a graduate of Massachusetts Institute of Technology, Mr. Burr came to Tennessee in 1915, assisting at first in the design of structures on the N. C. & St. L. Railway, and later, with the design of many important bridges for the State Department of Highways. As a structural engineer and mathematician he was without a peer in our ranks. Recently, he did outstanding work on the committee appointed by the Association to prepare a revised draft of the Building Code of Nashville. Mr. Burr's career encompassed a multitude of useful engineering activities, all of which bore the stamp of excellence. As a friend and as a member, we shall miss him from our ranks.

"To his family, we extend our sincerest sympathies and transmit a copy of these resolutions."

"ENGINEERING ASSOCIATION OF NASHVILLE.

"Approved, October 6, 1930, by vote of the Association."

He was married on October 4, 1916, to Mrs. Margaret Schillinger, formerly Margaret Poyntz, who, with an adopted daughter, Charlotte Schillinger, and his two sons, Henry A., Jr., and John Ramsey Burr, survive him. He is also survived by his mother, Mrs. Blanche Amsden Burr, and two brothers, Clarence T. and Paul T. Burr, who reside in Framingham.

Mr. Burr was elected an Associate Member of the American Society of Civil Engineers on January 15, 1923, and a Member on October 10, 1927.

## MAXWELL CUNNINGHAM BYERS, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 23, 1930

Maxwell Cunningham Byers was born in Pittsburgh, Pa., on February 2, 1878. He was the son of John Morton and Caroline Mann (Lewis) Byers. His father, as Chief Engineer, located and constructed many hundreds of miles of the present railways of the United States. Several of his uncles were also similarly engaged, one having been Chief Engineer of the Reading Railway Company. His grandfather and granduncle were likewise railroad and, earlier, canal engineers, the former having been engaged with the Pennsylvania Railroad Company in laying out the first lines west over the Allegheny Mountains. His mother's father was a manufacturer engaged in the early iron industry. Her brother was also an Engineer and Railroad Executive, having been at one time President of one of the roads which is now a part of the Pennsylvania System and a Consulting Engineer in connection with the construction of the Eads Bridge across the Mississippi River, at St. Louis, Mo.

Mr. Byers was enrolled in the Civil Engineering Course in the Western University of Pennsylvania, at Pittsburgh, from 1894 to 1896. Finding it necessary to leave the University in 1896, at the end of his second year, he accepted a position in the Transportation Department of the Pennsylvania Railroad Company, and by study after working hours completed his course in mathematics and important engineering subjects.

[1] Memoir prepared by C. R. Gray, Pres., Union Pacific System, Omaha, Nebr.

His engineering experience began in 1898, as Assistant on the Engineer Corps of the Pennsylvania Railroad. Until 1899, he was in charge of grade revision on the Chicago Division, and, from 1899 to 1900, was engaged in the design and construction of masonry arches and the revision of grades on the Logansport Division. In 1900, he was promoted to the position of Assistant Engineer on design and construction of steel bridges and masonry on the Marietta Division, and, in 1901 and 1902, he had charge of general engineering on the Indianapolis Division, including grade revision, second-track work, design and construction of steel bridges, and masonry work. He attracted the attention of L. F. Loree, M. Am. Soc. C. E., then General Manager, who when he became President of the Baltimore and Ohio Railroad Company, took Mr. Byers with him to that property, where he served from 1902 to 1904 as Assistant Engineer, Maintenance of Way.

He transferred to the St. Louis-San Francisco Railway Company with Mr. Loree in 1904, and was, successively, Assistant Engineer, Maintenance of Way; Engineer, Maintenance of Way, Third District, in charge of the Engineering Department, including the design and construction of bridges and buildings and also of river protection work on the Mississippi River; Assistant to the General Manager in charge of all construction on the System; Engineer, Maintenance of Way, in charge of the Engineering Department; and, from 1909 to 1913, he was first Chief Engineer and then Chief Engineer-Operation, his service being continuous with the St. Louis-San Francisco Railway Company from 1904 to 1913.

Mr. Byers was appointed Assistant to the President of the Great Northern Railway Company in 1913, a position which he held until March, 1914, when he entered the service of the Western Maryland Railway Company, which he served continuously until his death. From 1914 to 1918, he was Assistant to the President. During the period of Federal Control—1918 to 1920—he was General Manager and Federal Manager, with his jurisdiction extended over the Cumberland Valley Railway and the Cumberland and Pennsylvania Railroad Companies. From March 1, 1920, until his death, he was President of the Western Maryland Railway Company, and from 1926 had also served as Chairman of the Board of Directors.

Mr. Byers was a member of the Duquesne Club of Pittsburgh, and the Maryland Club and the Merchants Club of Baltimore, Md. He was a Director and Member of the Executive Committee of the Union Trust Company of Baltimore; a Director of the Eutaw Savings Bank, the First National Bank of Baltimore, and the Hagerstown Bank and Trust Company; a corporate member of the Hopkins Place Savings Bank of Baltimore; a Director of the Baltimore Association of Commerce; and a Director and Vice-President of the Industrial Corporation of Baltimore. Mr. Byers also belonged to the American Railway Engineering Association, the American Railway Association, and the American Railway Guild.

He had been a member of the Catonsville, Md., Presbyterian Church since 1914, serving most of the time as a member of the Board of Trustees. He was one of the most interested of the Building Committee during the development of the new church property at Catonsville, a suburb of Baltimore.

Mr. Byers was married at Point Pleasant, W. Va., on November 28, 1906, to Janet McCulloch who, with five sons, John Maxwell, Lewis Cunningham, Richard McCulloch, James Alfred, and Robert Morton, as well as a sister, Mrs. Mary E. B. Barbee, and a brother, Morton Lewis Byers, M. Am. Soc. C. E., survives him.

From 1904 to 1920, he was associated with the writer, and after the business relationship ceased, a close and intimate acquaintance was maintained. Mr. Byers was first an Engineer and an exceedingly good technician. His mind was an intensely practical one, and he was an ardent student of railroad operation, invariably working out problems with a view to producing practical economies in the movement of traffic. While he was still in the Engineering Department his advice was always eagerly sought by the operating officers, and their confidence in him was conspicuously shown, but it was not until he became President in 1920 that the real opportunity came to put into effect his own ideas of operating a railroad. The results speak for themselves. While steadily improving the physical condition of the roadway and equipment, he produced a transportation ratio which attracted wide attention and, as is well known, it is this feature of the operating side wherein efficiency is best reflected.

Mr. Byers was only 52 years of age when he died, and at the height of his intellectual powers. He was striking in appearance, his dark eyes sparkling with animation, and he had a most engaging personality. His work and his family engrossed his time. He had no fads and played little, but he had a capacity for work that was astounding, and as is natural this communicated itself to his entire organization. He was a bright, fearless, and honest man, a true friend, and an outstanding executive and railroad operator.

Mr. Byers was elected a Member of the American Society of Civil Engineers on June 6, 1911.

## WILLIAM CAIN, M. Am. Soc. C. E.[1]

### Died December 6, 1930

William Cain was born at Hillsboro, N. C., on May 14, 1847, the son of Dr. William and Sara J. (Bailey) Cain, of English, Scotch, Irish, and Welsh descent. His early education was received in a private school in Hillsboro, and at the Hillsboro Military Academy. In 1866, he received the degree of Master of Arts from the North Carolina Military Polytechnic Institute. The military training he acquired in these institutions enabled him as a lad of fourteen to drill troops for the Confederacy, a service which he rendered with conspicuous success.

Mr. Cain then became Assistant Engineer to W. C. Kerr, State Geologist, in the preparation of a map of North Carolina. Afterward, for a period of about eight years, he engaged actively in railroad engineering, as follows: 1867, Assistant Engineer, Western North Carolina Railroad Company; 1868,

[1] Memoir prepared by T. F. Hickerson, M. Am. Soc. C. E.

Assistant Engineer, on the line from Greensboro to Salem, N. C.; 1868 to 1874, Assistant Engineer and then Chief of Party on surveys and locations, also Resident Engineer, Raleigh and Augusta Air Line Railroad Company; Cape Fear and Yadkin Valley Railroad Company; and Wilmington, Columbia, and Augusta Railroad Company. From 1874 to 1880, he was Professor of Mathematics and Engineering at Carolina Military Institute, Charlotte, N. C. From 1880 to 1882, he was again engaged in the practice of railroad surveying and engineering as Chief of Party on the following projects: Lines from Lenoir, N. C., *via* Cook's Gap on the Blue Ridge, to Elizabethton, Tenn.; the Midland Railroad, from Salisbury, *via* Asheboro, to Goldsboro, N. C.; and the Atlantic Coast Line Railroad, from Wilson, N. C., *via* Fayetteville, to Pedee, S. C.

In 1882, he was elected Professor of Mathematics and Engineering at "The Citadel, the Military College of South Carolina", Charleston, S. C. In 1888, he became Professor of Mathematics and Engineering at the University of North Carolina, Chapel Hill, N. C., which position he held until his retirement from active teaching in 1920, with an adequate pension in recognition of his long and distinguished service. He then became Professor Emeritus, but only in name, for his labors never ceased. His brilliant and painstaking articles and his constructive discussions of current papers continued to appear none the less frequently in the *Proceedings* of the Society. On the very day of his death, at the age of 83, when he was struck the fatal blow by an automobile while attempting to cross the street in front of his home, manuscripts dealing with the theory of dams—sent to him for criticism by prominent engineers in practice—were found on his desk.

A veteran of the Civil War, Professor Cain brought forward into this modern age the bearing and manners, the ideals, the loyalties of the old South. And yet, with all his treasured memories and his alliance with the past, he kept abreast of the times. To the last he maintained a lively interest in the drama of passing events—in the changing aspects of science and literature, in invention, in the affairs of Government, in fashion, and in sports.

His chief recreations were hunting, fishing, and violin music, all of which had to be given up during the last two years of his life on account of injuries sustained in a previous automobile accident.

Professor Cain was one of the original five Kenan Professors, who were chosen as a mark of distinction by the Faculty of the University of North Carolina in 1918. The thoroughness and accuracy of his character marked his class-room teaching, and his distinguished scientific contributions to Engineering redounded to the credit of his institution. He received honorary degrees of Doctor of Laws from the University of South Carolina (1916), and Doctor of Science from the University of North Carolina (1920).

He was a member of the American Mathematical Society, and a Fellow of the American Association for the Advancement of Science. Professor Cain was a member of the Protestant Episcopal Church, and gave generously to its support. He served on the Vestry of the Chapel of the Cross a number of times, and his clear mind, coupled with his sense of humor, was always helpful.

In 1923, the Society presented him with the J. James R. Croes Medal for his paper, "The Circular Arch Under Normal Loads".[2]

Professor Cain's scientific publications date from 1874, when his paper, "Uniform Cross-Section and T Abutments", appeared in the November issue of *Van Nostrand's Engineering Magazine*. In his paper on "Earth Pressure",[3] he showed that all the experiments given by the late Sir Benjamin Baker, Hon. M. Am. Soc. C. E., in his notable paper on "The Actual Lateral Pressure of Earthwork", at least in cases where the backing was sand, nearly devoid of cohesion, could be reconciled with theory by rejecting the "ancient" theory used by Baker and adopting the "wall-friction" theory in which the friction of the earth on the wall is considered. In his paper, "Trusses with Superfluous Members",[4] there was presented for the first time to American readers the theory of trusses with redundant members. In "Positions of Live Loads Giving Maximum Strains for Single-Intersection Trusses",[5] a thorough discussion of this subject, about which little had been written, was given; and the method used in this paper furnished the basis for that given in the Second Edition of Professor Cain's book entitled "Maximum Stresses in Framed Bridges".

Another important contribution to engineering practice was the development, in a paper entitled "Unit Stresses",[6] of the "Cain-Launhart formula", in which Professor Cain modified Launhart's formula to allow for impact. Other valuable papers written by Professor Cain at this time deal constructively with the following subjects: Long Columns, High Masonry Dams, and Portal Bracing.

In 1891, in his "Determination of the Stresses in Elastic Systems by the Method of Least Work",[7] Professor Cain first introduced to American engineers the method of Castigliano, as embodied in his "Systémes Elastiques" (Turin, 1879). Professor Cain herein gave original demonstrations of the theorem of least work for framed structures with redundant members, by use of the method of virtual work, with applications.

In "Stresses in Masonry Dams",[8] Professor Cain presented a novel method for the determination of stresses at the battered faces of high masonry dams. In 1911, he published an elaborate paper, "Experiments on Retaining Walls and Pressures on Tunnels",[9] in which for the first time cohesion in earth is included, to reconcile the carefully conducted experiments of Leygue on small models, with theory; also, a complete graphical treatment of pressures in earth endowed with both friction and cohesion is given for the first time.

Following the publication of a paper on "A Shortened Method in Arch Computation",[10] by H. A. Sewell, M. Am. Soc. C. E., Professor Cain pub-

[2] *Transactions*, Am. Soc. C. E., Vol. LXXXV (1922), p. 233.
[3] *Van Nostrand's Engineering Magazine*, February, 1882.
[4] *Loc. cit.*, October, 1882.

lished one month later the demonstration of a still shorter method.[11] In 1914-15, he presented two exhaustive papers, "Stresses in Wedge-Shaped Reinforced Concrete Beams",[12] and "Cohesion in Earth: The Need for Comprehensive Experimentation to Determine the Coefficients of Cohesion",[13] in the latter of which all experiments available are given and shown to agree with Coulomb's hypothesis. The need for extensive experimentation is herein pointed out and apparatus in view criticized.

The following papers and monographs by Professor Cain,[14] dealing with mathematical and engineering problems, are given only by title: "Sanitary Engineering," Third Edition, North Carolina Board of Health, 1885; "Brief Demonstration of the Method of Least Work,";[15] "The Transition Curve,";[16] "On the Fundamental Principles of the Differential Calculus";[17] *Road Bulletin,* North Carolina Geological Survey, 1893; "The Stone Arch,";[18] "Exact Computation of Stresses in a Queen-Post Truss,";[19] "A New Method of Laying Out Grades for Sewers by Aid of the Transit";[20] "Note on the Algebraic Form, $\frac{0}{0}$";[21] "Imaginary Roots of a Cubic";[22] "Grain Pressures in Deep Bins";[23] "Crown Thickness of Masonry Arches"[24]; and "The Teaching of Elementary Dynamics".[25] A number of articles on arches, stresses in bridges, retaining walls, algebra and geometry, appeared in *Van Nostrand's Engineering Magazine,* and these were at once published in book form in Van Nostrand's Science Series, with the following original titles: No. 12, "A Practical Theory of Voussoir Arches" (1874); No. 38, "Maximum Stresses in Framed Bridges," (1878); No. 42, "Voussoir Arches Applied to Stone Bridges, Tunnels, Domes, and Groined Arches" (1879); No. 48, "Theory of Solid and Braced Elastic Arches" (1879); and No. 73, "Symbolic Algebra and Notes on Geometry" (1884). In 1888, at Mr. Van Nostrand's request, Professor Cain revised Arthur Jacob's "Practical Designing of Retaining Walls," doing it so thoroughly that he retained from Jacob's book only one figure. Eventually, Jacob's name as author was displaced by that of Professor Cain, and the book has passed through many editions.

In the First Edition of Science Series No. 42, (1879), an advance is made in the treatment of the stone bridge by considering the elasticity of the material, but the theory of the "elastic arch" is not yet applied in a precise manner. This volume contains much new material on the "barrel" or com-

mon arch, on tunnel arches, groined and cloistered arches, and on domes. A new edition (1901), bore the title, "Theory of Steel-Concrete Arches and of Vaulted Structures." Herein was given, for the first time, a complete, practical method for dealing with the reinforced arch of variable section by the elastic theory. The two books on reinforced arches, Science Series Nos. 42 and 48, have been repeatedly cited as authoritative in technical journals, and the methods set forth therein have been used in the design of a number of bridges. The distinguished English engineer, James Marsh, paid Professor Cain a high compliment by publishing his arch theory, with Professor Cain's permission, in his extended work on "Reinforced Concrete" (London, 1904).

A useful textbook, written with Professor Cain's habitual lucidity, is a "Brief Course in the Calculus", (1905). The results of many of his published papers and a wealth of additional research are incorporated in his "Earth Pressure, Retaining Walls and Bins" (1916).

One of Professor Cain's most valuable contributions to engineering literature was his paper previously mentioned on, "The Circular Arch under Normal Loads," in which he developed, by refined mathematical methods, formulas for computing moments and thrusts, and the resulting stresses in arches with "fixed" and "hinged" ends. This paper marked a distinctly forward step in advance of the approximate solutions then in vogue. Subsequently, Professor Cain, in a discussion[26] of a paper by B. F. Jakobsen, M. Am. Soc. C. E., entitled "Stresses in Thick Arches of Dams", developed further formulas, using more rigorous methods in certain particulars. The Cain formulas soon became established as acceptable standards in practice, as well as theory, by the Federal Power Commissions and by State and local public officials as well.

Professor Cain discussed[27] the elaborate paper by Cecil Vivian von Abo, Assoc. M. Am. Soc. C. E., on "Secondary Stresses in Bridges". As stated, he also gave a long and able discussion[28] of Mr. Jakobsen's paper on "Stresses in Thick Arches of Dams", in which frequent comparisons and references to the Cain formulas are cited, and acknowledgment is made to Professor Cain for encouraging its submission to the profession. Among the subsequent papers to which discussions were contributed by Professor Cain are the following: "Experimental Deformation of a Cylindrical Arched Dam",[28] by B. A. Smith, M. Am. Soc. C. E.; "Analytical Solution of Masonry Domes",[29] by David C. Coyle, M. Am. Soc. C. E.; "Design of Symmetrical Concrete Arches",[30] by Charles S. Whitney, M. Am. Soc. C. E.; "Notes on Arched Gravity Dams",[31] by B. F. Jakobsen, M. Am. Soc. C. E.; "A Graphic Method for Determining the Stresses in Circular Arches under Normal Loads by the Cain Formulas",[32] by Frederick H. Fowler, M. Am. Soc. C. E.; "Analysis of Arch Dams by the Trial Load Method",[33] by C. H. Howell, M. Am. Soc. C. E.,

and the late A. C. Jaquith, Esq.; "Load Distribution in High Arch Dams",[34] by R. A. Sutherland, Assoc. M. Am. Soc. C. E.; "Laminated Arch Dams with Forked Abutments",[35] by Fred A. Noetzli, M. Am. Soc. C. E.; and "Stresses in Gravity Dams by Principle of Least Work",[36] by B. F. Jakobsen, M. Am. Soc. C. E.

The first draft of Mr. Jakobsen's paper on "Stresses in Gravity Dams by Principle of Least Work", was submitted in advance for criticism to Professor Cain; and, consequently, his discussion was published simultaneously with the paper. It is singular that this unusual procedure occurred so shortly before Professor Cain's death, thus bringing to a glorious end a long series of constructive scientific articles covering a period of fifty-seven years.

The Student Chapter of the Society at the University of North Carolina was named "William Cain Civil Engineering Society", in his honor. Those who knew him well, called him "Major" Cain, a title he has held since his early days while teaching at a military school. He never was married. During recent years, he was a member of an "eating club" in Mrs. Patterson's home just across the street from where he lived. It was while attempting to cross the street to join his friends at the table that he met his death. The members of the club consisted of a dozen or so bachelors from the University Faculty, and they were called the "Old Soldiers". The following sentiment by one of them was published in *The Chapel Hill Weekly*:

"As Major Cain with unconscious strength held on to life after those terrific blows upon head and body, he was, in those last dozen hours, making death a true part of his valiant life. He had refused to surrender to age or deafness or any circumstance. In his eighty-third year he did his day's work with the zest of a great engineer who with the higher mathematics of strains and stresses built bridges and dams against both time and power to the end.

"One morning I found him in his room with papers all about him—an engineering treatise from Australia for review, a mathematical article from England for critical calculations, and the set-up of a dam in California in need of testing by his engineering formulas. In the quiet of his simple room, roads, dams, and bridges projected from his mind vigorous and clear over all.

"Not only so, but in that lovely home where Miss Blanche made gay among her 'Old Soldiers', the Major was the gayest of them all. With all his fun and kindly insight, his was a life of fierce loyalties and deep indignations. Injustice and shams blenched before his utter scorn. The 'Old Soldiers' loved the gracious strength of him, forthright first and gracious always. In his handsome person, tall and unbending, the spirit of the Old South lived on with unconscious courtliness into the midst of the new, bidding us to pause in our raucous hurry.

"He had been asked to retire to the shelter of relatives and take his ease, but he chose to do his day's work of high thinking in his own quarters. He scorned to let people guide him across the street even in darkness and mists. He met life face forward and death head on. His was the most gallant figure that walked our village streets."

Professor Cain was elected a Member of the American Society of Civil Engineers on November 7, 1888. He served as a Director of the Society from 1912 to 1914.

## GEORGE LINDEN CAMPEN, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 21, 1930

George Linden Campen, the son of John L. and Ann Hartford Campen, was born at Pittsford, Mich., on July 27, 1867. His preliminary education was obtained in the grade school at Pittsford and the High School at Hillsdale, Mich. He taught a number of terms in the district schools in order to help provide the means for his attendance at the Normal College at Ypsilanti, Mich., from which institution he was graduated in the Class of 1885.

Owing to his father's health, his parents moved to Wahoo, Nebr., in 1884, where Mr. Campen joined them after his graduation from the Michigan State Normal College. In 1885, he became an Instructor in the Wahoo grade schools, teaching through the years of 1885 and 1886 and until the spring of 1887, when he resigned to become a Rodman with the Burlington and Missouri River Railroad Company.

Deciding on an engineering career, Mr. Campen enrolled with the University of Nebraska, at Lincoln, in the fall of 1887, as a Special Student in Engineering, and completed his course in the spring of 1890. During the summer months of his post-graduate years he was employed as Rodman by the Burlington and Missouri River Railroad Company and as Rodman and Computer in the City Engineer's Office at Lincoln.

After completing his post-graduate course, his first position was with Kilpatrick Brothers and Collins, Cambria, Wyo., as Mine Surveyor which position he held for about six months. He left that firm to make a topographical survey for the Sundance Coal Company, in Wyoming.

In October, 1891, Mr. Campen entered the City Engineer's Office at Lincoln, as Assistant Engineer of Construction, in charge of the construction of about twenty miles of sewer laterals. In April, 1896, he was promoted to the position of Deputy City Engineer in charge of the construction and repair of sewers and paving, but resigned in 1898 to accept a position as Construction Engineer with the firm of J. R. Sheely and Company, Bridge and Municipal Contractors.

With the J. R. Sheely and Company, his work consisted of designing, bidding on projects, and the supervision of construction of municipal work and bridges. He resigned this position in July, 1901, to accept the appointment as Deputy Engineer in the City Engineer's Office at Lincoln; the same month he was appointed City Engineer, responsible for the maintenance and construction of water and sewer mains, pavements, pumping, and municipal lighting plants. He also was in charge of the construction of three bridges over the Loup River in Nance County, Nebraska, and a concrete dam across the Blue River at Fairbury, Nebr.

In December, 1905, by special leave from the City of Lincoln, Mr. Campen joined the Government forces at the Canal Zone, Panama. He resigned as City Engineer four months later, and assumed his duties as Water Commissioner in direct charge of preparing and carrying into effect plans and

[1] Memoir prepared by E. L. Brown, M. Am. Soc. C. E.

rules for the sanitary installation of plumbing, use of water, maintenance of service connections, and protection of paving in Panama and Colon; in December, 1906, he was made Superintendent of Public Works in the Canal Zone. In this position he recommended public improvements, supervised and directed inspectors of plumbing, the construction and maintenance of water mains, sewerage systems, and paving in Panama and Colon.

Mr. Campen was married in 1892 to Pearl Hershey, at her home at Hillsdale, Mich. He had met her at Hillsdale while attending High School there. Mrs. Campen accompanied her husband to the Canal Zone.

While he was employed in the Canal Zone he was offered a similar position with the Cuban Government. This position he declined at the request of the Governor-General, but a few months later, in 1909, he was compelled to resign his position and return to the United States because of his wife's ill health. Mrs. Campen died three years later and was laid to rest in her childhood home, Hillsdale.

In August, 1909, Mr. Campen accepted the position of Assistant City Engineer of Omaha, Nebr., under the City Engineer, G. W. Craig, Assoc. M. Am. Soc. C. E. In this capacity he was in charge of the construction and maintenance of pavements, sewers, and sidewalks. He resigned his position with the City of Omaha, April 30, 1912, and entered private practice as a Consulting Engineer with an office in Omaha where he remained until March 1, 1914. He then organized the Campen Company, of Omaha, as Contracting Engineers on foundation work, and became its President; because of financial difficulties the Company was dissolved in January, 1916.

He again entered the contracting business in July, 1916, when he became Superintendent of Construction for the Haynes Elevator Company, of Omaha, on a 1 000 000-bushel concrete elevator. This elevator was completed in July, 1917. He then accepted a similar position with W. E. Wickham, of Omaha, on the construction of the cantonment at Fort Omaha. He remained with this Company only three months, having received an appointment as Senior Highway Engineer with the U. S. Bureau of Public Roads, with headquarters at Omaha. This work consisted of the location, construction, and maintenance of Federal Aid Highways in the State of Iowa. He held this position until his death on September 21, 1930.

In May, 1917, Mr. Campen was married a second time to Therese Goodwin, of Omaha. To this union was born a son; but, again, Mr. Campen was left a widower, for, after nine years of happy married life, his wife passed away in February, 1926, from influenza.

For forty years Mr. Campen practiced as a Civil Engineer, most of which time he was a public servant, serving the City and Federal Government with sterling integrity and ability, his work having outlived him. He constructed the first asphalt pavement laid in the City of Lincoln, and pavement laid by him years ago in Omaha is in excellent shape to-day.

He was a strong character, fearlessly honest, a dynamic personality. This gained him many friends and he was respected and trusted by all. He took a keen interest in his work and always was ready to try an experiment for the best results and as quickly to discard it when the occasion required it. Mr.

Campen was a keen, far-sighted engineer, willing to give his opinion when requested. There are a number who regret that they did not follow the advice given by him; and many an engineer, reviewing his past services, can appreciate the kindly help and advice given to him by Mr. Campen; for this reason some of his friends called him the "Dean of Highway Engineers".

He had been failing in health for about a year and, on Sunday, September 21, 1930, after placing a floral wreath on the grave of his wife, accompanied by his mother-in-law and a friend, he died at the wheel of his car while returning to his home. He is survived by his son, George L., his father and mother at Pittsford, a brother, E. J. Campen, of Denver, Colo., and an adopted son, William, President of the Omaha Testing Laboratories. The funeral service was held in the Scottish Rite Temple, and he was laid to rest in Forest Lawn Cemetery, at Omaha, beside his wife.

Mr. Campen was elected a Member of the American Society of Civil Engineers on October 5, 1909.

## WILLIAM WALLER CARSON, M. Am. Soc. C. E.[1]

DIED FEBRUARY 7, 1930

William Waller Carson was born on June 2, 1845, in Adams County, Mississippi. Both his father and mother were descended from a long line of leaders who from Colonial times had been active in the development of the South.

Soon after the birth of William, the family moved to a plantation in Louisiana on the banks of the Mississippi River, about 35 miles above Vicksburg, Miss., and here his boyhood was spent in the surroundings of Southern hospitality and plantation life. Hunting, swimming, fishing, horseback riding, the home teaching, first by his mother and later by tutors—all these contributed to the physical vigor and moral character which were his through a long and active life. In a home the head of which was responsible for the physical health and moral training of more than 500 human beings, he learned that superior position brings responsibility, and while he was still a boy he appreciated that responsibility and carried his full share.

This free and independent life was interrupted suddenly by the Civil War. The Mississippi River became the path for gunboats. Flashes from cannon near Vicksburg lighted the sky. Although he was too young to enlist when the war broke out, Mr. Carson entered the Confederate Army at the age of 18, and served through the remaining two years of the war, first as Private and, later, as Sergeant-Major of the 4th Louisiana Cavalry.

These two years, filled with tedious work, exciting adventure, deprivation, and suffering, printed upon his memory many pictures which remained bright and vivid to the end of his life. He received a wound which nearly proved fatal, and which interfered seriously with his future work. Due to bad drinking water, he suffered for forty-six years from a condition under which a less vigorous constitution would not have survived.

[1] Memoir prepared by Dr. Charles A. Perkins, Knoxville, Tenn.

At the close of the war, like many other young men, Mr. Carson followed General Lee to Washington College—now known as Washington and Lee University—where for four years he studied to prepare himself for work as a civil engineer.

A most urgent need in the South at this time was the construction of highways, railroads, and public works, and, after receiving the degree of Civil Engineer (1868) and Mechanical Engineer (1869), he entered the office of the New Albany and St. Louis Railroad Company and, later, accepted similar work in the Sewer Department of the City of Louisville, Ky. From 1870 to 1873, he was employed on the Southern Division of the Mobile and Grand Trunk Railroad, occupying, successively, the positions of Transitman, Resident Engineer, and Engineer in Charge of Maintenance of Way of the completed Division.

In 1874, Mr. Carson went to New York, N. Y., and attended the School of Mines, Columbia University, for one session. From this time, his principal attention was given to his main life work—that of teaching. For six years, from 1877 to 1883, he was Professor of Mathematics at Davidson College, and, in 1885, he went to the University of Tennessee, in Knoxville, Tenn., where he spent the remainder of his life. At this time there were less than 200 students in the University, and of the 13 men on the Faculty, Professor Carson was the only one with engineering training or experience. Two years later—in 1887—there was a complete re-organization of the University, and of the former Faculty he was the only member to be retained by the new Administration. The standing almost immediately accorded to this institution in educational circles bears witness to the scholarship and teaching ability of the men who formed the new Faculty.

As a teacher, Professor Carson spared no effort to inculcate true engineering ideals in his students. He had too much practical experience to tolerate any slovenly or inaccurate work. His mind was too severely logical to overlook careless thinking or expression. Yet his boundless good nature, his kindness, and his warm heart, attracted his students and made them his life-long friends. Entirely sincere and absolutely upright in every act and thought, his fine character could not fail to command respect and impress itself upon all who came under his influence.

During his years as teacher, Professor Carson found time to write articles on a number of engineering subjects: Stresses in arches, transition curves in railway location, experiments on road resistance with different types of surfaces, articles on the calculus, etc. He designed and patented a method for protecting the banks of the Mississippi River from erosion, based on his familiarity with that stream. (The plantation where he spent his boyhood had long since been carried away by this river.)

Professor Carson interested himself in the welfare of the men who had fought by his side, and, as Commander of the Fred Ault Camp of the United Confederate Veterans for the last eighteen years of his life, he spent much of his time in making their conditions of living more comfortable. The monument which he has left is in the lives of those whom he taught and influenced.

In 1880, he was married to Rachel Finnie, of Memphis, Tenn., who survives him. Also surviving him are three children, Katherine W., Emma Carson McIlwaine, and W. Waller, Jr. One son, J. Finnie, died while he was a student at the University of Tennessee.

Professor Carson was elected a Member of the American Society of Civil Engineers on November 2, 1892.

## MAURICE WURTZ COOLEY, M. Am. Soc. C. E.[1]

DIED APRIL 27, 1930

Maurice Wurtz Cooley, the son of Justus and Elizabeth (Pine) Cooley, was born at Little Britain, N. Y., on August 16, 1861. He was directly descended from a Colonial great-great-grandfather who was the first Governor of the Free People of Dover, N. H., and, in a following generation, from those who served in the Revolutionary War.

Mr. Cooley received his preliminary education at Phillips Exeter Academy at Exeter, N. H., from which he was graduated in 1883. He then entered the Massachusetts Institute of Technology, where he was a student in Civil Engineering from 1884 to 1886, his summer vacations being spent as Rodman and Leveler for the late A. H. French, M. Am. Soc. C. E., of Brookline, Mass.

On leaving college, Mr. Cooley was engaged in the following positions: From July, 1886, to October, 1887, Draftsman and Instrumentman, for the Toledo, St. Louis and Kansas City Railroad Company; 1887 to 1889, Instrumentman, the Lake Shore and Michigan Southern Railway Company; 1889 to 1892, Assistant Engineer, the Michigan Southern Division of the Lake Shore and Michigan Southern Railway Company, in charge of drafting-room and field parties; the making of designs for bridge masonry, large terminal yards, and also for many changes of line and grade, including 150 miles of second-track construction; 1892 to 1898, and from February to October, 1899, Engineer, Maintenance of Way, the Toledo and Ohio Central Railway Company, in charge of the maintenance of bridges, buildings, and roadway.

During the Spanish-American War Mr. Cooley served as First Lieutenant in command of Company B, 2d U. S. Volunteer Engineers, from July, 1898, to February, 1899, designing and constructing a plant for supplying the 7th Army Corps with water near Havana, Cuba; he was also engaged on the construction of a dock for landing troops at the mouth of the Almendares River, and, in addition, he made surveys and designed a dock at Matanzas, Cuba, for which services he was promoted to the rank of Captain of Engineers.

After the war work was finished in Cuba, Captain Cooley served from November, 1899, to May, 1900, as Assistant Engineer of Construction on the Baltimore and Ohio Railroad in charge of the construction of a coal pier at Curtis Bay, Md., and the design of a terminal yard and masonry for the reconstruction of the Curtis Bay Branch. From May, 1900, to 1903, he was Manager of the National Contracting Company, having charge of the Company's

[1] Memoir compiled from information on file at the Headquarters of the Society.

business projects which consisted of the construction of a dam at Glens Falls, N. Y., and several sections of the Metropolitan High Level Sewer at Boston, Mass. From 1903 to 1906, he served as Manager of the New York and Bermudez Company and General Agent for the Trinidad Lake Asphalt Company, of Trinidad, British West Indies; and from 1906 until 1921, as General Manager of the Gilson Asphaltum Company and the Uintah Railway Company. He constructed the Uintah Railway, which is said to be the most crooked line in the United States. It utilizes 70 miles of trackage to traverse 40 miles in the mountains of Eastern Utah. It has several 3 and 4% grades and one 66° curve. This line is used to haul the gilsonite ore to the Denver and Rio Grande Western Railway at Mack, Colo.

In 1922 Captain Cooley entered the service of the American Asphalt Company in St. Louis, Mo., and, in 1924, went to Cuba to open mines for the Central Commercial Company, of Chicago, Ill., which had large interests there. During his last few years he lived in New York, N. Y., where he was actively interested in real estate promotion and in the sale of securities.

In April, 1930, Captain Cooley was summoned to Salt Lake City, Utah, as a witness in a suit between the Gilsonite Asphaltum Company and the Utah Gilsonite Company. While on this trip he stopped over a few days to visit with friends at Mack, Colo., where he was suddenly taken ill, and died in a hospital at Grand Junction, Colo.

He was Vice-President and Director of the Watson Oil Company, and President of the Mesa Oil Company; a Charter Member of the American Railway Engineering Association and a member of the Masonic Order, the Denver Country Club, and the Broadmoor Golf Club.

Captain Cooley was married at Toledo, Ohio, on July 7, 1887, to Emma E. Erwin, who, together with his sisters, Dr. Helen Cooley Palmer and Elizabeth Cooley, of San Marino, Calif., and a brother, Dr. Justus H. Cooley, of Plainfield, N. J., survives him.

Captain Cooley was elected an Associate Member of the American Society of Civil Engineers on March 7, 1894, and a Member on December 3, 1902.

---

## EDWIN DURYEA, Jr., M. Am. Soc. C. E.[1]

---

DIED MARCH 31, 1930

---

Edwin Duryea, Jr., was born at Craigville, N. Y., on July 12, 1862. He was the son of Edwin and Hannah (Rumsey) Duryea. His family were Huguenots from Burgundy, France, who came to the United States in 1675 and settled in Long Island. Their descendants fought in the French and Indian Wars and, later, in the American Revolution.

Mr. Duryea spent his boyhood in New York State, attending the public schools and Cornell University, at Ithaca, from which institution he was graduated in 1883 with the degree of Bachelor in Civil Engineering. In

[1] Memoir prepared by Charles D. Marx, Past-President, Am. Soc. C. E., and Charles B. Wing and H. L. Haehl, Members, Am. Soc. C. E.

1890, he received the degree of Civil Engineer from the same institution. His first engineering work was on the Northern Pacific Railroad Bridge over St. Louis Bay at Duluth, Minn., under the late E. H. Beckler, M. Am. Soc. C. E., Assistant Engineer, and the late Alfred Noble, Past-President, Am. Soc. C. E., General Assistant Engineer in charge of bridges.

From March, 1886, to April, 1889, Mr. Duryea was employed under the late George S. Morison, Past-President, Am. Soc. C. E., as Assistant Engineer on the Rulo Bridge at Rulo, Nebr. (with the late B. L. Crosby, M. Am. Soc. C. E., as Resident Engineer), and as Assistant Engineer in charge of borings, surveys, etc., for the location of the Memphis Bridge over the Mississippi River, at Memphis, Tenn.; he also acted as Assistant Engineer in charge of river protection and reclamation for the Nebraska City Bridge over the Missouri River at Nebraska City, Nebr., and as Resident Engineer on the new Omaha Bridge (Union Pacific Railway) over the Missouri River at Omaha, Nebr. He was also employed under the late Mr. Noble, as Resident Engineer on the Cairo Bridge (Illinois Central Railroad) over the Ohio River, at Cairo, Ill.

During 1889 and 1890, Mr. Duryea was engaged on the location of the Hutchinson, Oklahoma and Gulf Railroad, in Kansas; on the Chicago and Western Michigan Railroad, and the Detroit, Lansing and Northern Railroad, Grand Rapids, Mich., and as Assistant Engineer on the construction of the Traverse City Extension of the Chicago and Western Michigan Railway.

From January, 1891, to May, 1893, he served as Contractor's Engineer with Washburn, Shaler, and Washburn, Civil Engineers and Contractors, in charge of topographic surveys at the lower end of Lake Michigan, harbor studies, etc., as well as on studies and plans for stockyards, packing houses, railroad layout, and water supply and sewerage systems near Chicago, Ill. Under the same employment he was also engaged on computations for bids for the construction of the New Croton Dam, New Croton Aqueduct, for the New York City water supply, and on the construction of the Third Avenue Cable Railway, in New York City, as well as in serving as Contractor's Engineer and Assistant Superintendent on a part of the New Croton Aqueduct. From May, 1893, to September, 1895, he acted as Superintendent for the same firm of contractors on the construction of the dams of the New Croton Aqueduct.

Beginning in September, 1895, Mr. Duryea was engaged on the design and construction of the New East River (Williamsburgh) Bridge, New York City, including investigations for live load, grades, tower foundations, etc., and the design of anchorages and similar structures. He was later Resident Engineer in charge of the Brooklyn half of the New East River Bridge until 1900, after which time he was engaged in private practice in New York City.

In 1902, he went to San Francisco, Calif., as Chief Engineer of the Bay Cities Water Company, and its allied interests, being engaged on investigation and design for city water supply and power development in connection with that Company until 1910.

Beginning in 1907, Mr. Duryea became associated (as Senior member) with the engineering firm of Duryea, Haehl, and Gilman, of San Francisco. He

continued in that connection until 1920. His work during this period involved the construction of the system of the South San Joaquin Irrigation District in California, the completion of dams and power development on the Rio Conchos in Mexico, and many other important engineering works in connection with water supply, irrigation, and power development in California. During this time he was a member of the "Committee of Forty" appointed by the Mayor of San Francisco to advise on the rehabilitation of the city after the great fire of 1906.

Owing to ill health, Mr. Duryea retired from active practice in 1920 and remained thereafter at his home in Palo Alto, Calif.

He was always an active and enthusiastic member of the Society and participated whole-heartedly in its activities. He took his profession very seriously, was especially jealous of its honor, and punctiliously observant of its ethics. He was one of the Charter Members of the San Francisco Section of the Society, having served as its President during 1906. He was also a member of the Western Society of Engineers, of Chicago, and an Associate Member of the Institution of Civil Engineers, of London, England.

Mr. Duryea was a man of unusual force and personality, whose gentlemanly conduct and consideration of others impelled the respect and admiration of all those who knew him. The high order of his engineering work, the great interest which he took in his fellow-engineers, and the unselfish assistance which he rendered, particularly to young engineers with whom he came in contact, won for him the unreserved loyalty and friendship of all in his profession.

In December, 1888, he was married to Roberta Taylor, in Ithaca, who, with five children, Robert, Margaret, Anne, Philip, and Helena, as well as a sister, Mrs. Julia Tuthill, and a brother, Mr. Howard Duryea, survives him.

Mr. Duryea was elected a Junior of the American Society of Civil Engineers on February 2, 1887; an Associate Member on September 4, 1895; and a Member on February 2, 1898. He served as a Director of the Society from 1916 to 1918.

## HARRISON ROBERT FEHR, Sr., M. Am. Soc. C. E.[1]

DIED MAY 30, 1930

Harrison Robert Fehr was born in Nazareth, Pa., on March 20, 1863, the son of Michael M. and Anna Caroline (Edmonds) Fehr. He was educated in the public schools of Nazareth and at the Moravian Parochial School.

From 1880 to 1883, Mr. Fehr was a teacher in the public schools. He then entered the Civil Engineering Department of the Lehigh Valley Railroad Company, acting, successively, as Rodman, Transitman, and Assistant Engineer, from 1883 to 1889. At the end of this period he was engaged in the private practice of engineering for a time and, in 1890, was again associated with the Lehigh Valley Railroad Company as Bridge Engineer.

[1] Memoir prepared from information on file at the Headquarters of the Society.

The following year, 1891, he was elected City Engineer of Easton, Pa., and during his tenure of this office more than $250 000 was spent by this Department, under his supervision, on various municipal improvements. He served the city ably and well, furthering street paving, the building of macadam roads and retaining walls, the opening and grading of streets, and other improvements of a like nature. During this period his duties also included engineering for the Easton Board of Trade, the South Side Land Company of Easton, and for the Borough of South Easton.

In 1899, Mr. Fehr was appointed Engineer to the Easton Transit Company, and, except for short intervals, he was allied with this Company until 1920. His several positions during this period were as follows: 1901-1902, Chief Engineer, Trenton and New Brunswick Electric Railway; 1902-1904, Contracting Engineer; 1904-1913, President and General Manager, Easton Transit Company; and 1913-1920, President and General Manager, Lehigh Valley Transit Company, and Vice-President, The Pennsylvania Light, Power, and Gas Company. Mr. Fehr was also a promoter of the construction of the William Penn Highway between Bethlehem and Allentown, Pa.

In 1920, he again entered private practice as a Consulting Engineer in which he continued until his death. He was also active in the wholesale coal and coke business.

Mr. Fehr was a member of the Pennsylvania Street Railway Association (President, 1912), Lehigh Valley Engineers Club, the Pennsylvania Society, the Sons of Veterans, the Pennsylvania Society of Sons of the Revolution, the National Geographic Society, the Masonic Orders, and the Benevolent and Protective Order of Elks. He was also a member of the Livingston Club, the Country Club of Northampton County, and an Honorary Member of the Writers Club of Allentown. He was a Trustee of St. Luke's Hospital, Bethlehem, Pa., and a Director of the Penn Securities Company. His political interests were Republican. He was a life-long member of the Presbyterian Church.

He was married on August 6, 1881, in Nazareth, to Achshaw Walter who, with one son, Harrison Robert, Jr., survives him.

Mr. Fehr was elected a Member of the American Society of Civil Engineers on October 5, 1898.

## SAMUEL MORSE FELTON, M. Am. Soc. C. E.[1]

DIED MARCH 11, 1930

Samuel Morse Felton was born in Philadelphia, Pa., on February 3, 1853. He came of old English stock, his ancestors having settled in Salem, Mass., in 1633. His earliest paternal ancestor was Nathaniel Felton, Ensign and Lieutenant in the Salem Foot Company, who came to America from Great Yarmouth, Norfolk, England. His father, Samuel Morse Felton, was Superintendent of the Fitchburg Railroad in 1843, and, in 1861, as President of the Philadelphia, Wilmington, and Baltimore Railroad Company, arranged

[1] Memoir prepared by W. G. Lerch, Vice-Pres., C. G. W. R. R., Chicago, Ill.

for the secret passage of Abraham Lincoln from Harrisburg, Pa., to Washington, D. C., at the time of his first inauguration. He afterward became President of the Pennsylvania Steel Company. His mother, Maria Low (Lippitt) Felton, was the seventh in descent of Roger Williams, Captain in King Philip's War, and Governor of Rhode Island Colony, in 1654.

Mr. Felton's inclination and early training were along railroad lines. He was educated in private schools in Philadelphia, and, for two years, took an engineering course at the Pennsylvania Military Academy, at Chester, Pa., working during vacations as Rodman on the Chester Creek Railroad. After leaving the Academy at Chester he spent one year in the field with a locating party on the Lancaster Railroad, in New England, as Leveler and Assistant Engineer. Realizing the value of further technical training he entered the Massachusetts Institute of Technology, at Boston, Mass., and was graduated in 1873 with the degree of Civil Engineer. After his graduation, because of his earlier experience in the field, he was able to accept a position as Chief Engineer of the Chester and Delaware Railroad, a small line being constructed by the Reading Railroad Company along the Delaware River.

His ambition was to become the operating head of a railroad system, and, in 1874, at the age of twenty-one, he was appointed General Superintendent of the Pittsburgh, Cincinnati, and St. Louis Railroad Company, with which he remained until 1882. In 1881, Mr. Felton was also made General Superintendent of the Little Miami, and Cincinnati and Muskingum Valley Railroad Companies. In 1882, he became General Manager of the New York and New England Railroad Company; in 1884, Assistant to the President of the New York, Lake Erie, and Western Railroad Company, and General Manager of the New York, Pennsylvania, and Ohio Railroad Company, both of which are now a part of the Erie System. In 1885, he was made Vice-President in Charge of Traffic, later taking over, in addition, the duties of Vice-President in Charge of Operation. He remained in these positions until 1890, when he was elected President of the East Tennessee, Virginia, and Georgia Railway Company and, later, President of the Alabama Great Southern Railroad and the Cincinnati, New Orleans, and Texas Pacific Railway Companies. In 1893, when the latter company went into a receivership, Mr. Felton was appointed Receiver of that property by former President William H. Taft, who, at that time, was on the Federal Bench in Cincinnati, Ohio. He also in that year became Receiver of the Columbus, Sandusky, and Hocking Railway Company and the Kentucky and Indiana Bridge Company. He directed the operations of these properties until 1899, when the late E. H. Harriman secured control of the Chicago and Alton Railroad and, finding complete rehabilitation necessary, decided that Mr. Felton was best fitted to undertake the work. He prevailed upon him to come to Chicago, Ill., as President of the road, where he remained until 1907. During this time he rebuilt much of the line, installed modern facilities and equipment, and the Alton Railroad, when he left it, was as well equipped as any road in its territory. In December, 1907, he was elected President of the Mexican Central Railway Company and the Mexican American Steamship Company, continuing in those positions

until the Mexican Government merged all the principal railroads in the Republic into the National Railways of Mexico.

In 1909, Mr. Felton returned to the United States and became Chairman of the Tennessee Central Railroad Company. In the fall of that year after making an examination and report on the road for the re-organization managers he was elected President of the Chicago Great Western Railroad Company and its affiliated lines. He held this office until the end of 1925, when he was made Chairman of the Board of Directors, in which position he remained until his death. From 1912 to 1914 he was also Co-Receiver and President of the Pere Marquette Railway Company. When Mr. Felton took charge of the Chicago Great Western Railroad Company, it had just emerged from a receivership, but within a period of six years he completely rehabilitated the road and its equipment and placed the property on a dividend-paying basis. During the period of Federal operation of railroads incident to the World War, the road was not maintained, and when it was turned back to its owners in 1920, it was in a bad state of repair with its traffic diverted to other roads, necessitating doing over again what Mr. Felton had begun in 1910—the reconstruction and rehabilitation of the road and its equipment and the task of getting back its traffic. He went vigorously ahead and had practically completed the work with prospects for renewed prosperity of the Company in sight when illness assailed him, and he was compelled to relinquish the active direction of the railroad to others.

Mr. Felton maintained his interest in railroad problems, and was a member of the Executive Committee of the Association of Railway Executives, of the Western Association of Railway Executives, and of the Western Railway Committee on Public Relations. He was also a Director of the American Railway Association and President of the Western Railroad Association. During his railroad career he served on several important engineering commissions, having acted as Chairman of the Engineering Commission of the City of Cincinnati to select the location for a new water-works, and, in 1900, he was engaged by the Commercial Club of St. Louis, Mo., to report on a municipal bridge project. At different times, he made reports for banking interests and re-organization managers on 23 railroads aggregating more than 32 000 miles.

Mr. Felton's most spectacular service was probably in connection with the Spanish-American and the World Wars. During the former, while in charge of the Cincinnati, New Orleans, and Texas Pacific Railway, his road moved a larger number of troops than any other single line. At the outbreak of the war it handled the first troop movement south to Chattanooga, Tenn., which consisted of 31 trains leaving Cincinnati 10 min. apart and reaching Chattanooga on time, without delay or accident; and this was accomplished over a single-track road.

In June, 1916, while acting as President of the Chicago Great Western Railroad, he was requested by the War Department to organize troops to operate the railroads in Mexico in the event the United States Army found it necessary to advance south of the border. His title was Consulting Engineer and Adviser to the Chief of Engineers, United States Army. He went zealously

to work and, in a short time, engaged a sufficient number of railroad men, familiar with Mexican railways, to fill the most important positions thereon, and arranged under option, if needed, for locomotives, construction and wrecking trains, rails, and cross-ties to replace destroyed track, telephone and telegraph equipment, and other material. In June of that year he joined the Staff of General Funston, at San Antonio, Tex., and reported sufficient men and material ready for the initial movement of troops. This, however, became unnecessary as the tension between the two countries relaxed.

In the meantime the question of forming a reserve force of railroad men in the Engineer Corps was considered by the War Department, and Mr. Felton was requested to plan its organization. While this work was progressing, the United States entered the World War and the original plan was enlarged upon, as it was found necessary to organize, at once, nine regiments. The work of equipping and drilling these regiments was hurried, and they were among the first American troops to land in France. Mr. Felton was appointed Director General of Railways, United States Army, the title later being changed to Director General of Military Railways. He took up his residence in Washington and went actively to work organizing additional regiments, being empowered by the Secretary of War to make contracts and purchases, at his own discretion, without going through the customary formalities. Two days after his appointment as Director General of Railways, he contracted for the building of three hundred locomotives and in twenty working days thereafter the first one was crated ready for shipment. The total amount of contracts made under his direction was $612 000 000, covering: 3 750 standard gauge locomotives; 1 547 narrow-gauge locomotives; 91 519 standard-gauge cars; 8 930 narrow-gauge cars; 823 locomotive cranes; 76 gantry cranes; and materials for more than 100 water stations, 749 345 tons of rail (the equivalent of 5 951 miles of single track), and other items of like proportion. By careful buying a saving of more than $33 000 000 was made in connection with these contracts.

In addition to the purchasing of materials and supplies, 84 000 transportation men were organized in battalions and regiments for service overseas and, at the time of the Armistice, 70 000 transportation men were in France and 14 000 more ready to sail.

In 1918 Mr. Felton made a trip of inspection to France, traveling among all the battle lines. On May 23 of that year, he was made Vice-President of the Port and Harbor Facilities Commission of the United States Shipping Board, and, in 1918, became Acting Chairman, performing the duties of the office until he left Washington. He resigned as General Director of Military Railways on December 1, 1918.

Mr. Felton emerged from the war without military rank. He was twice offered a commission as Brigadier General, but refused, believing that a place in the military organization would prove a hindrance rather than a help in his work. He was awarded the Distinguished Service Medal of the United States Army, the first one granted to a civilian. In further recognition of his war work, the French Government made him an Officer of the Legion of Honor.

After the close of the war he was appointed Honorary Adviser to the Army Industrial War College, a member of the War Department Business Council, and Chairman of the Committee on Military Affairs of the Association of Railway Executives.

Notwithstanding the heavy responsibilities imposed upon him by his railroad duties, Mr. Felton found time to interest himself in many outside mercantile and financial activities, the success of which bore witness to his ability, and added luster to the corporations with which he was identified. He was a Director of the Central Trust Company of Illinois, the Central Securities Company, the Peoples Trust and Savings Bank of Chicago, the Equitable Life Assurance Society, the Chicago Surface Lines, and the Colonial Land Company. He was a member of the Western Society of Engineers, American Railway Engineering Association, Franklin Institute, American Legion, Civil Legion, Society of American Military Engineers, Veterans of Foreign Wars, Ohio Society, Sons of the Revolution, Ohio Society of Colonial Wars, and the New England Society, in New York; the Commercial Club of Chicago, Chicago Club, Chicago Athletic Association, Saddle and Cycle, and Old Elm Golf Club, of Chicago; the University Club of New York and the Commercial Club of Cincinnati.

There was conferred upon him the degree of Doctor of Laws by the Pennsylvania Military Academy and by Marietta College, of Marietta, Ohio. He was a member of the Corporation of the Massachusetts Institute of Technology.

Mr. Felton was married in 1880, to Dorathea Hamilton, of Pittsburgh, Pa. Mrs. Felton died in 1923. They had three daughters and one son.

Mr. Felton was elected a Member of the American Society of Civil Engineers on January 4, 1882.

## ROGER MORSE FREEMAN, M. Am. Soc. C. E.[1]

DIED JANUARY 21, 1925

Roger Morse Freeman, the son of John R. Freeman, Past-President and Hon. M. Am. Soc. C. E., and Elizabeth Farwell (Clark) Freeman, was born in Winchester, Mass., on July 20, 1892. His ancestry on both sides was English Colonial, dating back to Governor Winthrop's Boston Colony of 1636.

When he was about four years of age his father moved with his family to Providence, R. I., where the boy attended public and private schools, finishing his common school education as a graduate of Hope High School in 1908. During his high school days he was Manager of both baseball and football teams, playing on the eleven that won the year's New England High School championship in football. He carried this activity with him into college athletics where it is said some members of the faculty thought that for a time it overshadowed his interest in textbooks and formulas. However, Mr. Freeman claimed in after life, that this time was well spent because of the appreciation it gave

[1] Memoir prepared at the Headquarters of the Society from information supplied by John R. Freeman, Past-President and Hon. M. Am. Soc. C. E.

him of teamwork and human nature. Also, this interest in athletics from earliest boyhood developed an uncommonly fine physique which, in later years, could endure any required amount of overload.

Mr. Freeman entered the Massachusetts Institute of Technology in 1909, and was graduated with the class of 1913, but took his degree in Electrical Engineering with the class of 1914, meanwhile having spent a term at the Technical University of Charlottenburg, Germany, where he majored in the theory of internal combustion engines. Prior to this, he had spent a long summer vacation in Germany, in order to gain greater familiarity with the language than the college course permitted. The breaking out of the World War in 1914 prevented carrying out his intentions of further study in both Germany and France.

His practical experience in engineering began at the early age of fifteen, when being large and strong for his age, he obtained a summer job as Rodman in a surveyor's party on the New York Board of Water Supply. One of his college vacations was spent as Assistant in an engineering party in the eastern foothills and slopes of the Sierra Nevada Mountains in California, on the construction of the Los Angeles Aqueduct. Another was spent as a Machinist in the Marine Repair Shops of the Atlantic Works in East Boston, Mass.

After graduation from college Mr. Freeman spent about a year in his father's engineering office on water power development studies and designs. He then concluded that he could build more securely for the future by going where he would be forced to depend purely on his own efforts, or, as he expressed it, he desired to "try making progress on his own legs for ten years, after which, he would be glad to join forces with his father." In following out this idea, being always ready to enter an open door, without waiting for something precisely in his line of Electrical Engineering, he first took a Time-Keeper's job with the Turner Construction Company on the construction of a large factory building at Thomaston, Conn., in the belief, which later he often expressed, that this was the best possible post-graduate course for a young engineer, since it took him to every part of the work at least twice a day; gave him an opportunity to see how much could be done in a day; made him familiar with obstacles; and, if he was sympathetic, taught him the grievances of foremen and workmen and their psychology and reactions.

He next became Construction Engineer for the Chase Rolling Mills and Waterbury Manufacturing Company of Waterbury, Conn. At the time, this Company was concerned in the rush of war work, employing 10 000 workmen. Mr. Freeman designed and supervised the construction of several large multi-storied reinforced concrete factory buildings, and so gained the confidence of his employers that when later they decided to build a large machine shop, to be used in fabricating their own heavy special machinery for working brass and copper tubes, plates and similar articles, he was chosen to supervise the design and construction. He was given but one specification. As the President of the Company put it: "We need a machine shop about 400 by 100 ft. I am too busy with war problems to discuss details. Go to it! And make it the best of its size in New England".

As this undertaking neared completion, Mr. Freeman was summoned into conference with the Secretary of the Navy, the United States then having entered the World War. As a result he was requested to visit certain large steel works under construction for the manufacture of certain forgings most urgently needed, and to report, as one familiar with rush work, what, in his judgment, was causing the very apparent delay. On his return he reported: "Making decisions in committee meetings instead of 'off the bat'" * * * "Too many Bosses." * * * "Perhaps too much gold braid." A few hours later he was recalled and asked whether he would take these responsibilities, being given sole and full authority. In six months, employing three shifts, through one of the worst winters on record, he had completely built the plant, ready to forge crank-shafts and guns.

Meanwhile, as a result of his success in getting all hands to pull hard together, he was dispatched here and there to help speed up other constructions for war material that lagged. Sketches for starting rush work on a tall heat-treatment tower were made on the back of an envelope, and the structure was completed without stopping the progress of work in the old tower beneath it.

After the Armistice, the Navy officials had strong beliefs about the need for a larger Navy, which, in part, found expression in the building of an armor-plate plant at Charleston, W. Va. This plant was to serve for research in a large way and, at the same time, to check the actual costs on bids submitted by the great steel works, which some members of Congress had felt were unduly high.

Inasmuch as the technology of steel-making and steel-plant design were somewhat outside the regular curriculum of the Navy Department, and as Mr. Freeman had shown such resourcefulness and success at war emergency plants, he was again given a free hand. In two years, starting with practically an open lot and blank drafting paper, and aided by the engineering organization which he had built up, beginning at Waterbury, and also by the friendly co-operation from many sources within the Navy Department, he was able to complete a plant for armor-plate and heavy forgings, perhaps without a superior of its size in the world. This had successfully poured its first heats a short time prior to the first Disarmament Conference, since which time it has stood idle. He presented a paper[2] descriptive of this plant before the American Society of Mechanical Engineers in December, 1920.

Following his natural bent, Mr. Freeman had hoped to continue in metallurgical structural lines, but as no openings were found in the depressed condition of this industry after the war, he opened an office in New York, N. Y., and turned again to hydro-electric construction, in which he had had previous experience in his father's office. In this connection, his ability and experience, his friendliness with builders of hydraulic and electrical machinery, and his unbounded patience in attention to details, quickly brought to successful completion a plant of about 12 000 h.p., for the Insull interests, on the Tippecanoe River, at Norway, near Monticello, Ind., a model of low cost and efficiency.

The end found him driving ahead on the design and construction of a second hydro-electric plant of about 15 000 h.p. for the same interests near Oakdale,

[2] "The Armor-Plate and Gun-Forging Plant of the U. S. Navy Department at South Charleston, W. Va.", *Transactions*, Am. Soc. Mech. Engrs., Vol. 42 (1920), p. 983.

Ind., on the Tippecanoe River, with more than 500 men employed on a difficult piece of rush work under winter construction. The confidence of his employers may be judged from the fact that the formal contract for his services in designing and supervising the Oakdale plant had not been signed to the time of his death, although a draft had been prepared. He was proceeding with design and supervision of construction to the satisfaction of all concerned under his oral statement that he could produce plans as fast as the construction forces could be ready for them. The reservoir created by these works was subsequently named Freeman Lake in his honor.

In ten years, Mr. Freeman under exceptional conditions brought about by the World War had accomplished more in engineering design and construction than most men find an opportunity to achieve in a life time. The cost of structures completed under his design and supervision, during the brief practice of his profession, aggregated a total of about $25 000 000. Plans under way for joining forces with his father in consulting work on larger enterprises and for taking construction contracts, were cut short by his untimely death.

While he was at Thomaston, Mr. Freeman was married on March 2, 1918, to Mary Elizabeth Bradstreet, of that town, a lineal descendant of Colonial Governor Simon Bradstreet and of Anne Bradstreet, the eminent poetess of early Colonial days.

His death, when he was but 33 years of age, was caused by heart failure following an operation for appendicitis. Besides his widow and two children, Anne Bradstreet and Roger Morse, Jr., his father and mother, he is survived by four brothers: Hovey T. Freeman, Evert W. Freeman, Clarke Freeman, and John R. Freeman, Jr., and a sister, Mary Elizabeth Freeman, of Providence.

He was a member of the American Institute of Electrical Engineers, the American Society of Mechanical Engineers, the American Association of Engineers, and the Engineers' Club of New York City.

Mr. Freeman was elected a Member of the American Society of Civil Engineers on January 15, 1923.

## HORACE DELPHOS GATES, M. Am. Soc. C. E.[1]

DIED JANUARY 8, 1931

Horace Delphos Gates was born at Boston, Mass., on February 12, 1847. He never tired of recalling his early fondness for mathematics and natural philosophy when relating how, in making a choice of a vocation, he was attracted to surveying and engineering. Through mutual friends he was brought into contact with Mr. L. H. Shortt, a railroad engineer, originally from Canada, but at that time (sometime in the Sixties) already well established on work for several lines of railroads with terminals at San Francisco and Oakland, Calif. Mr. Gates became an Assistant to Mr. Shortt with part

[1] Memoir prepared by C. E. Grunsky, Past-President, Am. Soc. C. E.

time in the field and part time in the office and also with opportunity to continue his studies in mathematics and engineering under the personal supervision of his Chief.

It was during these years with Mr. Shortt that his surveys of railroads and proposed railroad extensions brought Mr. Gates into pleasant relations with the late E. A. Flint, M. Am. Soc. C. E., another railroad engineer of high attainments, who had spent eleven years in Chile where he has been employed on the construction of the railroads then being built by Mr. Harry Meiggs.

In 1867, Mr. Gates was called into the office of the City and County Surveyor of San Francisco by the then incumbent, Mr. William P. Humphreys. This promised to be a fairly permanent position, but when, a year later, Colonel Flint said "I want you", the prospective railroad work proved too alluring and Mr. Gates took charge of the location of about 20 miles of railroad from tide-water at Wilmington to Los Angeles, Calif.

Subsequently, he was again with Mr. Shortt on the location and building of the California Pacific Railroad from Vallejo to Sacramento, Calif. This was followed in 1870 by work on the Central Pacific Railroad under Chief Engineer S. S. Montague, in the northern part of California, and, later, under the late William Hood, M. Am. Soc. C. E., with constantly increasing responsibility.

This and other railroad construction kept Mr. Gates active in his favorite line of work until 1874 when he was called into the San Joaquin Valley, California, in charge of the extension of the San Joaquin and Kings River Canal from Los Baños to Orestimba Creek. This irrigation experience naturally led him into the newly organized State Engineer Department of California, under William Hammond Hall, M. Am. Soc. C. E., State Engineer. In 1878, Mr. Gates was Transitman under the late Isaac W. Smith, M. Am. Soc. C. E., on a topographic survey of Sacramento River from Knights Landing to the head of Suisun Bay. He was then assigned to hydrographic studies on the same river which were being made by the Engineer Corps of the United States Army, and then came other work with the Government engineers at various places on the Pacific Coast, covering a total period of three years.

A few months at a mine in Nevada and, again, some railroad surveys under Mr. Lyman Bridges for the Gould Syndicate in California, and then again five years on mining and railroad work in Nevada added variety to Mr. Gates' activities. Scarcely had he returned to San Francisco, when he was once more made an Assistant in the office of the City and County Surveyor, Mr. S. Harrison Smith, where he was retained for six years, or more.

Thereafter, he assisted in making the studies for San Francisco's new sewer system and, when the office of City Engineer was established, under a Board of Public Works in 1900, Mr. Gates was appointed as one of the Assistants to the writer who was then City Engineer. Mr. Gates retired from the City Engineer's Office in 1913, at which time he gave up active practice. He died at Sheridan, Calif., on January 8, 1931.

He is survived by his widow, *née* Grace Birdsall, to whom he had been married on April 29, 1902.

His was a charming personality. He was modest to a degree and every one who came in contact with him became his friend. In his professional work he was conscientious, energetic, and able, enjoying a long life of engineering activity followed by a few well-earned years of retirement.

Mr. Gates was elected a Member of the American Society of Civil Engineers on March 7, 1883.

## THOMAS GOLDING GERDINE, M. Am. Soc. C. E.[1]

DIED OCTOBER 31, 1930

Thomas Golding Gerdine was born at West Point, Miss., on June 2, 1872, the son of Dr. John Gerdine and Susan (Golding) Gerdine. He had two brothers and four sisters, all of whom are living and engaged in professional or educational work. Dr. Gerdine moved his family to Athens, Ga., in 1876, and continued the practice of medicine and the education of his children at that center.

After the completion of his elementary and High School studies at Athens, Mr. Gerdine entered the Engineering Department of the University of Georgia and was graduated in 1891 with the degree of Bachelor of Engineering. During his college course he was active in athletics and in fraternity affairs, being a member of the Sigma Alpha Epsilon Fraternity.

Shortly after his graduation he entered the public service and all his activities from that time were either in municipal or Federal Governmental work. His first position was as Assistant to the City Engineer of Athens, and he was placed in charge of field surveys, particularly the location and grading of streets and surveys for, and the inspection of, city sewerage and water-works systems.

On July 1, 1893, Mr. Gerdine joined the United States Geological Survey as Recorder in a topographic field party, working on the Santa Monica, Calif., Quadrangle. On May 3, 1894, he was appointed Assistant Topographer in the United States Geological Survey and, with the exception of his World War service, continued his work in the civil service of the Federal Government until his death. On April 22, 1895, he was transferred to the General Land Office and served for two years as Examiner of Surveys, acting as Federal Representative in the examination and approval of land surveys under the old contract system. On July 12, 1897, he returned to the Geological Survey, served as Party Chief in the extreme western part of the United States and in Alaska, and worked on difficult topographic and geodetic survey projects.

From May 1, 1899, to January 17, 1908, he was assigned to the Alaskan Division of the Geological Survey. He accompanied the party making the first survey of Chandalar River in interior Alaska, crossing a portage into the

[1] Memoir prepared by C. H. Birdseye, M. Am. Soc. C. E.

Koyukuk and descending that stream to its mouth, thence going to Nome, where, while awaiting transportation to the States, he supervised the making of the first map of the then newly discovered goldfields. Mr. Gerdine also conducted extensive surveys in the Copper River Region, Seward Peninsula, and Cook Inlet Basins in Central Alaska. Throughout his entire Alaskan service he showed not only marked professional ability, but all those other qualities, physical and personal, that are demanded of a leader of parties engaged in field work under difficult and unusual pioneer conditions.

Several of his assignments were with geologic field parties, which gave him a good conception of geological formations so essential to a mountain topographer's work. His experience covered all phases of topographic and geodetic surveys and fitted him especially for his later administrative work. In fact, he acted on the assumption that he should know all technical details and be able to prosecute actively any field operation which was under his supervision. In this connection of course he was overworked, but his physical and mental energy, coupled with a strong physique, enabled him to "stand the gaff" until shortly before his death. Major Gerdine falls more nearly in the category of men who "worked themselves to death" than any other man known to the writer.

On July 23, 1908, he was appointed Geographer in charge of the Pacific Division of the Geological Survey with complete administrative and technical charge of topographic and geodetic work in the Pacific Coast States and Hawaii. With the exception of his war service and with a few minor changes in areas, he continued in this administrative position until his death. In this work he came in contact with State and Federal officials, earned their admiration and respect, and gained the reputation of being the embodiment of cooperation.

He was commissioned a Major in the Engineer Officers' Reserve Corps on September 16, 1917, and was assigned to administration and supervision of military mapping, first in New Mexico and Texas, and, later, along the Atlantic Coast in Virginia and at some of the Eastern artillery training camps. He was discharged from the Army on March 31, 1919, and returned to his former administrative position on the Pacific Coast, making his home at Sacramento, Calif. At Sacramento, he was interested in the work of the Local Section of the Society and was always active in engineering and civic affairs. In his official work he brought to a successful conclusion the extremely difficult detailed mapping of the entire Hawaiian Islands.

Major Gerdine was twice married. His first wife was Frances E. Bishop, of Washington, D. C., to whom he was married in 1907 and who died in 1920. His second wife, to whom he was married in 1923, was Marguerite N. Rowell, of Falls Church, Va. He is survived by Mrs. Gerdine and three children, Suzanne, Eleanor, and Thomas F. Gerdine.

Major Gerdine was elected a Member of the American Society of Civil Engineers on June 6, 1921. He was also a member of the Society of American Military Engineers.

## THOMAS NIXON GILMORE, M. Am. Soc. C. E.[1]

DIED JANUARY 17, 1930

Thomas Nixon Gilmore was born in Manhattan, Ind., on December 10, 1863.

In 1880, Mr. Gilmore entered the service of the Vandalia Railroad Company, a part of the Southwest System of the Pennsylvania Railroad Company, as Special Apprentice in the Mechanical Department. He continued with this railroad until 1902, being employed, successively, as Draftsman, Engineer of Motive Power, Round-House Foreman, Division Foreman, and also, on various assignments, including studies in connection with fuel, steam heat, and oil.

In 1902, he entered the service of the Terminal Railroad Association of St. Louis, Mo., as Mechanical Superintendent in charge of the Mechanical and Car Departments. This position carried with it responsible charge of the design, construction, and equipment of extensive mechanical improvements preparatory to the World's Fair which was held in St. Louis in 1904. These improvements included locomotive shops and roundhouses, coaling plants, power houses, etc.

Mr. Gilmore was next engaged as Assistant General Superintendent of Motor Power for the Chicago, Rock Island and Pacific Railway Company during 1904 and 1905. In this position a large part of his time was devoted to improvements in standards of motor power facilities, in addition to the regular routine work connected with operation.

In 1905, he entered the service of Westinghouse, Church, Kerr and Company, as Engineer in charge of specific undertakings. The scope of this organization is well known and covers a great variety of engineering and construction operations, including railway lines, power facilities, industrial plants, and public utilities. The work under Mr. Gilmore's direction covered a large number of railway shops and terminals, including the West Springfield Shops of the Boston and Albany Railroad Company; the improvement and electrification of the Depew Shops of the New York Central and Hudson River Railroad Company; locomotive shops and power-house and incidental work at Silver Grove, Ky., and at other points, for the Chesapeake and Ohio Railroad Company; shops, power-house, and water supply at Havelock, Nebr., and West Burlington, Iowa, for the Chicago, Burlington and Quincy Railroad Company; the Ogden Shops of the Canadian Pacific Railway Company, near Calgary, Alta., Canada; and the Communipaw engine terminal at Jersey City, N. J., for the Central Railroad Company of New Jersey. His other activities included inspections and reports on the improvement of shops and terminal facilities for a number of trunk-line railroads.

Subsequently, Mr. Gilmore became Managing Engineer, giving both detailed and general supervision to works similar to those outlined. Later, he became Vice-President and Chief Engineer, and also a Director, of Westinghouse, Church, Kerr and Company, Incorporated. The activities of this

[1] Memoir prepared by James C. Boyd and Edwin J. Beugler, Members, Am. Soc. C. E.

Company were accented considerably during the period of the World War, and Mr. Gilmore's position as Chief Engineer contributed toward the expansion of the engineering and construction organization, which covered a large amount of industrial plant construction, warehouses, and special work, much of which was done directly for the United States and Canadian Governments in co-operation with the Army officers. A citation given to the Company after the war by the United States Government was due in a large degree to the efficiency of the organization developed under Mr. Gilmore as Chief Engineer.

In 1920, Westinghouse, Church, Kerr and Company was merged with Dwight P. Robinson and Company, continuing along the same lines of endeavor, and Mr. Gilmore became Consulting Engineer in the combined organization, giving particular attention to railroad shops, locomotive terminals, and power stations. In 1921, he entered private practice as Consulting Engineer, specializing on the lines in which he had been most actively engaged and thus continued until the time of his death.

Mr. Gilmore's contact with a great number of railway systems in the United States and Canada and his habits of observation and analysis fitted him for rendering unusual service in the development of designs and construction of railway facilities for any given location. Moreover, his faculty of co-operation with the various departments of the railroads for which he was doing work, produced results which reflected the best ideas of all concerned.

He was a member of the American Society of Mechanical Engineers, and the Structural Engineers' Association of Illinois. His connection with social organizations included the Engineers' Club of New York City, and the Echo Lake Golf Club of New Jersey.

Mr. Gilmore was elected a Member of the American Society of Civil Engineers on April 7, 1915.

---

## BENJAMIN MORTIMER HALL, M. Am. Soc. C. E.[1]

---

DIED NOVEMBER 19, 1929

---

Benjamin Mortimer Hall was born near Wynnsboro, in Fairfield County, South Carolina, on January 31, 1853, the son of Dr. Nathaniel Hall and Nancy (Boulware) Hall. The family moved to Georgia in the boy's childhood and located in Webster County, where his early youth was mainly spent. He attended the University of Georgia and was graduated in 1876 as Bachelor of Engineering. Following his graduation, he became Professor of Mathematics in the North Georgia Agricultural College at Dahlonega, in the Blue Ridge Mountain section of the State.

During the four years of his incumbency there Professor Hall became interested in the surrounding mining and hydraulic operations which influenced his studies in securing the Post-Graduate Degrees of Civil and Mining Engi-

[1] Memoir prepared by a Committee of the Georgia Section consisting of W. C. Spiker, *Chairman*, J. Houstoun Johnston, C. M. Strahan, and S. B. Slack, Members, Am. Soc. C. E.

neer bestowed by the University of Georgia in 1885 and which gave bent to his later professional activity and connection with mining work. Thus, from 1880 to 1890, he served as Mining Engineer and Superintendent of gold mines and marble quarries of Northeast and Northwest Georgia and established a reputation for thoroughness, initiative, character, and professional engineering ability of the highest order.

In 1890, together with his brothers, Max R. Hall, M. Am. Soc. C. E., and Mr. James R. Hall, he organized the firm of Hall Brothers, Engineers, with offices in Atlanta, Ga.; and through this firm, as its head and senior member, he served most acceptably a growing clientage in Georgia, Florida, Alabama, the Carolinas, Tennessee, Texas, New Mexico, and, later, in Porto Rico.

As Consulting Hydrographic Engineer for the United States Geological Survey (1896-1903), Mr. Hall directed the organization and active field operations for stream flow, run-off, and other significant water-power data on the principal streams and water-sheds of Georgia, Alabama, the Carolinas, and Tennessee. Under joint authorship with his brother, Mr. Max R. Hall, two important volumes, "The Water Powers of Georgia," and "The Water Powers of Alabama," published by the U. S. Geological Survey and by the respective States, record and attest the sound professional judgment and clarity of presentation with which Mr. Hall handled this large mass of basic and important hydrographic and water power information. To these larger publications, he added a goodly array of special reports and a store of personal records and memoranda which deservedly ranked him as an outstanding authority in hydrographic matters among the engineers of the Southeastern States.

Mr. Hall served from 1904 to 1907 as Supervising Engineer for the United States Reclamation Service. Connected therewith he built in the Southwest, the Hondo, Carlsbad, and Leesburg Projects, and negotiated the terms of the Mexico-Rio Grande Treaty at El Paso, Tex. He prepared the original plans for the Elephant Butte Dam and Rio Grande Project and supervised the settlement of all water-right disputes arising from this large storage and irrigation enterprise. The lake formed by Elephant Butte Dam which was named Lake B. M. Hall in his honor, is the largest artificial reservoir in the United States.

From his Texas and New Mexico experience, Mr. Hall was called as Chief Engineer to study, supervise, and construct (1908-1910) the widespread irrigation development for the Porto Rican Irrigation Service. This work has received distinct professional approval for its comprehensive planning, durability, and efficiency.

Returning to Atlanta in 1911 he acted for two years as General Manager for the Amicalola Marble Company in Pickens County. He also became active at this time in a growing consulting practice related to water power development and flood-water damage problems. The City of West Point, Ga., profited by his sound advice and by his proposals for flood protection.

Subsequent to 1917, Mr. Hall's services as Consulting Engineer were in great demand. He served on important boards of arbitration involving engineering issues, and was sought as an expert witness in many controversies. Among these should be noted long hearings in Raleigh and Durham, N. C., and in New York, N. Y., and Washington, D. C.

Mr. Hall was a member and supporter of the American Institute of Mining and Metallurgical Engineers. He was Chairman of the Water Power Committee at a session of the National Conservation Congress and performed important committee services for many engineering and civic organizations.

He was also a member of the Atlanta Board of Consulting Engineers for a number of years. His professional attainments were recognized by his charter membership in the Georgia Academy of Science, representing therein the Engineering Profession. He was always liberal of his time and means in civic and other altruistic movements. His support carried the weight of a strong clean-cut and high-minded personality which attracted friends to himself and the causes he espoused. He was an active member of the Civitan Club and other social organizations which he greatly enjoyed.

Mr. Hall had a systematic practice which can be commended to all his professional colleagues. He seldom failed to enter each day in a special pocket notebook brief data of the day's happenings; where he was, names and addresses of persons whom he met, and subjects of business matters discussed. Thus, his office library contained a special shelf of notebooks duly labeled which made a well-nigh complete inventory of his business contacts and matters handled. It served to solve many important problems regarding new projects or additions to old projects the original details of which had grown dim in memory through lapse of time. These notes furnished an explanation of the systematic thoroughness with which he executed all professional matters committed to his care, and show why he was a most convincing and accurate witness before Court, jury, or conference board.

Mr. Hall always showed unswerving loyalty and active interest in the work of the Society. He exemplified by precept and example its professional ideals and was a factor in advancing the standing of the Engineering Profession in public opinion. He was active in the organization of the Georgia Section of the Society and a constant supporter of its efforts. He took much interest in the young engineers of the Student Chapters at the University of Georgia and the Georgia School of Technology and honored them with timely addresses and advice.

He was long a devoted member of the Methodist Episcopal Church and a Steward and Trustee of the St. Mark's Church at the time of his death.

Mr. Hall was married on January 5, 1881, to Kate Chamberlin, of Weston, Ga., who died in August, 1929. They had two sons and a daughter, Mrs. Brainard K. Clapp. His sons, Benjamin Mortimer, Jr., and Warren Easterly, Assoc. Members, Am. Soc. C. E., in 1917 joined with him professionally under the firm name of B. M. Hall and Sons. He remained the active head of the firm until his death.

A kindly gentleman who attracted and enjoyed friends, he was genial, sagacious, clear-minded, professionally able, energetic, thorough, sympathetic, conscientious, and fair; such is the record which he has left.

Mr. Hall was elected a Member of the American Society of Civil Engineers on February 6, 1901.

## ALFRED ERNEST HARVEY, M. Am. Soc. C. E.[1]

DIED JULY 3, 1930

Alfred Ernest Harvey, the son of Alfred and Elizabeth George Harvey, was born on September 16, 1869, at Waverly, Ill. He was the eldest of four brothers. His father, who was a teacher in the public schools, moved the family, while the children were still quite small, to Paris, Ill., which was always considered by Mr. Harvey to be his home.

He received the degree of Bachelor of Science from the University of Illinois in 1891, and that of Civil Engineer from the same institution in 1894. His first work after leaving college was on surveys with the firm of Cole, Alvord, and Shields, of Chicago, Ill. Later, he was employed in the office of the Chief Engineer of the Chicago, Burlington, and Quincy Railroad Company as Draftsman, and, still later, was appointed City Engineer of Urbana, Ill. In 1892, he was Assistant Engineer of Sewers and Water Supply for the World's Columbian Exposition at Chicago.

Mr. Harvey's railroad career began in 1895 when he was employed by the Illinois Central Railroad Company as Instrumentman on the lake-front improvement work in Chicago. He was soon made Assistant Engineer in charge of the elevation of the St. Charles Air Line in Chicago, and later given charge of the construction of the Fort Dodge and Omaha Railway, now a part of the Illinois Central System. On the completion of this work he was made Roadmaster in charge of engineering and maintenance at Dubuque, Iowa.

In April, 1902, he left the Illinois Central Railroad Company to become Division Engineer on the Chicago Great Western Railway, with which he was connected until 1905, being actively engaged in maintenance work and the construction of various track extensions. In 1905 Mr. Harvey returned to the Illinois Central Railroad Company as Division Engineer in charge of construction of the Indianapolis Southern Railroad, from Indianapolis to Bloomington, Ind. Following this work, he became Division Engineer of the St. Louis, Iron Mountain, and Southern Railway at Little Rock, Ark.

At this time Mr. Harvey left railroad work and became associated with Mr. R. H. Elzy, of Marshalltown, Iowa, a railroad contractor. This firm handled the construction of double track on the Chicago Great Western Railway from Galena to Stockton, Ill., the extension of various tunnels on the line of the Chicago Great Western Railway, and extensive grading work in the Town of Gary, Ind. On the completion of the latter he again took up railroad work, and was placed by the Northern Pacific Railway Company in charge of station improvement at Billings, Mont. He then returned to the Chicago Great Western Railway Company as Division Engineer, and, later, became Division Superintendent, which position he held until 1911. From the latter company Mr. Harvey entered the service of the Kansas City Southern Railroad Company as Division Engineer in charge of various changes of line and grade then being carried on between Kansas City, Mo.,

[1] Memoir prepared by John V. Hanna, M. Am. Soc. C. E.

and Port Arthur, Tex. His work with this Company being completed, he entered the employ of the Kansas City Railways Company the owner of the street railway system of Kansas City, as Chief Engineer. At the time of his death, he occupied the position of Engineer of Way and Structures with the Kansas City Public Service Company, successor to the Kansas City Railways Company.

Mr. Harvey's position with the Kansas City Railways Company required him to give a great deal of study to the improvement of street railway track, and he developed several new types of construction which are now used extensively throughout the United States. He was considered an authority on this subject and has contributed liberally to various publications interested in work of this character.

He was an active member of the Engineers Club of Kansas City, and was a Past-President of that organization. He was also a member of the Standing Committee of the American Electric Railway Association and, at the time of his death, was President of the Kansas City Section of the Society. He was also a member of, and took an active interest in, the American Railway Engineering Association which, at the instigation of the late John F. Wallace, Past-President, Am. Soc. C. E., his close friend and adviser, he joined soon after its organization.

In 1892 Mr. Harvey was married to Clara Myers, a classmate at the University of Illinois, who survives him. He is also survived by a daughter, Mrs. Harriet Christie, and a son, Alfred Dallas Harvey, both of Kansas City.

He won the respect of his fellow engineers and business associates by his sense of fairness and honesty in his dealings with them. He won the affection of subordinates and equals by a sympathetic interest in their problems, and hearty co-operation in their activities, both at work and at play.

Mr. Harvey was elected a Member of the American Society of Civil Engineers on April 7, 1924.

## HARRY HAWGOOD, M. Am. Soc. C. E.[1]

DIED JANUARY 3, 1931

Harry Hawgood was born in Derbyshire, England, on April 28, 1853. He received his collegiate education and subsequently his engineering training in London, England. Apprenticed, as was the custom there, to one of the famous engineering firms, his training was of the most thorough and practical kind, and to the end of his life he always spoke with respect and affection of the able engineers who were his preceptors at that time.

In 1874, Mr. Hawgood was appointed to the Engineering Department of the Colonial Government Railways of the Cape of Good Hope, South Africa, and for five years he was employed on a wide range of engineering, from the design of bridges and other structures to maintenance of way and executive work. Leaving Africa with the highest commendations of his superiors, he

[1] Memoir prepared by a Committee of the Los Angeles Section consisting of C. R. Sumner, *Chairman*, and George S. Binckley, Members, Am. Soc. C. E.

came to the United States and entered the employ of the Chicago and Northwestern Railroad Company.

In 1881, he took charge of a large party for the Union Pacific Railroad Company, making an extensive reconnaissance through Montana, Idaho, and Eastern Oregon. Those were the years during which the engineers blazed the trails followed by the great transcontinental railroads, and Harry Hawgood was one of the most daring and active of the great railroad engineers of those times. Through wild and unexplored country with the lightest of camp outfits, over treacherous rivers and unknown mountains, for two years, winter and summer, he explored and studied and mapped that vast terrain. After making the location for the Oregon Short Line from the mouth of the Boise River and along the Snake, to the mouth of Burnt River, he began the first survey ever made through the 120 miles of canyon to the mouth of Salmon River. Before this survey was made, the only knowledge of that wild stretch of river was obtained some years before through the hair-raising adventure of a party who had successfully run a small steamer through the canyon during the period of high water. For two seasons Mr. Hawgood was baffled in his undertaking by the insuperable difficulties of the terrain, but during the third year, using such scant data as were furnished by the one party which had gone through before, he built some stout boats for the expedition, and, with these as his sole resource, pushed through successfully, losing but two men as the price of a notable achievement.

Following a year of studies for the improvement of the Oregon Railway and Navigation Company's lines along the Columbia River, and in charge of the construction of the line from Hilgard to Baker City, Ore., Mr. Hawgood entered private consulting practice in Portland, Ore. In this capacity, he was consulted on many railway and other engineering projects, including the Bull Run water supply for the City, and he was Chairman of the Board which passed on the great draw-span of the Willamette River Bridge. He was Consulting Engineer to the Oregonian Railway Company, and after serving as Chief Engineer of the Portland and Willamette Valley Railroad, he became, in 1888, Resident Engineer of the Southern Pacific Lines between Los Angeles, Calif., and El Paso, Tex.

From 1888 to 1894, Mr. Hawgood carried the heavy responsibilities of this position with energy and success. This period was one of the most active in his career, for during this time he was many times confronted with conditions which required instant and correct judgment—such, for instance, as the disastrous floods which devastated Los Angeles County in 1889. Every bridge across the Los Angeles River was washed out, and only a single wire to Chicago, Ill., remained, as communication with the rest of the world; in ten days Mr. Hawgood had restored normal rail traffic. So, again, in 1891, when the Colorado River broke across the desert for the first time known in the history of that region and flooded the Salton Basin, it was Mr. Hawgood who traced its course across the desert to the break.

From 1894, Mr. Hawgood was almost continuously in private consulting practice in Los Angeles. His work covered the field of hydraulics, railway, and harbor works, and in the long fight made by the City of Los Angeles for

the development of a harbor at San Pedro, Calif., his was not less than the greatest contribution. He was indefatigable in his labors in the interests of this harbor, in writing and in personal appearances before influential bodies of engineers. In April, 1896, he went to Washington, D. C., appeared before the Senate Commerce Committee, and was instrumental in the appointment of the Walker Board, which convened in Los Angeles to consider the question of the proposed harbor. Before this Board, Mr. Hawgood presented the technical side of the problem with such effect that it has been justly considered that his influence was probably more important than any other single factor.

Returning to railroad work in 1901, at the request of the late Senator W. A. Clark, Mr. Hawgood accepted the position of Chief Engineer for the location and construction of the San Pedro, Los Angeles, and Salt Lake Railroad, now a part of the Union Pacific System. On the completion of his labors he became Consulting Engineer for this road, and resumed his private practice in Los Angeles in 1905. From that time Mr. Hawgood was often consulted by the City of Los Angeles and other municipalities, was a member of the Board of Engineers Flood Control of Los Angeles County, and was tireless in his efforts to secure the building of a Union Railway Terminal at the Plaza site in Los Angeles. He designed and supervised the construction of the Huacal Dam near Nacozari, Mexico, and the Escondido Dam in San Diego County, California. His knowledge of the climatology and water resources of California was broad and thorough and his services were much sought in water litigation, not only on account of his expert command of the subject of hydraulics and water law, but because of the fact that his ethical standards and rigid integrity gave to his testimony a weight that was recognized by both Bench and Bar.

A quiet and unassuming man, with neither thirst nor talent for publicity, Harry Hawgood was none the less honored by those from whom he desired appreciation. He was a member of the Institution of Civil Engineers of Great Britain, Past-President of the Los Angeles Section of the Society, a member of the American Railway Engineering Association, an Honorary Member of the Southern California Chapter, American Institute of Architects, a member of the Arch Dam Committee, Engineering Foundation, and Chairman of the Test Dam Committee. He was a Director of the Los Angeles Chamber of Commerce from 1897 to 1898, and one of the oldest members of the Jonathan Club. To all these organizations he contributed freely of his services and support, and, in his later years, gave an increasing amount of his time and energy to research.

Such in brief outline is the record of a long, active, and successful professional life; but it is not a portrait of the man.

Harry Hawgood was of a physical type strongly characteristic of his race. Of medium height, with a fine head and brow but lightly furrowed, his face showed the strong strain of Danish ancestry which came down to him from the wild Vikings who first ravaged and then were absorbed by the England of the Ninth and Tenth Centuries. A strong chin and jaw gave more than a hint of courage and firmness. Keen but kindly grey eyes were set under

well-marked brows, and the firm but humorous mouth was shaded by a moustache. Thoughtful, deliberate, well-poised, he was an unforgettable man. Naturalized in 1895, there was not a more loyal citizen, yet to the end (unconsciously perhaps) he remained an Englishman, with all the curious reserve and "stiff-necked" personal pride of the best of his race. He was indeed a fine example of the English gentleman. Of high intellectual qualities, his traditions, education, and reading gave him a breadth of culture and taste that was as admirable as it was rare. His was a questing mind, and he never ceased to learn as the busy years of his life flowed past. There was nothing neutral in his character. Behind the quiet courtesy and consideration which marked his manner, there was plenty of steel if need be—plenty of courage, moral and physical. A man of perfect intellectual integrity, he detested hypocrisy and pretense of every kind. Unobtrusively but firmly he held to his own ideals, but never tried to force them upon others. He was no missionary, no propagandist. Tolerant, philosophical, he lived his own life and let others live theirs in peace. Many were his friends but few his intimates. He felt and appreciated sympathy and understanding, yet his characteristic reserve did not encourage its expression, and in his last years even those closest to him were not allowed to walk quite by his side in the shadow that was closing in.

Mr. Hawgood was married in December, 1897, to Harriet E. McWain, a descendant of one of the old Revolutionary families of Vermont. For thirty years his life with this admirable woman was one of mutual devotion. Those were his happiest and most fruitful years. Indefatigable in his profession, devoted to his home and all it implied, the loss of his wife in February, 1927, was a blow from which he never recovered. Already advanced in years, already warned of his failing health, only those closest to him could see a little through the brave screen of unfailing good cheer and interest in his work, and know the tragedy of his irreparable loss. In spite of an indomitable spirit, however, his strength failed steadily through those few lonely years until, after a brief illness, cheerful and gallant to the last, his life came to a peaceful end on January 3, 1931.

Taken only at the full term of a long and useful life, the passing of Harry Hawgood is none the less a personal loss that will long be mourned by those who knew him.

Mr. Hawgood was elected a Member of the American Society of Civil Engineers on May 4, 1909. He served as a Director of the Society from 1918 to 1920.

## ALLEN HAZEN, M. Am. Soc. C. E.[1]

DIED JULY 26, 1930

Allen Hazen, the son of Charles Dana and Abbie (Coleman) Hazen, was born in Hartford, Vt., on August 28, 1869. He attended the schools of his

[1] Memoir prepared by George W. Fuller, M. Am. Soc. C. E.

native town and the New Hampshire College of Agriculture and Mechanic Arts, from which he was graduated in 1885.

After completing a special course in Sanitary Chemistry at the Massachusetts Institute of Technology in 1888, Mr. Hazen was appointed, on the recommendation of Dr. T. M. Drown, then Chief Chemist of the Massachusetts State Board of Health, to take charge of the Board's Experiment Station at Lawrence, Mass. The Lawrence investigations were a classic pioneering work in the methods of purification of water and sewage from a combined engineering, chemical, and biological viewpoint and did much to direct attention to and confirm the germ theory of disease. With numerous severe epidemics of typhoid fever, this was a critical period in the development of improved water supplies for cities in the United States.

While Mr. Hazen was at Lawrence an epidemic of Asiatic cholera occurred at Hamburg, Germany, and the American public was much disturbed by the appearance of that disease on ships in New York Harbor. Under these stimulating circumstances, the investigations at Lawrence were continued and included extensive studies by Mr. Hazen of methods of measuring the physical properties of sands, gravels, and other materials, and of comparing their suitability for practical use in water or sewage filters. Widespread attention was given to the data of the Lawrence Station which was installed initially to demonstrate the feasibility of disposing of the sewage from the North Metropolitan Sewerage District of Boston on the Saugus Marshes, or otherwise by "land treatment". In fact, the Lawrence results, as contained in the State Board of Health reports for several years beginning in 1890, were regarded as epoch-making in establishing this branch of sanitary science on a sound modern basis; and this view was shared throughout the world, not only by engineers, but by medical health officers and laboratory workers in various fields.

In the design and supervision of construction of the intermittent sand filter for the Lawrence water supply, drawn from the polluted Merrimack River, the late Hiram F. Mills, Hon. M. Am. Soc. C. E., Engineer Member of the Massachusetts State Board of Health, who was assisted in that work by Mr. Hazen, availed himself of various studies and practical tests at the Experiment Station. In fact, the methods of mechanical analysis of sand developed by Mr. Hazen were at once adopted by engineers as standard and have been used almost exclusively since then.

Mr. Hazen's next work was at the World's Fair in Chicago, Ill., in 1893, where he was in charge of the disposal of sewage at the Fair grounds. Following this service he spent a year in Europe in travel and study, including courses in hydraulics and structures at the Dresden Polytechnic Institute.

Soon afterward he entered private engineering practice in Boston, Mass., with the late Albert F. Noyes, M. Am. Soc. C. E., under the firm name of Noyes and Hazen. After Mr. Noyes' death in 1896, Mr. Hazen transferred his offices to New York City, and, in 1897, was engaged in the design and construction of the water filter plant at Albany, N. Y.—the first modern, continuously-operating, slow-sand filter plant in the United States.

In 1904, Mr. Hazen formed a partnership with the late George C. Whipple, M. Am. Soc. C. E., which continued until Professor Whipple's death in 1924. In later years, there were associated with him in this engineering practice, Weston E. Fuller, Malcolm Pirnie, and Chester M. Everett, Members, Am. Soc. C. E., and Mr. L. N. Babbitt.

While in early years water purification was a major item in the practice of the firm, its activities related to all branches of engineering in the fields of water supply and water distribution, especially dams and large pipe lines, as well as valuation work for rate-making and municipal acquisition. Mr. Hazen served a large number of the prominent water departments and water companies in various parts of North America. In 1906, he advised the Water Department of Brisbane, Queensland, Australia.

He was particularly interested in hydraulics and in hydrography, and, in addition to writing many papers on sanitary subjects, made a number of valuable and practical contributions to engineering literature on the subject of run-off of streams. He also wrote several books on subjects of interest to water-works engineers and officials, including "Filtration of Public Water Supplies," "Clean Water and How to Get It," "Meter Rates for Water Works," and "Flood Flows" published in 1930. In collaboration with Gardner S. Williams, M. Am. Soc. C. E., he compiled a volume of "Hydraulic Tables," a book which is in extensive use. He was also Editor of the Water Supply Section of the American Civil Engineer's Pocket Book.

He was very active in the affairs of the Society and frequently contributed papers and discussions to its publications. In 1900, he received the Thomas Fitch Rowland Prize for his paper entitled "The Albany Water Filtration Plant,"[2] and, in 1915, the Norman Medal was awarded to him for his paper entitled, "Storage to Be Provided in Impounding Reservoirs for Municipal Water Supply."[3] He also represented the Society on various committees, several of which are included in the following: Special Committee to Codify Present Practice on the Bearing Value of Soils for Foundations (1916-1926); Joint Committee of Founder Societies Finance Committee on Joint Activities (1926-1927); Vice-Chairman, Executive Committee of the Board of Direction (1927); Honorary Membership Committee (1927); Committee on Soils (1928-1929); National Research Council (1930); and Committee on Dams (1930).

Mr. Hazen was a thorough student who acquainted himself personally with the various details of all his problems. He applied to them an unusually clear insight, and thus drew conclusions quickly and with precision. He had a remarkable aptitude for clear and concise statement both in speech and in writing, to which he added exceptional skill in putting the results of his investigations into simple and practical form so that others could readily make use of them.

The influence of Allen Hazen's leadership in advancing water-works practice during his engineering day and age was unquestionably great. That leadership was due largely to his unusual capacity for clear, straight thinking

[2] *Transactions*, Am. Soc. C. E., Vol. XLIII (June, 1900), p. 244.
[3] *Loc. cit.*, Vol. LXXVII (December, 1914), p. 1539.

on all major elements of an engineering proposition, and to a dominating personality. In whatever he undertook he was practical, sound, progressive, constructive, and tenacious. In his death from heart disease at Miles City, Mont., while taking a combined pleasure and business trip in the West, America lost one of its greatest engineers.

Mr. Hazen was an Honorary Member of the American Water Works Association. He was also a member of many engineering and technical societies in the United States, Canada, England, and France. He received honorary degrees of Doctor of Science from New Hampshire College in 1913 and from Dartmouth College in 1917.

In 1902 he was married to Elizabeth McConway, the daughter of William McConway, one of the leading citizens of Pittsburgh, Pa. He is survived by Mrs. Hazen, four daughters, and two sons.

At its meeting on September 29, 1930, the Board of Direction of the Society adopted the following resolution:

"In the death of Allen Hazen the Engineering Profession has lost a distinguished member who gave generously of his time and energy in its advancement.

"During his 34 years of membership in the American Society of Civil Engineers Mr. Hazen served as Director for 3 years, as Vice-President for 2 years, and on many important committees.

"The Board of Direction, cognizant of his loyal and active interest in the affairs of the Society, his contributions to technical literature, and his exemplification of the highest ethical standards, desires to place on record its appreciation of his services and to pay tribute to his qualities and attainments as a man and an engineer.

"The Board hereby records its deep regret at the loss of Mr. Hazen and extends its sincere sympathy to the members of his family."

Mr. Hazen was elected an Associate Member of the American Society of Civil Engineers on June 3, 1896, and a Member on March 6, 1900. He served as Director from 1907 to 1909 and as Vice-President during 1926 and 1927.

## ALBERT BANKS HILL, M. Am. Soc. C. E.[1]

DIED JANUARY 2, 1930

Albert Banks Hill and his twin brother, Arthur Bradley Hill, were born at Redding, Conn., on May 28, 1847, the youngest of seven children of Bradley Hill and Betsy (Banks) Hill. The family was of old New England stock, having descended from the William Hill, who emigrated from England in 1632, twelve years after the sailing of the *Mayflower*, and finally settled in Fairfield, Conn. It is recorded that "he was a man of note among the Colonists." One of Mr. Hill's grandmothers was a niece of Joel Barlow, LL.D., author, poet, and diplomat.

Mr. Hill attended the common schools of Redding and prepared himself for college with the aid of one term at a private school. He entered the

[1] Memoir prepared by E. M. T. Ryder, M. Am. Soc. C. E.

Sheffield Scientific School of Yale University and was graduated in the Class of 1869, with the degree of Bachelor of Philosophy. One year later he received the degree of Civil Engineer. During that year, in addition to studying, he acted as Instructor in Mechanics and Surveying in the Scientific School, and also began his practical professional work as Assistant on construction of water supply reservoirs for the Town of Danbury, Conn. Mr. Hill was also an Instructor at Yale for the following year, during which period he was at one time Chainman on a construction party for the New York and Boston Air Line Railroad and at another time in charge of a party on preliminary survey for the Saugatuck Valley Railroad.

These connections with the building of original railroad lines show how far back in the engineering history of the United States Mr. Hill's work began. It provides the background for the fact that, during the last years of his life, he typified to his younger colleagues the Profession of Civil Engineering, of which profession he was regarded as the Dean in the State of Connecticut. He was practically the last of that distinguished group of engineers who can never be replaced, whose practice covered nearly the entire field of Civil Engineering. Mr. Hill had a fine record of accomplishment in Railroad, Highway, Hydraulic, Structural, and Sanitary Engineering fields which one or two generations ago would have been covered to a considerable extent by a single person, but which have now expanded so that each has developed into a specialty that can well absorb the life work of an individual engineer.

In 1871, Mr. Hill gave up teaching to enter the Engineering Department of the City of New Haven, Conn., being at first in charge of survey work and then, in the following year, in charge of the Sewer Department. He continued in the City employ and from 1883 to 1892 was City Engineer of New Haven. In 1892 he took up private practice which he continued for nearly forty years, the entire span of his engineering work having covered more than sixty years.

During this period Mr. Hill was active in the civic life of Connecticut and became one of the State's most respected and useful citizens. Particularly marked was the effect of his kindliness and high standard of ethics upon the men in his own profession. As one prominent Connecticut engineer stated, he did "more than any one in this State to elevate the profession of Civil Engineering in the eyes of his fellow citizens."

Some of the works designed by Mr. Hill in Connecticut and executed under his direction as Engineer were: The swing bridge over Norwalk River, at South Norwalk; the steel arch bridges over Mill River, New Haven; over Lake Whitney, Hamden; and over Lieutenant River, Lyme; the suspension bridge over Lake Whitney (270-ft. span), for the New Haven Country Club; the stone arch bridges, East Rock Park; reinforced concrete arches in Cheshire, Hamden, Waterbury, and over Ash Creek, Bridgeport; park drives; the East Rock, West Rock, and Beacon Hill Park Drives, New Haven public park system; part of the New Haven sewerage system; sewerage systems for Danbury and Shelton, Conn.; disposal works for Litchfield, Conn.; outfall system for Greenwich, Conn.; electric railways, Norwalk to South Norwalk, South

Norwalk to Roton Point, Norwalk to Winnipauk, New Haven to Bridgeport, Bridgeport to Fairfield and Southport, New Haven to Derby, New Haven to Cheshire, Cheshire to Waterbury, Cheshire to Milldale, New Haven to Wallingford, New Haven to East Haven, and Palmer to Ludlow, Mass.; and the Manufacturers Electric Freight Railroad, New Haven.

As Consulting Engineer he designed the reservoirs, dams, standpipes, and pipe lines for the New Haven Water Company; the Bridgeport Hydraulic Company; the Birmingham Water Company; the Greenwich Water Company; the New Canaan Water Company; the Noroton Water Company; the Stamford Water Company; and the Water Department of the City of Meriden, Conn.

In 1905 he was President of the Connecticut Society of Civil Engineers and, later, was made an Honorary Member of that organization. He was a member of the following societies and clubs: Graduates Club, New Haven; Chamber of Commerce, New Haven; Connecticut Academy of Arts and Sciences; New England Water Works Association; and of the Finance Committee of the Organized Charities Association of New Haven.

Lacking a family of his own, Mr. Hill devoted almost his entire efforts to engineering work and to his friends in the Engineering Profession. He was one of only two Connecticut citizens who have served as Directors of the American Society of Civil Engineers.

The late Albert L. Webster, M. Am. Soc. C. E., a life-long personal friend, wrote of him:

"His one and only passion was devotion to honest constructive engineering work. The magnitude and importance of the task in hand had no influence on his attitude toward what lay before him for solution. His concentration was on the most faithful and best solution of his problem be it large or small. It was the integrity of his nature practically applied to daily tasks with deliberation and calm. Spectacular projects had no appeal to him. He was always busy, but never hurried, and the long list of his accomplishments bears record of unremitting industry and love of his profession. Vacations to him were but interruptions to the life he loved best, so he took only some few holidays from his office as he felt needful for recreation of body and mind and such as he took were spent in study and contemplation of the engineering work of others akin to some problems of his own or to tramping the countryside in review of possible expansion of water supply services with which he was associated.

"He looked upon engineering as a great and almost sacred calling to be devotedly upheld by serious and honest industry and integrity. Any other point of view he regarded as a traitorous denial of faith.

"His long line of Puritan ancestry with their devotion to duty and the dictates of conscience was reflected in his simple adherence to the faith of his fathers and he retained to the end membership in the Congregational Church of his native town of Redding, Conn., the town of his fathers, and while in New Haven was a consistent attendant at the Congregational Center Church on the green, whose echoes still recall the sturdy preaching of that staunch devotee of the Faith, Dr. Leonard Bacon."

At his death the editorial in the *New Haven Courier Journal*, of January 8, 1930, accurately reflected the feeling of the community. It reads as follows:

"A Faithful Servant and Citizen

"The passing of Albert Banks Hill from the active life of New Haven ought not to be lost in the mere occurrences of the day. His career as a civil engi-

neer is solidly written into the history of New Haven both as it reflects the activities of the local government during many years and as well the activities of private interests who found his talents indispensable. But it is not his professional ability which calls from us a tribute to his memory. That lives in certain achievements of a practical and enduring character. It is to the nature of the man that we desire to pay a delayed compliment. He was a quiet spoken, modest, and sincere man of affairs. What he was called upon to do for public or private interests he did thoroughly. In that respect he was a craftsman of the old school. He threw into his work both as teacher and practitioner the joy of the task. It fed his imagination and gave a personality to his achievement. The generation in which he was educated and trained is passing and the mass principle is affecting the life of to-day. Both as a public servant and a private citizen he possessed virtues which were translated into modest but effective service."

Mr. Hill's death occurred on January 2, 1930, in the eighty-third year of his age. He was active to the last, and had planned to go to his office as usual on the day when he passed on suddenly and quietly.

Mr. Hill was elected a Junior of the American Society of Civil Engineers on February 2, 1876, and a Member on March 5, 1884. He served as a Director of the Society in 1892.

## JOHN WILMUTH HILL, M. Am. Soc. C. E.[1]

DIED JUNE 22, 1930

John Wilmuth Hill, the son of Edmund J. Hill and Amanda Wilmuth Hill, was born at Covington, Ky., on October 10, 1848. He attended the public schools of Cincinnati, Ohio, from 1854 to 1863.

Mr. Hill's practical training in engineering was obtained in various machine shops of Hamilton and Dayton, Ohio, from 1865 to 1874. This early experience assisted him materially when he was called upon to design and supervise the large projects which he brought to a successful conclusion in later life. It was during this period that he was Superintendent and Designer for the firm of Barnett and Herckelrode, manufacturers of waterwheels. From 1866 to 1870 he conducted a model shop and made many models which were sent to the Patent Office at Washington, D. C.

When he was only twenty-six years old (1874), Mr. Hill was selected by the Commissioners of the Cincinnati Industrial Exposition as Chairman of a commission to conduct tests on the Corliss engines on display and to report on their efficiency in operation for purposes of giving them a much coveted award. As an appreciation of the thoroughness of these tests, the Commissioners of the Exposition awarded Mr. Hill a special complimentary Gold Medal which is now in the possession of his only surviving son, Mr. Henry C. Hill, of Cincinnati.

In 1875, the Commissioners of the Industrial Exposition again selected Mr. Hill to conduct tests on engines on display. The unbiased opinions rendered by him on these tests brought him in contact with many builders of machinery, and he was consulted on the operation and design of various plants.

[1] Memoir prepared by Adolph G. Wulff, Civ. Engr., Cincinnati, Ohio.

In 1878, Mr. Hill located in Cincinnati as a Consulting Engineer. During 1880 he invented and patented a system of surface condensation for pumping engines which was adopted by the Holly Manufacturing Company and others, whereby the water pumped under control was used for condensing purposes. The year previous Mr. Hill had invented an automatic grain scale which was adopted by the leading flour mills. At this time he served as one of the Commissioners of the Cincinnati Millers' Exposition, and as an interesting and unusual exhibit persuaded five of the then leading builders of automatic cut-off steam engines to exhibit their products for tests. These engines were approximately of the same cylinder diameters and piston speed. On display were the Harris-Corliss, Reynolds-Corliss, Wheelock, Babcock and Wilcox-Corliss engine, and the Brown and Buckey engines.

At the request of Mr. Harris, of the Harris-Corliss Steam Engine Company, of Providence, R. I., Mr. Hill compiled a 200-page manual for steam engineers. This was published in 1878 and had a circulation of 20 000 copies, some of which are in use at the present time.

Mr. Hill was an ardent student of the purification of public water supplies and early in his career advanced the theory that typhoid fever was essentially a water-borne disease, and the numerous tests, both chemically and bacteriologically, that he made convinced him that the typhoid rate of a city was a criterion of the purity of its water supply. He therefore applied himself diligently to investigations as to the best method of purifying the water supply of a city.

When the City of Cincinnati, in 1896, was ready to plan for the purification of its drinking water, it was with relief that the municipal authorities turned over this work to Mr. Hill who, in conjunction with the late George H. Benzenberg, Past-President, Am. Soc. C. E., of Milwaukee, Wis., and Samuel Whinery, M. Am. Soc. C. E., of Cincinnati, formed a Board of Consulting Engineers, with himself as Chairman, to report on the best method of supplying a purified water to the citizens. Many tests of water from various sources were made, but the Committee reported on a method of slow sand filtration which is now in use in this city. The plans were submitted and approved and with some modifications the works were built at a cost of $14 000 000.

In 1897-98 Mr. Hill conducted a long series of tests on the bituminous coal available for steam purposes in the Cincinnati market, for use at the waterworks. These tests were made under Galloway boilers and embraced the usual tests for commercial purposes. Fifty-five varieties of coal were tested following the procedure of Professor Walter Johnson, of the Navy Yard, Washington, D. C. Subsequently, caloric tests were made of vein samples of New River coal which were found to be equal to the famous Nixon navigation (Welsh) coal for steam purposes and gave it prompt recognition by the United States Navy and Merchant Marine for maritime purposes.

It was in 1898 that Mr. Hill wrote and compiled an octavo volume of more than 300 pages on the "Purification of Public Water Supplies" (Van Nostrand, 1898), which was considered as an authority in those days. In 1900, Mr. Hill became Consulting and, later, Chief Engineer for the improvement and filtration of the water supply of Philadelphia, Pa., a work which

required his exclusive time for six years. During his stay in Philadelphia, he was called upon by the United States Senate Committee on Affairs of the District of Columbia to give evidence as to the best methods for the purification of the Potomac River water, for use in Washington and Georgetown, D. C.

On his return to Cincinnati, he was Consultant on many improvements, notably, the water-works of Hamilton, Ohio, Knoxville, Tenn., Newport, Ky., and others.

Mr. Hill was chosen in 1904, by the Towns of Malden, Melrose, and Medford, Mass., as one of the experts to determine the value of Spot Pond, as a source of supply for part of the Metropolitan Water Supply of Boston and twenty-seven other towns forming the Metropolitan System. In 1905, in association with the late Col. Alex. M. Miller, U. S. A., and Rudolph Hering, Members, Am. Soc. C. E., he reviewed the plans prepared by Morris Knowles, M. Am. Soc. C. E., for the filtration of the Allegheny, Pa., water supply. During this year he was appointed by the Sanitary District of Chicago, Ill., as one of the experts to review the chemical and bacteriological changes in the water of the Chicago Sewage Canal at Lockport, Ill. This was an action *de novo* in the United States Supreme Court by the City of St. Louis and State of Missouri *vs.* the City of Chicago and State of Illinois, to restrain the Trustees of the Chicago Sanitary District from diverting water from the Drainage Canal for sewage dilution purposes.

In 1906 and 1907 Mr. Hill served as Chief Engineer of the old Cincinnati Water-Works preceding the completion for service of the new plant. In 1909, he was selected by the City Council of Hamilton, Ohio, to make a survey and report on the cause and prevention of floods of the Great Miami River at that city. After the serious flood of the Great Miami River in March, 1913, Mr. Hill was selected by the County Commissioners of Butler County, Ohio, to make a new and more extensive survey of the cause of the flood in this county and to report on a plan of relief for the Cities of Hamilton and Middletown, Ohio.

From 1908 to 1924, the major portion of Mr. Hill's time was devoted to the valuation of properties, both public and private, and acting as Adviser in Court proceedings, in such cases as the United Gas Improvement Company, Philadelphia, Pa.; Indianapolis, Ind., Water-Works; Chattanooga, Tenn., Water-Works; Dubuque, Iowa, Water-Works; Mobile, Ala., Water-Works; Baltimore County Water and Electric Company, Baltimore, Md.; Tampa, Fla., Water-Works; Bethlehem, Pa., Water-Works; and many others, totaling in value more than $200 000 000.

Mr. Hill was an ardent student and a great help to all younger engineers with whom he came in contact. He was very active in the civic life of his community. He was a life member of the American Water Works Association (entered 1886); a sometime member of New England Water Works Association, a member of the Franklin Institute, and the National Public Health Association; a member of the Ohio State Board of Health (1910-16); President of the Ohio State Board of Health (1915-19); and a member of the Military Staff of Governor James E. Campbell (1890-91), with rank of Colonel in the State National Guard.

Mr. Hill died at his home in Wyoming, Ohio. The land on which his home is situated has been in the possession of the family of the deceased since 1797, his grandfather, Captain Thomas Wilmuth, having purchased a homestead from the original owner, John Cleves Symmes.

One of the outstanding activities of Mr. Hill's life was the organization in 1907 of the "Schoolmates Club" which brought together annually the members of his class in the Fourteenth District and First Intermediate School. The surviving members were all present at his funeral services.

The esteem in which Mr. Hill was held by the Engineering Profession was well shown by the number of its members that attended his funeral, several of whom came long distances as a mark of respect to their former colleague. It is estimated that more than 20 000 000 people have been and are benefited directly by Mr. Hill's work, and the cost of the projects which he designed would total more than $180 000 000. During his life he published several hundred reports and pamphlets on various branches of engineering, particularly the purification of water supplies, in which he was an acknowledged expert.

In 1872, Mr. Hill was married at Dayton, Ohio, to Emma Jane Walker. He is survived by his son, Henry C. Hill, who was associated with his father for the last thirty-six years, maintaining the same office at 313 Brotherhood Bank Building, in Cincinnati.

Mr. Hill was elected a Junior of the American Society of Civil Engineers on February 3, 1875, and a Member on April 5, 1876.

## ALBERT HARRISON HOGELAND, M. Am. Soc. C. E.[1]

DIED MAY 14, 1930

Albert Harrison Hogeland was born in Southampton, Pa., on January 10, 1858, the son of John and Keziah D. (Willard) Hogeland. His early life was spent on his father's farm, and during this period he attended the public schools in Southampton. He later attended High School in Philadelphia, Pa., and afterward entered Lafayette College, Easton, Pa., from which he was graduated with the degree of Civil Engineer in 1877.

Mr. Hogeland went to St. Paul, Minn., in April, 1879, and secured employment with a surveying party on the St. Paul and Pacific Railway. This railway was just being acquired by the late James J. Hill, F. Am. Soc. C. E., and was the nucleus from which the present Great Northern Railway System has grown. His initial work was as Rodman on the first extension undertaken by Mr. Hill. This was from the northwesterly terminus of the then existing line at Fisher's Landing, Minn., to Grand Forks, N. Dak.

The history of the next few years of Mr. Hogeland's life was similar to that of many young engineers of that period. He took employment wherever railway construction was active, including the following engagements: September, 1879 to March, 1880, Leveler on surveys for a projected line of railway from

[1] Memoir prepared by Oscar S. Bowen, M. Am. Soc. C. E.

St. Paul to Chicago, Ill.; April, 1880, to February, 1882, Leveler, Transitman, and Topographer on the location of the main line of the Northern Pacific Railway, Yellowstone and Rocky Mountain Divisions; February, 1882, to March, 1884, Assistant Engineer for the same Company on the construction of the Bozeman Tunnel; April to September, 1884, Assistant Engineer on the St. Paul, Minneapolis, and Manitoba Railway on construction in North Dakota; and September, 1884, to June, 1885, Assistant Engineer for the Northern Pacific Railway Company on construction on the Wisconsin Division.

In July, 1885, Mr. Hogeland again entered the employ of the St. Paul, Minneapolis, and Manitoba Railway Company, and remained continuously with this Company and its successor, The Great Northern Railway Company, until his death. During these years he held positions, successively, as follows: From July, 1885, to September, 1890, Assistant Engineer on construction and maintenance on lines in Minnesota, North Dakota, South Dakota, and Montana; September, 1890, to August, 1896, Engineer of Maintenance of Way, Eastern District; August, 1896, to March, 1902, Resident Engineer, Eastern District; March, 1902, to February, 1903, Assistant Chief Engineer; February, 1903, to May, 1925, Chief Engineer; and from May, 1925, to the time of his death, Consulting Engineer.

In 1929, Mr. Hogeland planned and supervised the construction of the latest extension undertaken by the Great Northern Railway Company—a branch line in Montana, extending from the Town of Saco on the main line, in a northwesterly direction, 80 miles to the Town of Hogeland, which was named for him.

It will be noted that he was connected with the first and last pieces of line construction thus far carried out by Mr. Hill and his successors in creating the Great Northern Railway System. Of his 51 years of active career, he spent 46 years with the Great Northern Company, the last 45 of which were continuous. He served as Chief Engineer for 22 years and, during this period, planned and supervised the construction of about 2 500 miles of the Great Northern System, as well as extensive betterments.

Some of the larger improvements carried out under Mr. Hogeland's supervision were: Extensive steel and concrete ore-handling docks and grain elevators, at Superior, Wis.; electrification of the old Cascade Tunnel, 2¾ miles long, including the construction of a hydro-electric plant near Leavenworth, Wash., on the east slope of the Cascade Mountains; ocean docks and warehouses at Everett, Wash., and Vancouver, B. C., Canada; and about nine miles of timber and concrete snowsheds in the Cascade Mountains. The Cascade Tunnel and these snowsheds were abandoned in the fall of 1928 on the completion of a new tunnel, eight miles in length. He also supervised the construction of extensive terminal improvements at Seattle, Wash. These included a double-track tunnel under a part of the city, giving the Great Northern Railway an entrance to the city without grade crossings. He also planned and supervised large freight and passenger terminals at Vancouver, B. C.

In addition, his work included a number of freight terminals with the necessary buildings and other facilities; the enlargement and rebuilding of facilities at other terminals; a large number of steel bridges, including a bascule bridge across Salmon Bay, at Seattle, and lift-span bridges across the Missouri and Yellowstone Rivers. He was likewise instrumental in effecting extensive line revisions.

Mr. Hogeland was also Chief Engineer for the Glacier Park Hotel Company, a subsidiary of the Great Northern Railway Company, and supervised the extensive developments of that Company in Glacier National Park, including roads, hotels, and chalets; and one of his latest works was the construction of the Prince of Wales Hotel and other improvements in Waterton Lakes Park, located in Canada, north of and adjoining Glacier National Park.

Seldom does it fall to the lot of an engineer to assume responsibility for the creation of such extensive physical property, and to leave behind such a record of service and accomplishment. This was possible through an unusual capacity for work, persistent, untiring effort, and a great loyalty which his efficient leadership and helpful fairness developed in his associates. Also, Mr. Hogeland had the unusual privilege of close association, during a considerable portion of his career, with Mr. James J. Hill, to whose great vision and remarkable energy is due the creation of the Great Northern Railway System.

The passing of Mr. Hogeland was an occasion for deep regret on the part of a host of associates and friends from the Mississippi Valley to the Pacific Coast. His extended career through this section had given him a wide acquaintance, and one of his strongest characteristics was his ability to form enduring friendships. In his passing the world has lost a most useful citizen, the Engineering Profession, an outstanding member, and his associates, a most helpful friend.

He died May 14, 1930, while still actively engaged in his work. His health had been failing for about a year, but the severe illness which resulted in his death was of only a few days' duration.

Mr. Hogeland was a member of the American Railway Engineering Association, the Engineers' Society of St. Paul, the Minnesota Club, and the Town and Country Club of St. Paul.

He was married on January 10, 1889, to Elizabeth T. Trego, of Newtown, Pa., who, with his daughter, Mrs. John de J. Pemberton, survives him.

Mr. Hogeland was elected a Member of the American Society of Civil Engineers on May 2, 1906.

## HENRY HOLGATE, M. Am. Soc. C. E.[1]

DIED JANUARY 22, 1930

Henry Holgate was born at Milton, Ont., Canada, on September 14, 1863, the son of John and Jane (Browne) Holgate, who were of English descent.

[1] Memoir prepared by M. J. Butler, M. Am. Soc. C. E.

His early education in the public schools and in the High School in Toronto, Ont., Canada, prepared him for an apprenticeship, from 1878 to 1883, to the Northern Railway Company of Canada, under the direction of F. W. Cumberland, Chief Engineer and Managing Director.

On the completion of his service, Mr. Holgate was placed in charge of the Northern Railway and the Hamilton and North Western Railway, both of which were absorbed by the Grand Trunk Railway Company of Canada, under the general management of Sir Joseph Hickson, President of the Grand Trunk, with headquarters in Montreal, Que., Canada, to whom Mr. Holgate reported directly. During the tenure of office under Mr. Holgate, these railways were practically re-built, permanent structures being erected in place of the temporary works. The gauge of the Northern Railway was changed to the standard 4 ft. 8½ in., from the former 5 ft. 6 in., and yards and depots were gradually improved to a fairly high standard. This period extended from 1883 to 1892.

From 1892 to 1894, Mr. Holgate acted as Engineer for the Central Bridge Company at Peterborough, Ont., Canada, designing and building highway and railway bridges and various structures, including the Union Station at Toronto. During the next two years (1896 to 1898), he served as Chief Engineer and Manager of the Montreal, Park, and Island Electric Railways, a suburban system of Montreal, and as Construction Engineer for the Company on suburban electric railways.

From 1898 to 1900, he was Chief Engineer and Manager of the West India Electric Company, of Kingston, Jamaica. He developed power on the Rio Cobre, transmitted it to Kingston, built and equipped twenty-seven miles of electric railway, and also operated it. In 1900, he engaged in general engineering practice, maintaining an office in Toronto. He built the hydro-electric plant for the Canadian General Electric Company, at Peterborough, and constructed the hydraulic work for the Seven Islands Power Company, on the north shore of the St. Lawrence River, 320 miles northeast of Quebec, having previously explored the region and selected the site for the piers, power plant, etc.

From 1901 to 1911, Mr. Holgate was in partnership with Mr. Robert A. Ross, an eminent Electrical Engineer. During this period the firm built a great number of hydro-electric plants, notably for the International Nickel Company, on the Spanish River; the West Kootenay Power Company, in British Columbia; the Sherbrooke Light and Power Company, the Disraeli, the Farnham, and others. In 1907 Mr. Holgate was appointed by the Government of Canada as Chairman of a Commission to report on the causes that led to the Quebec Bridge disaster. He and his associates produced a fearless and masterly report.

When the partnership with Mr. Ross was terminated in 1911, Mr. Holgate again engaged in private practice. His next work of importance was the 180 000-h.p. Cedar Rapids Development, on the St. Lawrence River. In 1915, he prepared and presented a paper on this work[2] before the Canadian Society of Civil Engineers (now the Engineering Institute of Canada), for

[2] "The Hydro-Electric Power Plant of the Cedars Rapids Hydraulic Manufacturing Company, at Cedars, P. Q.", *Transactions*, Canadian Soc. of Civ. Engrs., Vol. 29 (1915), Pt. 1, p. 440.

which he was awarded the Gzowski Medal. He also was engaged on a number of other works, his last outstanding service as a Consulting Engineer having been a report, made in collaboration with Mr. J. A. Jamieson, on the St. Lawrence Deep Waterway Project.

Mr. Holgate was a gentleman of courage and ability, and his death, from a sudden attack of angina pectoris, is a loss to the Engineering Profession. While he did not confine himself to hydro-electric development, he was internationally known as an expert on that subject, and was much sought as a Consultant.

He was a member of the Engineering Institute of Canada, American Society of Mechanical Engineers, and the Engineers Club of Montreal, of which he was a Past-President.

He was married at Milford, Del., on September 19, 1888, to Bessie Bell Headley who, with two sons, Henry W. and Edwin H., survives him.

Mr. Holgate was elected a Member of the American Society of Civil Engineers on October 2, 1901.

## RICHARD LEVERIDGE HOXIE, M. Am. Soc. C. E.[1]

DIED APRIL 29, 1930

Richard Leveridge Hoxie, the son of Joseph and Jacqueline (Barry) Hoxie, was born in New York, N. Y., on August 7, 1844. He came of Colonial stock, both his great-great-grandfather, Lt.-Col. Gideon Hoxie, and his great-grandfather, Lieut. Peleg Hoxie, having served in the Revolutionary Army. He attended schools in New York, Pennsylvania, and Italy, from 1851 to 1858, and was a student at Iowa State University from 1858 to 1861.

At the outbreak of the Civil War Mr. Hoxie enlisted in the First Iowa Cavalry and served as Bugler, Private, and Corporal in Company F of that Regiment from June 13, 1861, to June 9, 1864. While he was still in the Army, he received an appointment as a Cadet at the United States Military Academy, at West Point, N. Y., from Iowa. He entered that institution on July 1, 1864, was graduated third in his class on June 15, 1868, and was appointed on that date as a Second Lieutenant in the Corps of Engineers, U. S. Army. He began his commissioned service with the Engineer Battalion at Willets Point (now Fort Totten), N. Y., where he remained until 1870, when he was transferred to duty on the public works at Boston Harbor, Massachusetts.

In 1872, Lieutenant Hoxie was assigned to duty under the orders of Lieut. George M. Wheeler, Corps of Engineers, U. S. Army, then in charge of the geographical survey of the United States west of the 100th Meridian; he served as Assistant on this work until 1874.

In 1874, Lieutenant Hoxie was appointed Engineer to the old Board of Commissioners of the District of Columbia and served in this capacity

[1] Memoir prepared under the direction of Maj.-Gen. Lytle Brown, Chf. of Engrs., U. S. A., M. Am. Soc. C. E., Washington, D. C.

until 1878, when under the new District of Columbia Government he became Assistant to the Engineer Commissioner. He was promoted to the grade of Captain, Corps of Engineers, in 1882, and remained on duty as Assistant to the Engineer Commissioner of the District of Columbia until 1884. During the last two years of this service he was also on duty in connection with the extension of the Washington Aqueduct for the improvement of the water supply of the National Capital.

In 1884, Captain Hoxie was assigned to duty at Montgomery, Ala., where he remained until 1889 in charge of various river and harbor improvements in Alabama, Georgia, and Florida, and also of the defensive works at Pensacola, Fla. He was then transferred to duty at Willets Point, where he served as Instructor at the Engineer School of Application and with the Battalion of Engineers, until 1893. His next station was at Pittsburgh, Pa., where he was in charge of the improvement of the Allegheny and Monongahela Rivers until 1897. He reached the grade of Major in the Corps of Engineers in 1895.

In 1897, Major Hoxie was transferred to duty at Portland, Me., in charge of river and harbor and fortification works in Maine and New Hampshire, where he remained for about one and one-half years. In 1898 he was assigned to duty as Engineer Secretary of the Lighthouse Board, in Washington, D. C.

He served with the Lighthouse Board until 1901 when he was sent to St. Paul, Minn., in charge of the works of river and harbor improvement in that District. In 1903, Major Hoxie was transferred to Baltimore, Md. His duties in Baltimore consisted of river and harbor improvements and fortification work and, in addition, he served as Engineer of the Fifth Lighthouse District and as a member of the Board of Engineers for Rivers and Harbors. He reached the grade of Lieutenant-Colonel, Corps of Engineers, in 1904, and that of Colonel, in 1907. On August 7, 1908, while still on duty at Baltimore, having reached the statutory age of retirement—sixty-four years—he was placed on the retired list of the Army, with the rank of Brigadier-General.

General Hoxie's service to his country was practically continuous over a period of nearly half a century. It began when as a boy, at the outbreak of the Civil War, he responded to the call for volunteers. He was the last member of that group of officers of the Corps of Engineers who had active service in the field during the great conflict of 1861-65. He participated in the explorations which gave to the people of the United States the first accurate information of the territories of the Far West, a vast area that sixty years ago was practically *terra incognita*. His services as City Engineer in Washington, then at the beginning of its development, were characterized by foresight and engineering skill. Much of the sewer and water systems, and many of the streets which serve the people of the Capital City to-day, were planned and built by him more than fifty years ago.

In 1873, General Hoxie made a visit to Florida and at that time realized its advantages as a winter resort. He was a close friend of Mr. Henry M. Flagler, who later developed the east coast of Florida and built the Florida East Coast Railway.

After his retirement, General Hoxie spent part of each year in Washington, in his boyhood home in Iowa City, Iowa, and in Miami, Fla., where he maintained a winter home. He died in Miami, and his remains were brought back to Washington, where, after a simple service in his home, his ashes were placed in the Arlington National Cemetery, the last resting place of an ever-increasing company who have served their country loyally and well.

General Hoxie was married on May 28, 1878, to Vinnie Ream, the celebrated sculptress, who died on November 20, 1914, leaving one son, Richard Ream Hoxie. On April 30, 1917, he married Mae Ruth Norcross, who, with his son, survives him.

General Hoxie was a member of the Grand Army of the Republic, the Sons of the American Revolution, the Loyal Legion, and of the Metropolitan, Army and Navy, and Cosmos Clubs of Washington. At one time he belonged to the Duquesne Club of Pittsburgh and the University Club of Baltimore.

General Hoxie was elected a Member of the American Society of Civil Engineers on June 2, 1886.

## WILLIAM HAUSMER HOYT, M. Am. Soc. C. E.[1]

DIED NOVEMBER 10, 1927

William Hausmer Hoyt was born at Owatonna, Minn., on October 13, 1867, the son of Americus V. and Catherine A. (Colvin) Hoyt. The family moved to Minneapolis, Minn., in 1870. He was educated in the public schools of Minneapolis, was graduated from the University of Minnesota as Bachelor of Civil Engineering in 1890, and received the degree of Civil Engineer in 1895. He was a member of the Sigma Chi Fraternity.

Mr. Hoyt spent the summer of 1888 as Instrumentman for the Chicago and Great Western Railway Company, and that of 1889 in charge of a party on general surveying for a firm in Duluth, Minn. Duluth was then in the early stages of its development into a great transportation center. To this development almost all of Mr. Hoyt's professional life was devoted.

He spent the first year after his graduation in charge of street grading, paving, and the construction of a water system and sewer system for Lakeside, now a part of Duluth; for the next two and one-third years he was in charge of the installation of machinery, and the construction of about twenty miles of line for the Duluth Street Railway Company; he then spent more than three years as Assistant Engineer of the Duluth and Iron Range Railroad Company in charge of the location and construction of lines on the Vermilion and Mesabi Iron Ranges; this was followed by six months on road construction for St. Louis County.

From June, 1897, to December, 1900, Mr. Hoyt was Junior Assistant Engineer under the U. S. Engineer Office, at Duluth, on the construction of the Presque Isle Breakwater, at Marquette, Mich. (1897); on harbor improvements

[1] Memoir prepared by a Committee of the Duluth Section consisting of O. H. Dickerson, W. A. Clark, and W. E. Hawley, Members, Am. Soc. C. E.

at Ashland, Wis. (1898); and on the construction of the foundation for the harbor entrance at Duluth (1899 and 1900). From January, 1901, to April, 1903, he was Principal Assistant City Engineer of Duluth in charge of all construction.

In April, 1903, Mr. Hoyt began his work as Assistant Engineer of the Duluth, Missabe, and Northern Railway Company, and continued with this Company until his death. In January, 1905, he was made Assistant Chief Engineer in charge of all construction work, maintenance of way and bridges, buildings, ore piers, and coal piers. He became Chief Engineer in February, 1920, and was elected a Director of the Railway Company on July 1, holding both positions until his death.

During the years of his service, the Duluth, Missabe, and Northern Railway Company completed a great amount of construction work, building a large coal-receiving pier, three large ore piers, one of wooden construction, and two of steel and concrete, besides an extensive program of new lines, numerous bridges, and double-tracking. A large car shop and roundhouse and many other projects were also constructed.

Mr. Hoyt's ability and zeal were widely recognized in the Society, and at the time of his death he was prominently mentioned as a candidate for Director from his District. He was active in promoting the regular monthly meetings of local members of which the first was held on November 17, 1914, and from which the Duluth Section of the Society was organized on April 17, 1917. On July 15, 1918, the Section appointed him its Representative on the Committee of Development of the Society, of which he was a very active, devoted, and progressive member.

Believing with many other engineers that the profession should secure much greater public recognition, he gave much thought as to how this could be done. Two methods often have been suggested, namely, more effective organization of engineers, and the more general and active participation of the engineer in public affairs.

Mr. Hoyt was an outstanding pioneer and leader in the more effective organization of the entire Engineering Profession, and he exemplified for many years of his life, in a very remarkable way, that part of the Code of Practice of the Society which refers to the relations of the engineer with the public.

At the Annual Meeting of the Minnesota Surveyors and Engineers Society, at Duluth, early in 1912, he suggested the formation, by co-operative action, of a body which could effectively represent all the architectural and engineering organizations of the State.

In 1915, he and five other leaders in six of the engineering organizations of the State formed a voluntary body which, in 1916, became the Minnesota Joint Engineering Board officially representing these organizations. He was a leader in the work of this Board and in the planning for its development into the present Minnesota Federation of Architectural and Engineering Societies, which very efficiently represents 10 member organizations with a total of about 1 000 members of the professions in the State.

He was also active in forming the Duluth Engineers' Club, in 1918, and served five years as its first representative on American Engineering Council.

Mr. Hoyt was an active member of the American Railway Engineering Association, serving four years as Chairman of Committee VII—Wooden Bridges and Trestles. He was the first Chairman of the Duluth-Superior Joint Harbor Commission, appointed by the Governor of Minnesota, and was long active in the Duluth Chamber of Commerce. At the time of his death he was Director-Chairman heading three groups: The Legislation and Taxation Committee, the Safety Bureau, and Public Health.

He was a member of the First Presbyterian Church of Duluth and was Chairman of its Board of Trustees. He had also served as a member of the State Committee of the Young Men's Christian Association for several years.

Mr. Hoyt was an active member of all the Masonic bodies, having been a Thirty-third Degree, Scottish Rite Mason, Past Master of Palestine Lodge No. 79, a member of Duluth Commandery, Knights Templars, and a Noble of Aad Temple of the Mystic Shrine.

He was married to Jessie May Nicol, at Minneapolis, on October 3, 1895. Mrs. Hoyt, with a son, Allen N., and a daughter, Margaret Helen, survives him.

Mr. Hoyt was elected a Member of the American Society of Civil Engineers on June 30, 1911.

## MARION COLUMBUS HUCKABY, M. Am. Soc. C. E.[1]

DIED AUGUST 13, 1930

Marion Columbus Huckaby was born near Coushatta, La., on July 22, 1889, the son of M. P. C. Huckaby.

He attended the public schools of his native State, the Polytechnical Institute, at Ruston, La., and, in 1914, received the degree of Bachelor of Science, from the Louisiana State University. Subsequently, he took a post-graduate course at Columbia University, New York, N. Y., and, in 1917, he received the degree of Master of Science.

On the completion of his college course, at the age of 28 years, Mr. Huckaby entered the United States Army, at Fort Sam Houston, San Antonio, Tex. After a short period, he was transferred to Fort Scott, San Francisco, Calif., and, later, to Fort Ward, Washington, ranking at the close of the war as First Lieutenant, Coast Artillery. He was ordered overseas, just prior to the signing of the Armistice.

In civil life, Mr. Huckaby had the following engineering connections: The Illinois Highway Department, the Missouri Highway Department, and the Louisiana Highway Department. For a limited time, he was in private practice at Baton Rouge, La., later becoming identified as Engineer Representative of the Southern Surety Company, with headquarters at St. Louis, Mo. For more than a year previous to his untimely death, he was associated with the U. S. Fidelity and Guaranty Company, with headquarters at Oklahoma City, Okla.

Aside from his technical ability, Mr. Huckaby had a pleasing personality, and a disposition to co-operate in the betterment of the Engineering Profes-

[1] Memoir prepared by James C. Travilla, M. Am. Soc. C. E.

sion and to aid in local civic affairs. He was a member of the Engineers Club of St. Louis; the American Legion; the Oklahoma City Chamber of Commerce; and the Modern Woodmen of the World. He was also a Thirty-second Degree Mason and a member of the Presbyterian Church, at Normandy, Mo.

Mr. Huckaby's death was most distressing to his family, friends, and associates, as he was killed in an airplane crash at the Municipal Airport, Oklahoma City, on August 13, 1930.

On June 8, 1918, at Seattle, Wash., he was married to Urath Dorsey McCall. Mrs. Huckaby, two daughters, and a son, survive him.

Mr. Huckaby was elected a Junior of the American Society of Civil Engineers on October 9, 1917, an Associate Member on April 19, 1920, and a Member on April 21, 1925.

## HECTOR JAMES HUGHES, M. Am. Soc. C. E.[1]

DIED MARCH 1, 1930.

Hector James Hughes was born on October 23, 1871, at Centralia, Pa. His parents were James H. and Mary (Miller) Hughes. He was prepared for college partly at the public schools of Williamsport, Pa., partly by a tutor, and partly by his private studies. For more than two years before entering Harvard College, he worked as a clerk. His studies, which gave no indication of his coming career, were mainly the Classics, German, French, English, History, and Economics. In 1894, when he was graduated from Harvard College, with the degree of Bachelor of Arts, he received Honorable Mention in the last named subjects.

Immediately following his graduation Mr. Hughes accepted a position as a Rodman in the office of the Chief Engineer of the Town of Brookline, Mass. He worked in this capacity until the fall of 1897, by which time he was entirely sure of his profession, for he then registered in the Lawrence Scientific School of Harvard University as a third-year student in Civil Engineering, receiving the degree of Bachelor of Science in 1899. He also served as Assistant in Mechanics in 1898 and 1899. He then accepted a position in the office of the Chief Engineer of the Chicago, Burlington, and Quincy Railroad Company, in Chicago, Ill., and, in 1900, was assigned to take charge of certain pieces of construction work in Iowa. From April to August, 1902, he was employed by the American Bridge Company, at Pittsburgh, Pa.

In the fall of 1902 Mr. Hughes was appointed Instructor in Hydraulics at Harvard University and from that time made Cambridge, Mass., his home. His successive appointments in his chosen field were as Assistant Professor of Hydraulics and Sanitary Engineering, 1903 to 1908; Assistant Professor of Civil Engineering, 1908 to 1913; Associate Professor of Civil Engineering, 1913 and 1914; and Professor of Civil Engineering, 1914 to 1930. From September, 1906, to 1911, in addition to his teaching, Professor Hughes was a member of the firm of Burke and Hughes, Consulting Engineers, of Cambridge.

Professor Hughes' contributions to the science of engineering include "A Treatise on Hydraulics" (with A. T. Safford, M. Am. Soc. C. E.), "Roads and

[1] Memoir prepared by Theodore Reed Kendall, M. Am. Soc. C. E.

Toll Roads in America", "Highway Engineering Education", and two articles on roads for the Cyclopædia of American Government. He was a member of many scientific bodies, including the American Society for Testing Materials, the International Navigation Congress, the Society for the Promotion of Engineering Education, the Boston Society of Civil Engineers, the National Association of State Highway Officials, the American Society for Municipal Improvements, and the American Road Builders Association. He was also a Fellow of the American Association for the Advancement of Science, a member of the American Academy of Arts and Sciences, and the Harvard Engineering Society. He was a member of the Harvard Club, of Boston, Mass., of the Oakley Country Club, Belmont, Mass., the Woods Hole Golf Club, at Woods Hole, Mass., and the Kittansett Club, Marion, Mass.

Professor Hughes was a regular attendant at the Annual Meetings of the Society and made frequent trips to New York City to attend the meetings and the Annual Dinners of the Harvard Engineering Society, in the development of which he showed constant interest.

Hector James Hughes was distinguished chiefly as an administrative officer. His executive capacity was first evidenced by the conspicuous success of his administration of the Harvard Engineering Camp, at Squam Lake, N. H. This led to his appointment as its Director in 1909, an appointment which he held until the close of his life. The many students who subjected themselves to the hard work and rigid discipline of the camp, look back with satisfaction on that experience.

During the life of the co-operative agreement between Harvard University and the Massachusetts Institute of Technology, Professor Hughes, with other Harvard professors, gave instruction at the Institute. On the establishment of the Harvard Engineering School, in 1919, he was appointed Chairman of the Administrative Board and, in 1920, was appointed Dean of the School. He held this appointment until his death.

The record of Hector James Hughes as Dean is one of faithful devotion, of sanity, and of clarity of mind in meeting the problems of re-establishing and developing the Harvard Engineering School; of a quiet insistence on the maintenance of the highest ideals in the work of the School; of firmness, understanding, and sympathy in his relations with students; and of unfailing helpfulness in his contacts with his colleagues.

On April 15, 1902, he was married to Elinor Lambert, of Cambridge, who, with their two daughters, Katharine Porter and Elinor Lambert, survives him.

The following appreciation of Professor Hughes appeared in the Harvard Engineering Society *Bulletin*, for April, 1930:

"A Soldier has gone West.

"He might have spared himself and enjoyed his one recreation—golf—and remained with us for a score of years, but that was not his way. He stayed at his post until it was too late to reinforce his ebbing strength.

"Few of us have known the real Hector James Hughes until the last few years when we began to realize the burdens he had assumed. It was his aim to relieve the other members of the Faculty as much as possible of all administrative work, taking unto himself those labors that the staff might give itself unstintingly to teaching. We know that the success of the Harvard Engineering School is in large measure due to Dean Hughes' administrative zeal.

"Dean Hughes' memory will stand as a guiding beacon to all Harvard engineers, an example of determination and faithful performance of duty as he saw it."

The *Harvard Alumni Bulletin*, of March 13, 1930, carried the following words of appreciation:

"In the death of Dean Hughes, the University has lost a leader whose guiding hand was greatly needed in the further development of its instruction in engineering. Of the personal bereavement his passing brings to friends and colleagues in the University and the profession, this is not the place to speak at length. There was in him a kind of honest sweetness, a slightly quizzical kindliness and faithfulness in the performance of the day's work, that endeared him to all with whom he came into continued contact. He took his tasks and problems seriously and brought to them great clarity of mind and an essential common sense; but he had in him, nothing of the showman or the propagandist. His was a leadership that was especially of value under the circumstances which have attended the growth of the Engineering School since 1920.

"The task he faced [in re-organizing the Harvard Engineering School after 1918] had in it unusual elements of difficulty. A great co-operative plan had been abandoned because of legal difficulty under the McKay bequest. The Engineering School was thrust back into the University as an undergraduate department and it had to find itself anew. The Dean had to re-unite the Faculty that had been merged for a time into a larger and more complex organization and thus in part disrupted. The business of building technical curricula for undergraduates and yet maintaining close connections with Harvard College had to be safely and expeditiously accomplished. There were courses to be organized, men to seek, machinery to set up and rehabilitate, and students to attract without a falling off in standards. The McKay endowment gave to the School the promise rather than the reality of affluence. The whole enterprise had to be reconceived, established on a permanent and satisfactory basis, and made to commend itself by its results.

"Into the complexities of this situation Dean Hughes brought a patient, painstaking, experimental industry. The School made no dramatic moves, but it went forward quietly, steadily, and continuously. It faces now its greatest problem. Just as Harvard College was taking on a new character under the House Plan, with resulting perplexities as to the disposition of the undergraduates in engineering, the School has been robbed of a leader who had won affection, respect, and confidence in every quarter. It is hard to estimate the debt it owes to his watchfulness and insight."

Professor Hughes was elected a Member of the American Society of Civil Engineers on May 3, 1905.

## JOHN EDWARD JENNINGS, M. Am. Soc. C. E.[1]

DIED MARCH 27, 1929

John Edward Jennings was born in Brooklyn, N. Y., on April 18, 1875, the son of John S. Jennings and Mary A. (Sigsworth) Jennings.

Mr. Jennings attended the Brooklyn Public Schools until he reached the age of fifteen. At this time he secured a position in the Construction Department of the Central Railroad Company of New Jersey. While so employed he

[1] Memoir prepared by a Committee consisting of Messrs. Theodore M. Avery, and R. D. Coombs, and E. M. Van Norden, M. Am. Soc. C. E., and E. J. Staubitz, Assoc. M. Am. Soc. C. E.

continued his studies at Cooper Union, from which institution he was graduated in 1896. His efforts resulted in a rapid promotion, and when he left the employment of the railroad (in the year of his graduation from Cooper Union), he held the position of Rodman.

Subsequently, Mr. Jennings was employed in the Drafting Rooms of the Berlin Iron Bridge Company, the Elmira Bridge Company, and the Dominion Bridge Company; he also was associated with the firms of Post and McCord and Levering and Garrigues. In 1898, he entered the employ of Milliken Brothers, Incorporated, as Draftsman and Checker. His ability soon placed him at the head of a squad having complete charge of detailing many large hotels, office buildings, and similar structures. His supervision also included mill buildings of various kinds, including some of the largest sugar-mills in the Hawaiian Islands. In 1901, Mr. Jennings received further recognition by being placed in complete charge of the Designing Division of the Company. He continued in this capacity until 1906, during which period he supervised and controlled the design of many large structures. From 1906 until 1908, he held the position of Assistant Chief Engineer.

In 1908, steel towers for supporting high-tension transmission lines came into prominence. The investigations, testing, and developments of these structures were put under the supervision of Mr. Jennings. His investigations and testing of full-sized structures led to the conclusion that the accepted methods of design were unsatisfactory. He introduced many new ideas in reference to loadings, safety factors, and working stresses to govern the design. While progress has demanded some modifications, it is a tribute to his exceptional ability and far-sightedness that his fundamental principles still govern the design of many of the present-day transmission-line structures.

When radio became a commercial possibility, Mr. Jennings quickly realized the necessity of structures for supporting the antennæ. With his wide experience in the transmission field he was in an excellent position to undertake the studies of these structures. He developed a standardized design of tower which proved highly satisfactory, and is now used at many of the important wireless stations throughout the world, including many of the broadcasting stations in the United States.

In 1918 he became Vice-President and Chief Engineer for Milliken Brothers Manufacturing Company, Incorporated. While in this position he was frequently consulted by many of the large power companies and syndicates, as well as by the Government of Norway. His work in connection with the tower designs for the Norwegian Government called him from the United States in 1920 and resulted for him in a trip around the world for a study of transmission-line conditions and construction. His travels led him to Australia, where his skill made itself evident in the design of the 100-mile transmission line extending from Melbourne to the Morwell brown-coal fields. In addition to work in the transmission and radio tower field, he was also responsible for the design of towers used for supporting the cableways in Colombia.

A few of the outstanding operations with which Mr. Jennings was connected were: Transmission towers for the Great Western Power Company; the

Southern California Edison Company (Big Creek Line); the Utah Power and Light Company; the Pacific Gas and Electric Company; the Montana Power Company; Southern Power Company; the American Gas and Electric Company; the Nevada-California Power Company; the Ebro Power Company, in Spain; Victoria Falls, South Africa; the Norwegian Government; the Nipon Electric Power Company; the São Paulo Tramway, Light and Power Company, in Brazil; and many others.

He was also responsible for major engineering work in connection with the electrification of the South African Railways; the Great Indian Peninsular Electrification Scheme; the Perak River Hydro-Electric Development; and the Central Scotland Electricity Development. Other important work under his charge included the Gammarra Cucuta Cableways, Cable del Norte, and Cable del Choco, all of which are in Colombia, South America.

Mr. Jennings was held in high esteem by his associates and employees. His fine character and ability resulted in a world-wide circle of friends. His passing has left a deep sense of loss to those who have been privileged to be associated with him in any way during his career. He was an active member in the Brooklyn Engineers' Club until his work required extensive travel abroad. He was also a member of Kane Lodge, F. and A. M., as well as the Royal Automobile Club of London.

Mr. Jennings was elected an Associate Member of the American Society of Civil Engineers on November 30, 1909, and a Member on December 3, 1913.

## PETER JUNKERSFELD, M. Am. Soc. C. E.[1]

DIED MARCH 18, 1930

Peter Junkersfeld was born at Sadorus, Ill., on October 17, 1869. He was graduated from the University of Illinois in 1895, with the degree of Bachelor of Science in Electrical Engineering. His scholarship was excellent and he was made a member of Tau Beta Pi, the Engineering Honor Fraternity, Editor of *The Technograph*, and was generally prominent in student activities. In 1909, after presenting his thesis, he was awarded the degree of Electrical Engineer. From 1911 to 1913 he served as President of the University of Illinois Alumni Association.

Subsequent to his graduation Mr. Junkersfeld went to work in Chicago, Ill., for the Chicago Edison Company (now the Commonwealth Edison Company) with which he occupied a very insignificant position. He later became identified with the Engineering Department and was a Mechanical Engineer. Afterward, as Electrical Engineer, he was Assistant Vice-President in charge of engineering and construction.

The Commonwealth Edison Company, being a pioneer in the development of the steam turbine for use in central stations, sent Mr. Junkersfeld to England, in conjunction with the firm of Sargent and Lundy, to study the mechanical features of the steam turbine. He was closely identified with

[1] Memoir prepared by M. J. Whitson, M. Am. Soc. C. E.

this great development from its very beginning in the United States until the end of his activities.

When the Officers' Reserve Corps of the Army was organized Mr. Junkersfeld was one of the first to be commissioned as Major in the Army Engineers Corps and during the emergency in 1917 when the United States entered the World War, he was one of the first to be called into active service. He was assigned to the Construction Division of the Army, an emergency organization operating directly under the Secretary of War for the construction of camps, cantonments, embarkation camps, and army bases and terminals. He was promoted to the rank of Lieutenant-Colonel and, later, to that of Colonel. In August, 1918, he was awarded the Distinguished Service Medal for his services.

During his two years' service in the Army, due to his training, his superior judgment, his great energy, and lovable character, Colonel Junkersfeld was able to perform a service in the Construction Division which perhaps should be credited as the greatest performed by any single officer. The work of this Division in providing facilities and quarters for the training of the troops and for the assembling and expediting of supplies, was very great, and Colonel Junkersfeld was called upon to give the best that was in him in these emergencies.

In 1919, he was selected as Engineering Manager for Stone and Webster and was made Vice-President of the Division of Engineering and Construction. Two years later, with Mr. W. McClellan, he organized the engineering firm of McClellan and Junkersfeld. This firm did a large engineering and construction business, among its projects being the $35 000 000 Cohokia Power Plant, at East St. Louis, Ill.

During the last two years of his life, in addition to his association with McClellan and Junkersfeld, Colonel Junkersfeld was Vice-President of the Stone and Webster Engineering Corporation.

Colonel Junkersfeld was a Fellow of the American Institute of Electrical Engineers; a member and Past Vice-President of the Western Society of Engineers; President of the Association of Edison Illuminating Companies, in 1916-1917; and First President of the Construction Division Association. He was a member of the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, the Franklin Institute, the National Electric Light Association, and the American Electric Railway Association, as well as of the following clubs: The Chicago Athletic Club, the University Club of Chicago, the Illini Club of Chicago and New York, the Engineers' Clubs of Chicago and New York, the New York Lawyers Club, and the Scarsdale Country Club, at Scarsdale, N. Y.

He was the author of many technical papers. Among these is included "General Review of Current Practice in Steam Generating Stations", of which George A. Orrok, M. Am. Soc. C. E., was co-author, and which was presented at the first World Power Conference in London, England, in 1924.

Peter Junkersfeld, born in the heart of the Middle West of sturdy and substantial parentage, learned the principles of perseverance and honor on an

Illinois farm. He sought higher education at the University, at Champaign, Ill., and afterward during his entire life he was identified with its activities and those of its alumni organizations. When his life was ended, the President and Deans of the University assembled as honorary pall bearers when he was taken to his final resting place at St. Mary's Cemetery, in South Champaign.

During his entire life Colonel Junkersfeld was extremely fond of engineering. He pursued and developed its technical phases, and applied it in its general scope to the large business enterprises with which he was connected.

Even above his love for his profession was his spirit of responsibility as a citizen. As stated, he left his responsibilities with the Commonwealth Edison Company to help the United States when the great emergency arose in 1917. Serving without personal consideration, he gave himself completely to the service of his country. His character was without blemish. To know him was to be his friend—he had no enemies.

On June 19, 1901, he was married at Champaign, Ill., to Anna C. Boyle, who, with two daughters, Florence Rita and Mary Josephine, survives him.

Colonel Junkersfeld was elected a Member of the American Society of Civil Engineers on June 16, 1919.

## THOMAS PEARSON KINSLEY, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 23, 1930

Thomas Pearson Kinsley was born in Manchester, N. H., on October 11, 1845, the son of Benjamin and Eliza Ann (Pearson) Kinsley. His early education was received in the public schools of his native city. At the age of thirteen years he entered the Engineering Department of the Portsmouth and Concord Railroad Company on the preliminary surveys for changes of its lines, and continued with the road during its construction. He remained with the Chief Engineer of the Concord Railroad Company (which had absorbed the Portsmouth and Concord Railroad Company) for about six years, on the construction of its various lines, and on city surveys. During this period he rose to the grade of Transitman and Leveler.

In 1864 Mr. Kinsley entered the Chandler Scientific Department of Dartmouth College, with advanced standing, so that he was graduated in two years (1866) with the degree of Bachelor of Science. During two vacations from Dartmouth, he acted as Leveler on the preliminary surveys for two railroad lines.

After his graduation Mr. Kinsley was employed in August, 1866, as Rodman by the Brooklyn (N. Y.) Park Commission, but was promoted in the following month to be a Leveler on the First Division under the late Wilson Crosby, M. Am. Soc. C. E. In the spring of 1868, Mr. Kinsley was promoted again to be Assistant Engineer in charge of the construction of Fort Greene Park, remaining with this work until it was suspended in November, 1869.

[1] Memoir prepared by Herbert C. Keith and Edward Gagel, Members, Am. Soc. C. E., and Robert Ridgway, Past-President, Am. Soc. C. E. Mr. Gagel died on February 11, 1931.

In later years it was a great pleasure to him to recall his experience on this work.

After an interim of nine months, during which he was employed by the Peteler Portable Railroad Company as Engineer, General Foreman, and Paymaster, Mr. Kinsley returned to the Park Commission as Division Engineer in charge of the construction of the East (or Jamaica) Parkway, of Douglas and Degraw Streets, the widening and extending of Washington Avenue, and the improvement of the East Side Lands.

In 1876, he left the employ of the Brooklyn Park Commissioners to become Chief Engineer of the Brooklyn, Flatbush and Coney Island Railroad (later known as the Brighton Beach Line), on its construction from the Brighton Beach Hotel, at Coney Island, to a junction with the Long Island Railroad at Atlantic Avenue near Flatbush Avenue, in Brooklyn. Recognizing the danger of a stairway in a crowded public passage in case of a panic, Mr. Kinsley was led to question the advisability of using stairs for the approach to the tracks at the Atlantic Avenue Terminal. Later, in 1883, his fears were justified by an accident of this nature on the Brooklyn Bridge, resulting in a serious loss of life. Crude experiments with a drawing-board supported by blocking at one end to give different grades, led to the construction of a ramp with an 8% grade, which grade later became a recognized standard for footwalk ramps where no special non-slip pavement was used. It is supposed, also, that it was on this road, under Mr. Kinsley's direction, that concrete was used first for the rim, track, and center of a railroad turn-table.

After the completion of the Brighton Beach Line in 1879, he was engaged for several years on railroad construction in New York State (the Delaware, Lackawanna and Western Railroad), Delaware, Maryland (the Western Maryland Railroad), and in South Carolina, New Hampshire, and Massachusetts (the Massachusetts Central Railroad). He was a member of a firm that rebuilt fifty miles of the Chesapeake and Ohio Canal, and, in 1890, constructed about thirty miles of electric street railway in Baltimore, Md.

For about two years, from May, 1900, to 1902, Mr. Kinsley was Engineer for L. B. McCabe and Brother, Sub-Contractors for 3½ miles of New York City's first Rapid Transit Subway (Sections Nos. 13 and 14, from 133d Street to Hillside Avenue), and he continued on this work for a number of years following the sub-contractor's retirement from it. The first actual construction work for this pioneer subway except for certain auxiliary structures like sewers, etc., was on this Section No. 13. Mr. Kinsley was himself the subcontractor for the concrete foundations of a mile of elevated structure connected with that subway. In 1910 and 1911, he was Superintendent for the Bonticou Stone Company which operated a quarry on the slope of the Shawangunk Mountains for furnishing the stone required for the construction of nine miles of the Catskill Aqueduct.

From 1911 to 1923 (when he retired from the active practice of his profession), he was Contractor and Engineer on landscape work in beautifying numerous private estates—largely in the vicinity of Cleveland, Ohio.

Mr. Kinsley was married on November 16, 1871, to Marion O. Blake, of New York, N. Y., who, with their two daughters, Mrs. F. Taylor Woodruff, of New Haven, Conn., and Mrs. Edwin L. Findley, of Cleveland Heights, Ohio, survives him. After his retirement, he and Mrs. Kinsley made their home with the Woodruffs in Leroy, N. Y., and in New Haven.

He was much interested in the promotion of knowledge of United States history; this led him to join the Brooklyn, Maryland, and New Haven Historical Societies during his residence in those several localities. Mr. Kinsley was a member also of the New York Railroad Club, the American Forestry Association, and the National Geographic Society. He was a member of the Phi Zeta Mu Fraternity (now Sigma Chi) of Dartmouth College.

He was an earnest Christian, being at the time of his death a member of the Euclid Avenue Congregational Church, of Cleveland, where formerly he had made his home for several years. His was a Christianity that made his life a benediction to all with whom he came in contact, whether in business or in social life. The affection for him that is shown by those who have worked under, beside, or over him, and by those who knew him only after the close of his active engineering life, is wonderful. Ample confirmation is found for the testimony given in the weekly calendar of the Euclid Avenue Church after his death: "He brought to us a life singularly fine, generous, and inspiring. 'So he passed over, and all the trumpets sounded for him on the other side'".

One of his former engineering associates writes,

"He was a man of most likable personality and very enthusiastic about his work; and his ability commanded the respect of his associates. It is hard to measure the value to the world of such a man."

To one who knew him only after he said that he had ceased his usefulness, the secret of the affection shown for him is plain—he loved others; they could not do otherwise than love him. "Ceased his usefulness?" The usefulness of such men never ends.

Mr. Kinsley was elected a Member of the American Society of Civil Engineers on February 5, 1873; he was the senior member of the Society for several months prior to his death on September 23, 1930.

## GEORGE CHARLES KREUTZER, M. Am. Soc. C. E.[1]

DIED NOVEMBER 23, 1929

George Charles Kreutzer was born on a ranch in Douglas County, Colorado, on March 6, 1884. He was the son of Edward D. and Jane Eliza (Keppel) Kreutzer. His father came to America from Germany in 1867, remained in New York and Pennsylvania for a few years, and then, in 1874, with his wife, a native of England whom he had married the preceding year, moved to Colorado where he finally established himself on a ranch in Douglas County about ten miles west of Sedalia.

[1] Memoir prepared by Elwood Mead and R. F. Walter, Members, Am. Soc. C. E.

Mr. Kreutzer's boyhood days were spent in hard work on his father's ranch where he gained that background of practical experience in agriculture, irrigation, and lumbering, which was to prove so valuable to him in later years.

He attended Grammar School at Sedalia and High School in Castle Rock, Colo. He entered the Colorado Agricultural College at Fort Collins, Colo., in 1903 and was graduated in 1908, with the degree of Bachelor of Science in Engineering, having taken his major work in civil and irrigation engineering. He worked his way through college under great difficulties, but even so, he made an excellent scholastic record and was an outstanding leader in all student activities. In 1922, the degree of Master of Science was conferred upon him by his Alma Mater.

On leaving college in 1908, Mr. Kreutzer's first employment was as Special Field Agent, Bureau of Irrigation Investigation, United States Department of Agriculture. Although he only occupied this position for a few months, it was the beginning of a useful career in the public service, both State and National, largely in irrigation development and land settlement problems.

From September, 1908, to April, 1910, he was employed by the Colorado Experiment Station, and was engaged in the studies of practical irrigation problems, animal husbandry, and agronomy. In April, 1910, Mr. Kreutzer again entered the employ of the United States Government for a brief period, this time with the Bureau of Reclamation, Department of the Interior, as Assistant Superintendent of Irrigation, on the Shoshone Project, in Wyoming, where he supervised the operation of the Garland Division during the summer and had charge of all survey parties during the fall and winter. He continued in this position until January, 1911.

In 1910, Elwood Mead, M. Am. Soc. C. E., Chairman of the State Rivers and Water Supply Commission of the State of Victoria, Australia, was visiting the United States. Among its other duties, this Commission operated all irrigation and water supply works serving the farming districts. While in the United States Dr. Mead asked Dr. Charles A. Lory, President of the Colorado Agricultural College, to suggest some one qualified to serve as Superintendent of one of the Australian projects, the requirements for the position being marked executive ability combined with good engineering and agricultural training and experience. Mr. Kreutzer was recommended by Dr. Lory and, as a result, he accepted an offer made by the Commission and early in 1911 was appointed Superintendent of the Cohuna Irrigation District in Northern Victoria, Australia. This assignment, which first brought Mr. Kreutzer in contact with Dr. Mead, was the beginning of an enduring friendship and professional relationship. Mr. Kreutzer's success in this work was so marked, and the progress of the District under his administration so satisfactory, that he was later transferred to the Central Office in Melbourne, Victoria, Australia, and made a general Economic Adviser in the creation of new projects and the reconstruction of old ones. He continued in this work until 1916 when, owing to the interruption in irrigation development in Australia, due to the World War, he resigned his position and returned to the United States.

In July, 1916, Mr. Kreutzer was appointed Agricultural Adviser of Kern County, California, as a part of the Agricultural Extension Service of the University of California, in co-operation with the U. S. Department of Agriculture. In this work he gave special attention to co-operative marketing and war production. His duties were later enlarged to include the supervision of county agents engaged in similar work in Kern, Kings, Tulare, and Fresno Counties. In 1918, the Legislature of California passed the State Land Settlement Act, to be under the control of a commission of which Dr. Mead was Chairman, he having returned to the United States in advance of Mr. Kreutzer. This Act had for its purpose the creation of planned farming communities of home owners organized to co-operate and to have the benefit of long-time payments and low interest rates in the purchase and improvement of their farms. Mr. Kreutzer was made Superintendent of the Durham Settlement, the first to be established under the Act, and remained in this position, which he filled with great fidelity, until 1924.

Continuing a professional association of many years' standing, Mr. Kreutzer followed when Dr. Mead was appointed by the President, in the spring of 1924, as Commissioner of Reclamation, U. S. Department of the Interior. Concordantly, in June of that year Mr. Kreutzer was appointed Chief of the Division of Reclamation Economics, under Dr. Mead. In this position, which he held until his death, he was untiring in his efforts to improve the economic status of the settlers on the Federal Irrigation projects.

He was married on March 4, 1914, in Melbourne, Australia, to Dorothy McFarlane, the daughter of an English clergyman. They had two children, William Elwood and Adelaide Dorothy, both of whom, with his widow, survive him. Also surviving him are one brother, Mr. William R. Kreutzer, and three sisters, Mrs. Minnie Cell, Mrs. Bessie Grandy, and Mrs. Agnes Klant.

Mr. Kreutzer brought to all his work the influence of a remarkable personality. In it were combined warm human sympathy, and a delightful sense of humor, together with unusual clear business sense. He was a man of much natural ability, fine personality, and extraordinary skill in dealing with people of all walks of life. He was honest, gracious, frank, and generous, loved by all who knew him for his sterling qualities of character, and respected and admired by all his co-workers for his outstanding ability and fairness.

Mr. Kreutzer was elected a Member of the American Society of Civil Engineers on January 16, 1928.

## KING YANG KWONG, M. Am. Soc. C. E.[1]

DIED OCTOBER 19, 1929

King Yang Kwong, better known among his Chinese friends under the name of Kwong, Sun-Mo, was born at Nanhai District, Kwangtung Province, South China, on February 8, 1863. He received his early education in his native town and was sent to the United States in 1874, when he was only

[1] Memoir prepared by Pao-Ling Yang, M. Am. Soc. C. E.

eleven years of age. He was one of the first thirty students who constituted a group known as the First Chinese Educational Mission, sent by the Imperial Chinese Government to the United States. His first few years in America were spent in Washington, D. C., where he received his preparatory education under the guidance of the veteran Chinese educator, Dr. Yung Wing, who was the Chinese Minister to America at that time. He then entered Williston Seminary at Easthampton, Mass., and in 1880, following his graduation from this school, Mr. Kwong was admitted to the Massachusetts Institute of Technology. He studied Civil Engineering there for two years, but was recalled to China by his Government in 1882, together with 119 other Chinese youths who were studying in America at that time.

The first position Mr. Kwong held upon his return to China was that of Assistant Engineer to the Kaiping Mining Company, at Tangshan, which Company has since been re-organized under the name of the Kailan Mining Administration, the largest coal mining company in the East to-day. In 1886, he was appointed by the Imperial Government to be the Assistant Engineer in charge of the construction of the railway from Shukochwang to Lutai, which line has since been extended to become the Peking-Mukden Railway. Mr. Kwong had the honor, therefore, of being the first Chinese railway engineer. On the completion of the section mentioned, Mr. Kwong was transferred to the position of Maintenance Engineer of the Lutai-Kuyeh Section of this railway. In the spring of 1897, he was sent to the outside of the Great Wall to take charge of the construction work on the Lienshang-Chinhsien Section. The Nüerh Ho Bridge on this section, consisting of sixteen 60-ft. spans, was built by him.

In 1900, the Boxer trouble broke out in China, and the whole line from Yinkow to Peking was seized by the foreign troops. As a result of this, in 1901, Mr. Kwong left the railway for Shanghai to become the Assistant Engineer of the Pinghsiang-Liling Railway, a short line, 60 miles long. On the completion of this line in 1902, he returned to the Peking-Mukden Railway to supervise the construction of the Koupangtse-Hsinmingfu Section near Mukden. In 1904, he was given charge of the construction of the Hanku Bridge across the Peitang River. The width of this river was approximately 500 ft., with a depth at low tide of about 23 ft., and at high tide of about 30 ft. The bridge consisted of three spans of steel trusses, two of 200 ft. and one of 90 ft. The two abutments and one pier were built on wooden piles.

In the autumn of 1905, Mr. Kwong was appointed District Engineer to the Peking-Kalgan Railway. His district extended from Ching Ho to the north of Pataling, the most difficult section of the whole line. Before he completed this work, however, he was transferred to become the Chief Engineer of the Canton Section of the Canton-Hankow Railway. At Canton, he met with innumerable difficulties. He had to solve not only the problems due to the sandy nature of the embankment and flood difficulties of the North River but, at the same time, he was forced to fight against the superstition of the people, and this, in addition to the training of workmen who were without any experience in railway construction. Later, the funds were exhausted, and the work had to be suspended. The line was completed to Shaokwan, a distance of 140

miles, leaving the remaining 70 miles to the southern border of Hunan Province unfinished as it still remains.

The most important works on the Canton-Hankow Railway were the bridges at Yintak and Shaochow. The piers of these bridges reached a depth of more than 30 ft. below the river bed. The Yintak Bridge was 300 ft. in length and the Shaochow Bridge, 700 ft., composed of spans of 100 ft. each. Mr. Kwong also established a workshop at Hwangsha for the purpose of erecting and repairing cars and locomotives. On the river bank in front of the locomotive shed a wharf was built, and a crane of 25-ton capacity was installed for the loading and discharging of cargo for steamers. The equipment of the workshop at Hwangsha was considered the most up to date of its kind in China at that time, for not only could repair work be done there, but cars could be built for the railway. The cost of construction for the whole line compared favorably with other lines in the Southern Provinces of China at that time.

In 1911, Mr. Kwong was transferred to the North and appointed Chief Engineer of the Peking-Suiyuan Railway. This road was an extension of the Peking-Kalgan Line, but owing to lack of funds it was not completed until 1921. Its total length was 204 miles and, later, a further extension of 90 miles was built to connect it with the Town of Paotou on the Yellow River. The building of the railway around the City of Peking was also done by Mr. Kwong at that time.

During the construction of the Peking-Suiyuan Line, the most difficult work experienced was the rock excavation in the mountains, in order to provide the necessary grades for the railway, and the building of the bridge at Tatungfu. This bridge comprised eighteen 100-ft. span steel girders, the rail level being about 55 ft. above the river bed. While acting as Chief Engineer of the Peking-Suiyuan Line, Mr. Kwong held concurrently the positions of Locomotive Superintendent and Works Manager to look after the building and repairing of locomotives and cars, and, during 1914 and 1915, he was also the Associate Managing Director of that line.

In his position as Locomotive Superintendent, he improved the locomotives to meet the requirements of the heavy freight traffic on the Peking-Suiyuan Railway. Air-brakes were installed on the line to increase safety while passing through the Pataling Pass. In the workshops, motive power was increased for use in repairing the rolling stock. The question of coal and water was solved by building a branch line of 14 miles to the Kouchuan Mines, from which the Tatung coal was carried to the markets. The line itself has been well supplied with this fuel since 1916.

In 1917, a disastrous flood occurred in Chihli Province, which affected seriously the Northern Section of the Tientsin-Pukow Railway. For ten miles near Tientsin, the line was entirely submerged. At this time Mr. Kwong was transferred to the position of Chief Engineer of the Northern Section. He at once took the matter in hand, and, in a short time, the railway was restored to good condition.

The construction of the entire line of the Peking-Suiyuan Railway was completed in 1920, and the increased amount of freight traffic rendered it necessary to increase the number of trains correspondingly. The question of

power then arose, and Mr. Kwong introduced the use of heavy locomotives for the Pataling Pass. He was re-appointed Chief Engineer and at once started work on the strengthening of the bridges in the Pass in order to meet the requirements of the new heavy locomotives which are the largest of their kind in the Orient.

Owing to political changes as a result of the Chihli-Mukden War in 1921, Mr. Kwong retired from active service until 1929 when His Excellency, Sun Fo, Minister of Railways, appointed him Technical Adviser to the Ministry. He had served on the railways for more than thirty years and was the first engineer to enter the Chinese railway service. From a position of Assistant Engineer, he gradually rose through long years of hard work and experience until he reached the highest position in the Chinese Government Railways. He took great interest in his work and devoted himself entirely to his profession for which he earned the respect of his friends and associates.

Mr. Kwong was the first Chinese engineer who joined the American Society of Civil Engineers and had the honor of being the first President of the Association of Chinese and American Engineers. He held the rank of Expectant Taotai during the late Ching Régime and was decorated with Third-Class Chiaho, Third-Class Paokwong-Chiaho, and Fourth-Class Wenhu Medals by the Chinese Republican Government in recognition of his services. He died of heart trouble in Peking at the age of 66, and is survived by his widow, a son, and a daughter.

In writing of him, J. A. L. Waddell, M. Am. Soc. C. E., states:

"Mr. Kwong was one of the truly great men of China, and was affectionately termed by his brother engineers 'The Grand Old Man of the Engineering Profession in China.' All who knew him intimately loved him, and every one acquainted with him held him in profound respect, not only because of his genial, kindly nature, but also on account of his noble qualities and high ideals in relation to both professional and social life. He was a true friend, an engineer of wide renown, a man of unusual intelligence, broad vision, and sound judgment, a most interesting conversationalist, and a highly polished Chinese gentleman—than whom no finer type of man can be found anywhere on earth.

"His passing is a distinct loss to the Chinese Republic; for, although failing health for several years had interfered with his active usefulness, he was always ready to aid the younger men of the profession with sound and kindly advice and to give counsel to the country's rulers whenever so requested."

Mr. Kwong was elected a Member of the American Society of Civil Engineers on April 1, 1908.

---

## EUGENE McLEAN LONG, M. Am. Soc. C. E.[1]

DIED JUNE 23, 1928

Eugene McLean Long was born in Bedford County, Virginia, near Big Island, on April 13, 1868. His father was Gen. Armistead Lindsay Long, a Confederate officer, who was Military Secretary to Gen. Robert E. Lee, and who was also the author of the "Memoirs of Lee". His mother was Mary Herron Sumner, a daughter of Maj.-Gen. E. V. Sumner, of the Federal Army.

[1] Memoir prepared by J. C. Meem, M. Am. Soc. C. E.

It is thus seen that, like many men of his generation, he came of stock that gave allegiance to both sides in that great upheaval of 1861, and it is not too much to say of McLean Long (or "Mack" as he was called by his intimates and friends), that he inherited and possessed many of the best qualities of the Puritan on the one hand, and the Cavalier on the other. Of fine physical appearance, he was also a fine upstanding exponent of the theory that a sound mind is housed in a sound body.

After preparation at home and at local schools, Mr. Long entered the University of Virginia, from which he was graduated in 1889, with the degrees of Bachelor of Science and Civil Engineer. The first eight years after his graduation were spent largely in the United States Geological Survey and in land and town-site irrigation work, except that during the last two years of that period he was Professor of Civil Engineering at Columbian University, Washington, D. C., being engaged between times in the private practice of engineering. For the next ten years his bent turned more toward steel inspection and erection, and he was employed at various times by the United States Government, the Baltimore and Ohio and the Pennsylvania Railroad Companies, and by New York City and various other municipalities, including Larchmont and Syracuse, N. Y. For the latter city he worked extensively on street and sewerage problems. In 1909, he became a member of the firm of Long and Miller, which firm was engaged mainly in general engineering and the design, as well as the construction and inspection, of large buildings, bridges, etc.

A contract having unusually interesting features was that of The Narrows Siphon constructed under the direction of and for the Board of Water Supply of New York City, in 1914 and 1915. The firm of Long and Miller acted as Engineers for the Merritt and Chapman Company, in laying a 30-in. pipe in a dredged trench across The Narrows. It was on this contract, at the westerly end of the work, that master-piling was first used in connection with steel sheet-piling. Here, also, the discovery was made, and the invention perfected, that steel can be burned or cut under water. The other undertakings designed or constructed, or both, by this firm, include a bridge over the Passaic River; a plant for the International High Speed Steel Company of New Jersey; bridges and piers for the Gulfport and Western Railroad Company, in Mississippi; street and sewerage system for Fort Slocum, New York, etc.

In 1917, Mr. Long resumed practice in his own name, and designed the steel plant for Halcomb and Davidson, Detroit, Mich., and a floating dry dock for the United States Shipping Board. He was also Engineer in charge of construction and maintenance of properties for several estates and for the Munson Steamship Company. In connection with foundation and other work for Swift and Company, and for Armour and Company, the writer was associated with Mr. Long on one special case and was greatly impressed with the painstaking care for detail as well as the forceful way in which he met and handled his problems.

In April, 1921, he was married to Mary Florence Gregory, of Skaneateles, N. Y. They had no children. His widow survived him only a short time.

Mr. Long was a member of the Engineers' Club and of the Society of the Virginians in New York City. His death occurred at the age of 60, at his home at Port Washington, Long Island, on June 23, 1928.

As life is measured to-day, Mr. Long was a comparatively young man; in fact, his span was ten years short of the three-score and ten allotted by the Psalmist; but measured by events and achievements he had lived a life of much greater length. Paraphrasing the words of Mayor Gaynor, as he sailed away from New York City to his death, "I have been Mayor," Eugene McLean Long could have looked back over his own constructive life and said, "I have been an Engineer."

Mr. Long was elected an Associate Member of the American Society of Civil Engineers on June 1, 1898, and a Member on July 6, 1920.

## HENRY HOWELL LOTTER, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 9, 1930

Henry Howell Lotter was born on September 3, 1875, in Moberly, Mo., the son of Julius H. and Charlotte (Howell) Lotter. He was of Welsh and French-German descent.

Mr. Lotter attended the public schools of his native town and following graduation from the Moberly High School, he entered the University of Missouri at Columbia, Mo. While a student at the University he was very prominent in campus activities. He held the rank of Captain in Company A in the Missouri State Military School, which was the student military organization in the University at that time. He was a member of Tau Beta Pi, honorary engineering fraternity, and of Sigma Chi, being one of the charter members of the Missouri Chapter. He was also a member of Theta Nu Epsilon. He was graduated from the University of Missouri in 1897, with the degree of Bachelor of Science in Engineering. Two years later he received his Civil Engineer Degree from the same institution.

From September, 1897, until January, 1900, Mr. Lotter was employed by the United States Deep Waterways Commission, working throughout a large part of New York State and in the Detroit, Mich., Office, in the capacities, first, of Rodman, then of Recorder, then of Instrumentman, and, lastly, of Assistant Engineer.

From January, 1900, until June, 1901, he served as an Engineer on the United States Isthmian Canal Commission. During this time he worked for six months on surveys in Panama, with headquarters at Colon. One year of this time was spent on work in Washington, D. C., preparing estimates upon the basis of which the United States Government acquired the Panama Canal.

From September, 1901, until January, 1902, he was Principal Assistant Engineer for the Louisiana Purchase Exposition Company. This work consisted chiefly of preliminary surveys in preparation for the World's Fair Exposition which was held at St. Louis, Mo., in 1904.

[1] Memoir prepared by C. W. Brown, M. Am. Soc. C. E.

From January, 1902, until October, 1904, Mr. Lotter was employed as First Assistant Engineer on the colossal double-track railroad bridge constructed by the Southern Illinois and Missouri Bridge Company, over the Mississippi River at Thebes, Ill. After the completion of his work on the Thebes Bridge, Mr. Lotter accepted a position as Assistant Engineer to Ralph Modjeski, M. Am. Soc. C. E., on the Vancouver-Portland double-track draw-bridges over the Columbia River and Oregon Slough, at Vancouver, Wash. The work on this project was completed in July, 1908.

He was next employed as Construction Engineer by the United States Reclamation Service, Yakima Project, North Yakima, Wash., from July, 1908, until March, 1909, at which date he resigned to become City Engineer of Vancouver, which is situated across the Columbia River from Portland, Ore., and is the seat of a prominent United States Military Post. His work here consisted of general municipal improvements on streets, parks, and sewers. In addition to his duties as City Engineer, Mr. Lotter was Engineer for the Washington-Oregon Corporation for water, gas, and electric railway systems. In this capacity he built the electric road from Vancouver to Sifton, Wash. He also served during this period, from March, 1909, until January, 1912, as Engineer for the Town of Camas, Wash.

From January, 1912, until July, 1913, he was engaged in general engineering practice and contracting at Vancouver, and was also City Engineer for Kalama, Wash., directing street and sewer improvements.

On leaving the Pacific Coast in July, 1913, Mr. Lotter became associated with the United States Bureau of Public Roads, in the Department of Agriculture, in the capacity of Senior Highway Engineer, with headquarters in Washington, D. C.

During the next seventeen-year period until the time of his death (1913-1930), the territory over which he worked included large sections of the eastern half of the United States, ranging from the Gulf Coast States and the Southeastern Atlantic Seaboard States to as far north as Michigan and then back to the States of the Middle West.

Mr. Lotter's first work with the Bureau of Public Roads consisted of the construction of post roads in the State of Mississippi, followed by similar work in the State of Iowa. The peace-time road program was interrupted in 1917 by the entrance of the United States into the World War, and, in consequence, a large part of the Bureau's activities was directed toward war work, in the construction of roads to and through cantonments to facilitate the mobilization of troops. Mr. Lotter was employed in this work at Camp Dodge, Des Moines, Iowa, and on its completion early in 1918, he was transferred to Montgomery, Ala. He traveled in the interests of the Bureau through the States of Alabama, Georgia, Florida, and South Carolina, and assisted in the construction of roads to Camp Wadsworth, South Carolina, and in the road through Camp Sevier, South Carolina.

In July, 1918, Mr. Lotter was transferred to Federal District 5, with headquarters at Omaha, Nebr., where he remained until July, 1919. While in this District, he also assisted in the road building at Fort Riley, Kansas.

During this period of a year, the war having ended, work in the Bureau was intensively re-directed to the general road-building program. Mr. Lotter traveled a large part of the time, inspecting numerous Federal Aid road projects in the States of Iowa, Nebraska, Missouri, and Kansas, the four States that comprise Federal District 5.

In July, 1919, it was decided by Bureau officials in Washington to establish a Bureau Office for Federal road work in the State of Missouri, with headquarters at Jefferson City. Mr. Lotter was selected to become the head of this responsible post. During the eleven years that followed, he worked tirelessly in every way for the improvement and expansion of the road system of his native State. He traveled throughout all Missouri, giving advice and making inspections on hundreds of Federal Aid road projects. He had been in failing health for several years, but kept up his work until he was seized with the sudden attack of heart failure which caused his death at his home in Jefferson City, on September 9, 1930.

Ever an ardent and enthusiastic engineer, Mr. Lotter, at all times, exemplified and advocated the high standards of honor, diligent work, and efficiency for which his profession stands. In every community in which he lived he was regarded as a useful and highly respected citizen, and he was held in high esteem by his professional associates everywhere. His fine character, interesting personality, and ready wit made for him a nation-wide circle of friends.

Mr. Lotter served as a Colonel on Governor Baker's personal staff. He took an active interest in community affairs at Jefferson City, serving for a time as Secretary of the Commercial Club. He was a member of the Jefferson City Rotary Club, Jefferson Lodge, No. 43, A. F. and A. M., Jefferson City Chapter No. 34, Royal Arch Masons, Ezra Council No. 32, R. and S. M., and Prince of Peace Commandery No. 29, Knights Templars. He served as a member of the Advisory Council of the Order of DeMolay. He was a member of the Knights of Pythias Lodge. He was also a loyal member of the Presbyterian Church at Jefferson City and served as a Trustee, an Elder, and as Assistant Sunday School Superintendent.

He was known and loved for his interest in young people. He took great joy in the church, fraternal, school, and athletic activities in which young people engage, giving much of his time and attention to these enterprises.

Mr. Lotter's character has been well epitomized in the following editorial from the *Jefferson City Capital News:*

"'The evil that men do lives after them; the good is oft interred with their bones.' Thus spake Shakespeare, but like many other sayings of the Bard of Avon, it is not true to the experience of the race. The good men do lives after them much longer than does the evil, because a good influence is more lasting than an evil one.

"Take the case of Howell Lotter. He was a good man; his hands were full of kind deeds; men, women, and children loved him; he so lived to set in motion a wave of influence for the good that will widen as it runs, as the years come and go. How true it is of Howell Lotter that he still lives, though dead.

"At the Rotary luncheon Monday, strong men spoke with emotion of his admirable qualities of head and heart. A tribute to his ability and fidelity

was paid by Chief Engineer Cutler. Others spoke of him as a Churchman, a friend, a neighbor, a Rotarian, a public-spirited citizen, and as a Christian gentleman. All paid him the highest encomium of love and respect.

"Cut down in the midst of a useful career, his days were all too few. But he left his family and his friends and comrades the rich heritage of a good life. The world is better for Howell Lotter having lived in it. The Memorial Service at the Rotary luncheon was a beautiful tribute to a life that enriched this community."

On June 18, 1902, Mr. Lotter was married at Jefferson City to Gertrude C. Geisberg, who survives him, with two daughters, Dorothy and Charlotte.

Mr. Lotter was elected a Member of the American Society of Civil Engineers on September 9, 1919.

## JACOB LOTT LUDLOW, M. Am. Soc. C. E.[1]

DIED AUGUST 18, 1930

Jacob Lott Ludlow was born at Spring Lake, N. J., on December 20, 1862, the son of Samuel and Nancy (Johnson) Ludlow. He obtained his Civil Engineering Degree at Lafayette College at Easton, Pa., in 1885, and five years later was awarded the Honorary Degree of Master of Science by the same College.

Soon after his graduation Mr. Ludlow located at Winston, N. C., at that time a sister city to the old Moravian Town of Salem and, later, as President of the Board of Trade of Winston, he led the successful campaign for the consolidation of Winston and Salem into one municipality now known as Winston-Salem, N. C.

He was the first City Engineer of Winston and as such succeeded not only in establishing a sanitary sewerage system in that city, but materially assisted in the establishment of one of the first street railway systems to be installed in the United States. He started a program of paving which to-day has made Winston-Salem one of the most thoroughly paved cities in the South.

During the boom years following 1890, Mr. Ludlow did much sub-division work throughout the South and, to-day, many a city can thank him for its splendid parks which he with far-sighted vision invariably included as a part of his plan, dedicating such areas forever to public use.

However, the greater part of his active life was spent in the development of public water supplies throughout the South. For a period of twenty-five years, he was the Engineer Member of the North Carolina State Board of Health and untiringly directed his efforts toward improving sanitary conditions in the State, drafting the laws for the protection of public water supplies that have placed North Carolina well in the forefront in such matters. He was the only lay member of the North Carolina Medical Society.

As a practicing Municipal Engineer there are few cities and towns in the South Atlantic States that were not served by him in some capacity during his long career.

For eight years he served as Chief Engineer of the North Carolina National Guard with the rank of Colonel. This was during the period prior

[1] Memoir prepared by William M. Piatt, M. Am. Soc. C. E.

to the World War when the National Guard of the country constituted an important part of the National defense. During this time he designed and established the camp equipment and rifle range at Camp Glenn, near Morehead City, N. C.

During the World War, Colonel Ludlow supervised the construction of Camp Greene, at Charlotte, N. C. Following this, until the close of the war, he was Supervising Sanitary Engineer for the United States Shipping Board at the many shipyards in the South Atlantic and Gulf States, paying particular attention to the correction of the drainage in the neighborhood of the yards and the removal of the malarial conditions that existed there.

Following the World War Colonel Ludlow confined himself to a consulting practice and also acted as Consulting Engineer for the Ludlow Engineers, of which organization Major E. W. Myers was the active head. After the death of Major Myers, Colonel Ludlow continued the organization, serving as active head to the time of his death. The organization has been discontinued.

During this period, in 1924 and 1925, Colonel Ludlow also served as a Member of the Engineering Board of Review of the Sanitary District of Chicago on the lake-lowering controversy.

Colonel Ludlow was a member of the Phi Delta Theta Fraternity, a York Rite Mason, a Shriner, a member of the American Institute of Consulting Engineers, the American Public Health Association, the American Water Works Association, and the North Carolina Society of Engineers. He was also a member of the Rotary, Twin City, and Cosmos Clubs of Winston-Salem, and a member of the Presbyterian Church.

During his lifetime he held many prominent positions not previously enumerated, among which may be included that of Chairman of the Sanitary Engineering Section of the American Public Health Association, President of the North Carolina Section of the American Water Works Association, Director of the American Association for the Study and Prevention of Tuberculosis, Director of the North Carolina Tuberculosis Association, National Councillor of the Chamber of Commerce of the United States, and Past Potentate of Oasis Temple, A. A. O. N. M. S.

Colonel Ludlow was married in 1887, to Myra Margarette Hunt, of Easton, and to them were born three daughters, Mrs. Joseph F. Cannon, of Concord, N. C., and Mrs. Henry B. Shelton and Mrs. R. A. McBrayer, of Winston-Salem, who, with Mrs. Ludlow, survive him.

The widespread editorial comment throughout the South and particularly throughout North Carolina where he was more intimately known, is concrete evidence that in the passing of Colonel Jacob Lott Ludlow the South lost one of its great benefactors.

Coming there as a young man soon after his graduation from college, to a field where municipal engineering was practically unknown and which had scarcely recovered from the ravages of the Civil War, he early became a large factor in the upbuilding of the South, and his many activities during the past forty-five years, aside from his engineering work, stamped him as no less a great citizen than a great engineer.

In the sanitary engineering field Colonel Ludlow was a pioneer and with the construction of the separate sanitary sewers in the City of Raleigh, N. C., in 1888, one of the first systems of that type in the world, was begun the development of a technique that has become standard practice throughout the Southern States.

As an ethical practitioner he was without a peer, never failing in the conduct of his work to recognize his position as arbitrator and the rights of the contractor as well as the client. The profession as well as the Society owes much to Colonel Ludlow for the example set for the guidance of the younger engineer.

These are some of the high lights of an active, unselfish career of forty-five years, which only a lengthy biography could fully cover and which at every step reflected credit upon the Engineering Profession.

Colonel Ludlow was elected a Member of the American Society of Civil Engineers on March 3, 1897.

## JOHN LUNDIE, M. Am. Soc. C. E.[1]

DIED FEBRUARY 9, 1931

John Lundie was born in Arbroath, Scotland, on December 14, 1857, the son of James and Anne Honeyman Lundie. On his father's side, he was descended from the Lundies of Forfarshire, in a direct line from Sir John Lundie who was keeper of Stirling Castle in the Fifteenth Century. His mother's ancestry derived directly from James the Fifth, the Stuart King, one of whose descendants married Andrew Honeyman, Bishop of Orkney, in the Seventeenth Century.

After his graduation from the High School of Dundee, Scotland, in 1873, Mr. Lundie served a pupilage of four years in the office of the Harbor Engineer of the Port of Dundee, where he obtained some excellent experience in concrete sea walls, land reclamation, locks, graving docks, pumping machinery, harbor-railway work, power machinery, surveying, and general hydrographic engineering. He later entered the University of Edinburgh where he finished the four-year course in three years and was graduated in 1880 with the degree of Bachelor of Science in the Department of Engineering. He was First Prize man in Mathematical Physics.

Immediately after his graduation Mr. Lundie came to the United States and started on railroad work in Oregon and Washington Territory, continuing thereat for four years. During this time he was occupied with mountain preliminary and location surveying, general construction, maintenance, and yard work, besides having complete charge of the building of the Table Rock Tunnel.

From 1884 to 1885 he was engaged in private practice in Chicago, Ill., devoting his attention mainly to municipal work. It was during this time that he became a citizen of the United States.

[1] Memoir prepared by J. A. L. Waddell, M. Am. Soc. C. E., and Edward J. Murphy, Esq.

In 1886 Mr. Lundie entered the employ of the City of Chicago, as Assistant Engineer in charge of work, and continued in this position during four years under the direction of Francis Murphy, Harbor Engineer. He obtained experience in sewerage, steel work, water supply, tunneling, and bridges. He made the preliminary survey for the Chicago Drainage Canal and designed several of the city's bridges. For the last eighteen months of this service he was Principal Assistant City Engineer. One of his colleagues at this time was the late John E. Ericson, M. Am. Soc. C. E., who died in 1927, after serving as City Engineer of Chicago for nearly forty years.

In 1890, Mr. Lundie became Engineer and General Agent in Chicago for the King Bridge Company, of Cleveland, Ohio. During the four years that he held the position he designed and erected numerous bridges and other structures, and contracted for and erected the structural steelwork of four of the World's Fair Buildings and the Illinois Central Railroad Train-Shed at Chicago.

He then returned to private practice in Chicago, designing for that City its first low-level drainage system, as well as the sewerage system of Kenosha, Wis. He did his first electrial engineering work in 1895 for the Chicago and Worth Electric Railway Company. Also, he investigated and reported on an artesian water supply system for the City of Memphis, Tenn. During this investigation Mr. Lundie developed a method for the determination of the yield of artesian water areas.

In 1896, at the request of the late C. P. Huntington, F. Am. Soc. C. E., he visited the Isthmus of Panama, in order to make a survey and examination of the Pacific Mail Company's property at Colon and report thereon.

One of Mr. Lundie's principal achievements belongs to this period of his career, namely, an investigation and report on the application of electricity to the suburban train service of the Illinois Central Railroad. He spent an entire year in studying the subject; and during the research he enunciated the principle of "rapid acceleration", indicating the advisability of utilizing a high percentage of the weight on the driving wheels in economic movement of certain railway operations. From the results of this research he prepared a thesis containing a record of his original investigations, presented it to his Alma Mater, the University of Edinburgh, and received therefor the degree of Doctor of Science. This thesis enunciated the principle and economy of rapid acceleration, the scientific power rating of electric railway motors, and the law of fluctuations in power stations, and also established the Lundie formula for train resistance. He made some similar tests of train resistance on the South Side Elevated Railroad of Chicago, and some automobile tests for the *Chicago Times-Herald* competition.

In 1898, he was called to New York, N. Y., by the Sprague Electric Company to solve some heavy traction problems; and soon afterward he engaged in private practice in New York City, where he made many electric motor power tests for the Brooklyn Elevated Railroad, the Boston Elevated Railroad, and the Brooklyn Rapid Transit Companies.

About this time, Dr. Lundie reported on the power handling of freight at the Savannah Terminal of the Georgia Central Railroad Company, and, in the course of this investigation, he designed the first combined electric hoist and traveler, since called a "telpher". He designed and patented also the Lundie Ventilated Rheostat, now used quite extensively.

Dr. Lundie was widely consulted by various railways and other companies in the East, West, and South, on important electrification problems, and was called to London, England, on the electrification of the Metropolitan Underground System of Railways. He was retained thereon for two years, after which Sir William Preece, of London, sent him to Canada on some important electric railway work.

In 1904, he reported to the General Electric Company on the conditions and prospects for water power development and the utilization of electric power on the Isthmus of Panama; and while he was there he was retained by the Panama-American Corporation to direct its affairs on the Isthmus. After that, he did considerable important electrical engineering work in the States of Alabama, Tennessee, and New York.

Dr. Lundie served as efficiency expert for the Tennessee Coal, Iron, and Railroad Company, introducing much greater efficiency in railroad operation, especially by applying, with remarkable success, the "straw boss" system among the negro laborers.

In 1913, he designed and patented the Lundie Tie-Plate, an appliance for the promotion of safety, economy, and ease of movement on railways, and, later, a duplex rail-anchor, and thereafter he devoted a large portion of his time and energy to the exploiting of these inventions. The work thus involved became eventually so extensive and onerous that there was formed the Lundie Engineering Corporation to take care of it, Dr. Lundie being its President and principal stockholder until the time of his death. This shifting of the burden of commercial interests to other shoulders left Dr. Lundie time to devote himself mainly to research and technical work.

In 1921, he became associated with the United Central America Corporation as its Technical Adviser in connection with its engineering projects.

Dr. Lundie was a member of many professional scientific organizations, among these being the American Institute of Consulting Engineers, the American Association for the Advancement of Science, the American Iron and Steel Institute, the American Institute of Electrical Engineers, and the American Railway Engineering Association.

He was also a Mason and a Knight Templar, and a Fellow of the Royal Society of Arts, of London.

He was a member of the New York Athletic Club of more than thirty years standing; of the Old Colony Club, the Railroad Club, and of many other societies, such as the American Iona Society, St. Andrew's Society, etc.

In 1906, Dr. Lundie was married to Iona Oakley Gorham, a grandniece of former Governor Sterling Price of Missouri. She died in 1925. In 1929, Dr.

Lundie was married to Mrs. Alice Eddy Snowden, the widow of Dr. Albert A. Snowden. In addition to Mrs. Lundie, he is survived by two brothers, Mr. Robert Honeyman Lundie, a publisher of Dundee, Scotland, and Mr. William Honeyman Lundie, of Chicago; and two sisters, Mrs. George Davidson and Miss Georgina Lundie, both of Adelaide, South Australia.

Although in delicate health for some time, Dr. Lundie had remained active in business until a brief illness from pneumonia caused his death on February 9, 1931. His ashes are buried in Oakland Cemetery, Dallas, Tex., beside those of his first wife.

He will be missed not only in the scientific world to which he contributed such brilliant and valuable services, but by a host of associates who knew him as a cultured gentleman and as a generous, high-minded friend.

Dr. Lundie was elected a Member of the American Society of Civil Engineers on July 4, 1888.

## HENRY MARTYN MacKAY, M. Am. Soc. C. E.[1]

DIED OCTOBER 25, 1930

Henry Martyn MacKay was born at Plainfield, Pictou County, Nova Scotia, on June 18, 1868. His father, Angus MacKay, had come to Canada in 1821 from Sutherlandshire, Scotland, and married Elizabeth MacKay, a native-born Nova Scotian, although no relation to his own branch of the family.

Angus MacKay was a staunch supporter of the Established Church of Scotland, and active in promoting the educational interests of the country community in which he lived. It was to be expected that his own sons and daughters should receive the best schooling his limited means could afford. Therefore, when he had absorbed all that the local teachers could give him, young Henry was sent to Pictou Academy, an institution which has an extended and excellent reputation.

From Pictou Academy, Henry MacKay entered Dalhousie University in Halifax, Nova Scotia, from which he was graduated in 1888 with the degree of Bachelor of Arts, and with high honors in mathematics and mathematical physics. Although his University career convinced him that his natural aptitudes were scientific rather than classical, he was not sure that they were sufficiently strong to warrant his adoption of engineering as a life work; his personal tastes, however, inclined in this direction. His native shrewdness and caution impelled him to consider the matter of his future carefully; if he were to follow the Engineering Profession, he must needs have more specialized education, and for that money would be required. He, therefore, spent the three or four years following his graduation from Dalhousie in teaching, and then entered McGill University, Montreal, Que., Canada, from which he received the degree of Bachelor of Science in Civil Engineering in 1894, winning the Governor-General's Medal for the highest standing in his class in any course.

[1] Memoir prepared by R. DeL. French, M. Am. Soc. C. E.

Immediately after his graduation from McGill University, Mr. MacKay entered the service of the Survey of Tides and Currents of Canadian Waters, under the late Dr. W. Bell Dawson. Here he remained until 1897, when his old school, Pictou Academy, called him to be Mathematical Master, which position he occupied until 1899. He was eminently successful as a teacher.

Henry MacKay early developed an intense interest in structural engineering. When, therefore, the opportunity arose of entering the employ of Waddell and Hedrick, Consulting Engineers, of Kansas City, Mo., he accepted it instanter. At that time, this firm was well-known in America, and its reputation was second to none. In addition, the Senior Member was a graduate of McGill University and a personal acquaintance of Mr. MacKay.

From 1899 to 1904, he served this firm in various capacities. For a few months, at the beginning of his term of employment, he was engaged in drafting and design in its Kansas City Office, but in November, 1899, he was appointed Resident Engineer on the construction of the Iowa Central Railroad Bridge, at Eddyville, Iowa, and thereafter was always in the field. From April to November, 1900, he was in charge of the erection of the Agnes Avenue Viaduct for the Metropolitan Street Railway Company, of Kansas City.

In November, 1900, his firm sent him to Mexico on the bridge work of the Vera Cruz and Pacific Railway, for which its members were acting as Consulting Engineers. For about a year Mr. MacKay was stationed at the Pahaloapam Bridge, and, finally, in October, 1902, he was given charge of all permanent bridges on the line, about one hundred in number and varying in span from 20 to 225 ft.

In June, 1903, he returned to the United States and served, successively, as Resident Engineer on the James Street Bridge and on the reconstruction of the Ohio Avenue Bridge, both of which are in Kansas City.

Dr. H. T. Bovey, then Dean of the Faculty of Applied Science at McGill University, had never lost sight of his brilliant graduate, and repeatedly had tried to induce him to return to his Alma Mater as an Instructor; finally, in December, 1904, Mr. MacKay accepted the appointment of Special Lecturer in Civil Engineering. A natural-born teacher, in love with his work, he was rapidly promoted through the grades of Assistant Professor and Associate Professor to William Scott Professor of Civil Engineering and Head of the Department, in May, 1908.

Always a strong proponent of thorough instruction in the fundamentals of engineering, Professor MacKay devoted the next sixteen years to the building up of his Department. Firm in his convictions, but fair in his judgments, he earned the respect and admiration of his colleagues to such an extent, that when the position of Dean of the Faculty became vacant through the retirement of Dr. Frank Dawson Adams, he was the logical choice of the Corporation of the University for the office, to which he was appointed in June, 1924.

Although Dean MacKay's innate modesty and the fact that his major interests lay in the field of teaching and collegiate administration tended to throttle his output of professional work, he yet found time to contribute materially to the progress of his especial branch of civil engineering, namely, bridges and structures. All the time that his strict sense of duty to the University would permit him to use, was occupied by consulting engagements.

Perhaps the most noteworthy of these was his investigation of the behavior of full-sized steel columns under heavy loads, for the St. Lawrence Bridge Company, Limited, of Montreal, in connection with the construction of the Quebec Bridge, and described in the Appendices of the report of the Board of Engineers on that structure. Another investigation which led to important results was that on the effect of haunching I-beams with concrete, which he conducted jointly with the late Professor Peter Gillespie, of the University of Toronto, and with Professor S. Baulne, of L'Ecole Polytechnique, in Montreal. His last consulting engagement was as a member of the Advisory Board of Engineers of the Montreal Harbor Bridge over the St. Lawrence, which was opened in May, 1930.

In recognition of Dean MacKay's efforts in the field of engineering education and of his professional attainments, Dalhousie University, in 1929, conferred on him the degree of Doctor of Laws, *honoris causa*.

Dean MacKay possessed the rare faculty of making a complicated matter appear clear, simple, and obvious. To this talent was perhaps due his success as a teacher. Singularly gentle in personality, he could be inflexible when occasion demanded, although always inspiring the respect and love of his colleagues and the hundreds of students who passed through his hands in the twenty-six years during which he had served the University. Although abhorring enforced or artificial intimacy, such was his character that he was the repository of the confidences of staff and students alike.

In 1910, he was married to Lilian Norton Evans, who, with two children, Ian Norton and Elizabeth Nora, survives him.

Although essentially a home-lover and happiest in the heart of his family, Dean MacKay was ever ready to support any worthy work both financially and by means of his own services. He was a member of the Church of the Messiah (Unitarian), and of the University Lodge, A. F. and A. M.

He was affiliated with the following professional societies: the Engineering Institute of Canada, which he served as Counsellor; the American Society for the Advancement of Science; the Society for the Promotion of Engineering Education; the American Society for Testing Materials; the Canadian Engineering Standards Association; the Canadian Railway Club; and the Society of the Sigma Xi. For many years he had been a member of the Honorary Advisory Council for Scientific and Industrial Research, a Federal Government body. He was also a member of the University Club, the Faculty Club, and the Art Association of Montreal.

Dean MacKay was elected a Member of the American Society of Civil Engineers on July 10, 1907.

## WILLIAM WALTER MACLAY, M. Am. Soc. C. E.[1]

DIED JUNE 8, 1929

William Walter Maclay, the son of Archibald and Julia Ann (Walker) Maclay, was born in New York, N. Y., on March 27, 1846. He was a descen-

[1] Memoir prepared from information on file at the Headquarters of the Society.

dant of Henry Slater, one of the most notable pioneers of Colonial days who came from England in 1709 and settled for a time in Virginia. Henry Slater subsequently purchased a tract of land and made his home on what was then known as "Chestnut Ridge", about nine miles northwest of Baltimore, Md. He became prosperous as a planter and in 1742 erected the first Baptist Church in Maryland. It is one of the famous landmarks in American history and was built contemporaneously with Faneuil Hall, Boston, Mass., the old Lutheran Meeting-House, Philadelphia, Pa., and the Baptist Church, Ringwood, N. J.

Mr. Maclay was a maternal grandson of Isaac Walker (1786-1868), an original member of the Association of Defenders of Baltimore in 1814, a private in Captain Thomas Watson's Company, 39th Regiment, Maryland Infantry, and among those who served with Lt.-Col. Benjamin Fowler at the Battle of North Point.

Archibald Maclay, the father of William Walter Maclay, was a prominent physician of New York City (1812-92). His grandfather, the Rev. Archibald Maclay, was a graduate of the University of Edinburgh, Scotland, Pastor of the Mulberry Street Baptist Church, New York, and, later, served as Traveling Agent of the American and Foreign Bible Society. He was an able preacher and an earnest advocate of the Bible cause, and to this day his influence is felt among the English and Welsh-speaking people of the United Kingdom as well as the United States.

William Walter Maclay received his early education at the Grammar School of the University of the City of New York, and, in 1860, entered the United States Naval Academy, at Annapolis, Md., as a Midshipman. He was graduated in 1863, the youngest member of his class, and commissioned an Ensign. This was the class from which were chosen the Captains for most of the battle-ships in the Spanish-American War.

During the Civil War, in 1864-65, he served on the *Ticonderoga* in both bombardments of Fort Fisher and made a voyage around the world as Navigating Officer to Commodore Goldsborough on the U. S. S. *Shenandoah* (1865-69). During this period his letters in description of the places he visited, were contributed to various New York publications.

On the conclusion of his journey in 1866, Ensign Maclay was appointed by the Japanese Government on a Lighthouse Board to consider the lighting of Yeddo Bay. In the same year he was commissioned Lieutenant and, in 1868, Lieutenant Commander. He was subsequently appointed Fleet Lieutenant and Acting Fleet Captain of the United States Naval Asiatic Squadron. In 1869, he became Assistant Professor of Mathematics at the Naval Academy, Annapolis, which position he resigned in 1871.

He then pursued a course of study in Civil Engineering at the University of the City of New York and was graduated with the degree of Civil Engineer in 1873, having received the degree of Master of Arts in 1866 from the same institution. He was further honored by receiving the Norman Gold Medal from the American Society of Civil Engineers in 1878, for his paper entitled "Notes and Experiments on the Use and Testing of Portland Cement."[2]

[2] *Transactions*, Am. Soc. C. E., Vol. VI (1877), p. 311.

For many years Mr. Maclay served as Principal Assistant Engineer in the Department of Docks, New York City, on the construction of the new pier and bulkhead system. He was also prominently identified with the Portland cement industry of the United States. As a Civil Engineer using large quantities of this material and as a Portland Cement Expert and Manufacturer, he was one of the foremost men in bringing about the present development of the industry. It was upon Mr. Maclay's recommendation to the late James B. Eads, M. Am. Soc. C. E., that American Portland cement was used in building the jetties at the mouth of the Mississippi River. This occurred at a time when the use of such cement in the United States was in its infancy, as it had been made only in a small way by one company. Inasmuch as it was also the first public recognition of the ability of American manufacturers in this line, the subsequent expansion of the trade was accordingly greatly influenced.

In 1893, Mr. Maclay removed to Glens Falls, N. Y., where he built the large Portland Cement Works of which he was President and General Manager until about 1904, at which time he resigned. He then spent a few years in foreign travel, after which he returned to the United States and rebuilt a country home in Lee, Mass.

In addition to his paper on "Notes and Experiments on the Use and Testing of Portland Cement" previously mentioned, Mr. Maclay was the author of "Portland Cement for Engineering Works". He was a member of the Institution of Civil Engineers, of London, England, the International Society for Testing Materials, and a Corresponding Member of the New York Historical Society. He was also a member of the University and Manhattan Clubs of New York, and of The United States Naval Academy Graduates Association.

He died at his home in Lee, on June 8, 1929, in his eighty-fourth year. He lived only a little more than a year after the death of his wife, Marian Bensel Maclay, to whom he was married, in New York, on September 16, 1874. His daughter, Mrs. Robert S. Linn, and a grand-daughter, Mrs. Frank E. Carlson, survive him, both of whom live in the Middle West. A son, Walter, died in 1887.

Mr. Maclay was elected a Member of the American Society of Civil Engineers on November 6, 1872.

## GEORGE ARNOLD McCARTHY, M. Am. Soc. C. E.[1]

DIED NOVEMBER 13, 1930

George Arnold McCarthy was born at Moncton, N. B., Canada, on December 19, 1871. Educated at Moncton, he was graduated with the degree of Bachelor of Science at McGill University, Montreal, Que., Canada, and obtained his preliminary engineering practice during a period of seven years in the office of the Chief Engineer of the Intercolonial Railway Company, at Moncton.

Having definitely chosen engineering as his profession, Mr. McCarthy obtained an appointment first with the Canadian Pacific Railway Company in

[1] Memoir prepared by R. C. Harris, Esq., Toronto, Ont., Canada.

the Lake Superior District, and, later, with the Algoma Central Railway Company. From 1901 to 1905 he was Principal Assistant Engineer for the Canadian Niagara Power Company, at Niagara Falls, Ont., Canada; from 1905 to 1909, Chief Engineer of the Temiskaming and Northern Ontario Railway Commission; from 1909 to 1912, Western Manager for Messrs. Smith, Kerry, and Chace at Calgary, Alberta, Canada, and with the same firm in Toronto, Ont., Canada, from 1913 to 1914, after carrying out some work as Resident Engineer on the Feather River Development for the Oro Development Company, of San Francisco, Calif.

In 1914, Mr. McCarthy entered the service of the Department of Works of the City of Toronto, in which he remained until his death. As Engineer in charge of the Railway and Bridge Section, he was responsible for the administration of the civic car lines, and for the construction of several large works, including the Bloor Street Viaduct and the Strachan Avenue and Crawford Street Bridges. From 1922, he was in charge of the Sewer Section of the same Department, and many large works of sewer construction were carried out under his direction, notably, the North Toronto Sewerage System and Sewage Treatment Works, the largest complete system ever constructed by the City.

Mr. McCarthy was always active in general engineering matters, and spent much time in the service of his profession in the various societies with which he was connected. He was a member of the following: The Engineering Institute of Canada, the American Railway Engineering Association, the American Institute of Electrical Engineers, and also of the Association of Professional Engineers of the Province of Ontario. He served as a member of Council of the Engineering Institute of Canada during 1917, 1918, and 1919, and as Chairman of the Toronto Branch for one year. In engineering circles, he will long be remembered as a man whose presence was a help and an inspiration to his fellows.

He was married in Montreal on October 21, 1901, to Jennie M. Moffatt. Besides his widow, there are three children surviving, namely, Doris McCarthy, of Toronto, Douglas F. McCarthy, of Kapuskasing, Ont., Canada, and Dr. K. C. McCarthy, of Toledo, Ohio.

Mr. McCarthy was elected a Member of the American Society of Civil Engineers on November 6, 1907.

## WILLIAM EDWARD McCLINTOCK, M. Am. Soc. C. E.[1]

DIED MARCH 2, 1930

William Edward McClintock was born in Hallowell, Me., on July 29, 1848, the son of Captain John McClintock, a well known navigator, familiar with every sea, who crossed the Pacific with an ordinary watch for a chronometer and a school atlas for a chart, and Mary Bailey (Shaw) McClintock. On his paternal side he was of Scotch-Irish ancestry, descended

[1] Memoir prepared from data on file at Society Headquarters.

from William McClintock, a defender in the Siege of Londonderry in 1689. His earliest American ancestor was William McClintock, who came to the United States, a babe in arms and whose parents settled in Medford, Mass., in 1735. On his mother's side, he was descended from the Rev. John Bailey, a prominent Puritan clergyman.

Mr. McClintock's early education was acquired in the public schools, supplemented by a four-year course at Hallowell Academy, and one year at Kent's Hill Seminary, at Readfield, Me. His early manifested taste for engineering was inherited from his paternal family, his grandfather, William McClintock, having been an expert land surveyor, some fine examples of whose work are now on file in the State of Maine.

On the completion of his preparatory education Mr. McClintock entered a period of training for his profession, including both office and field work, and he also received instruction from a private tutor. His first work as an engineer was in connection with the United States Coast and Geodetic Survey with which he was engaged from 1867 to 1876 on work in Maine, Massachusetts, New York, North Carolina, South Carolina, Georgia, Florida, Louisiana, and Mississippi. From 1876 to 1879 he was employed on a survey of the City of Portland, Me., and from 1877 to 1879 on a survey of Boston Harbor, and also on a re-location survey for the Boston and Maine Railroad Company, including all its branches in Massachusetts. In 1880, he was elected City Engineer of Chelsea, Mass., which position he retained until 1890 when he went into business with Mr. J. Leslie Woodfall under the name of McClintock and Woodfall.

Mr. McClintock's special engineering works have included surveys for the South Pass Jetties, at the mouth of the Mississippi River; surveys for the improvement of the harbors of New York, N. Y., Boston, Mass., and Portland, Me.; surveys for the improvement of the Saco, Savannah, Pamlico, St. Mary, St. John, and Nassau Rivers; and the installation of sewerage systems for the cities and towns of Chelsea, Revere, Gardner, Westfield, East Hampton, Andover, Lenox, Natick, and Lexington, Mass.; Bennington, Vt.; Bath and Calais, Me.; Exeter, N. H.; and St. Stephen and Milltown, N. B., Canada. He also served as Consulting Engineer on sewer and water-works construction in Holyoke, Spencer, North Brookfield, North Attleboro, and several other towns in Massachusetts as well as in other States.

Mr. McClintock was actively identified with the Good Roads Movement in Massachusetts and, in its advocacy, he wrote various papers, and delivered addresses in nearly every city and town in the Commonwealth. In 1892 the old League of American Wheelmen, which had been agitating the question of better roads for several years, was publishing a magazine in an effort to stimulate public interest. At that time Mr. McClintock was building roads in various towns in Massachusetts, Maine, and New Hampshire. Through the efforts of the League, Governor W. E. Russell appointed a Commission to investigate and report on the improvement of highways in Massachusetts, and Mr. McClintock was appointed as the Engineer Member, together with George A. Perkins, a lawyer, and Nathaniel Shaler, widely known as Professor of

Geology at Harvard University. The result of the studies of this Commission showed that outside the thickly settled communities there were practically no good roads in the State.

In 1893, the Legislature passed an Act providing for the establishment of the Massachusetts Highway Commission and these same three men were appointed to form the new Commission. Mr. McClintock was subsequently re-appointed by Governors Greenhalge, Walcott, Crane, Guild, and Bates. In 1898, he was made Chairman of the Commission which position he retained until 1908 when he relinquished this work to give his services to his own home town which had been devastated by fire. He may be identified as a pioneer in the Good Roads Movement, and had much to do with organizing the Engineering Staff that was to carry out the Massachusetts system of road-building, a system which has been widely studied and copied throughout the country. He was nationally known as the "Father of Good Roads."

It was during his administration as Chairman of the Massachusetts Highway Commission that the increasing motor-vehicle traffic showed the impracticability of the water-bound macadam highway which until that time had been considered the finest road in existence. Under Mr. McClintock's leadership the bituminous macadam highway was devised, and it has since been the standard for the superior motor highway, except in sections of the heaviest travel where concrete has been adopted.

In 1908, came the Chelsea fire, during which more than 17 000 people were rendered homeless, and churches, public buildings, and schools were destroyed. Mr. McClintock was the man to whom every one looked to take charge of the relief operations, and so effectively was this done that when it was decided that Chelsea was to have an emergency commission form of government for five years, Mr. McClintock was selected by Governor Eben Draper as Chairman of the Board of Control. In this capacity he again had an opportunity to show his executive and constructive ability in the rebuilding of the city, and to this end he gave unremittingly of his time and service. Despite some opposition and many difficulties, this Board brought Chelsea out of its stricken condition. It rebuilt all the public buildings, laid out new streets, and left the city with better structures than it had previous to the fire. It was while he was engaged whole-heartedly in this work that he was recognized by Governor Charles E. Hughes, of New York State, as the leading authority in the United States on the construction of modern highways, and he was invited to accept the Chairmanship of the New York Highway Commission. He refused this offer because he was devoted to his community and to the work on hand.

In 1913 when the city returned to the Mayor and Board of Aldermen form of government, he was appointed Superintendent of Chelsea Ferry which position he held until the ferry was discontinued. He then became connected with the State Department of Education, in its field of University Extension. He died at his home in Chelsea on March 2, 1930, in his eighty-second year.

Mr. McClintock served on the Board of Aldermen, and School Committee, and was a Vice-President of the Chelsea Savings Bank. He was one of the organizers and first President of the Massachusetts Highway Association, a

member of the Boston Society of Civil Engineers, and, in addition, an Instructor in Highway Engineering at Lawrence Scientific School, at Harvard University. He was a member of the Robert Lash Lodge of Masons, and the Royal Arch Chapter of the Shekinah, and of the Review Club. He was prominently connected with the Church of the Redeemer (Universalist) of Chelsea.

He was married in Portland, Me., in 1873, to Mary Estella Currier. They had five children all of whom are living: William J., of Melrose, Mass., Francis B., Samuel, and Dorothy, of Chelsea, and Paul, of Hillside, N. J.

Mr. McClintock was elected a Member of the American Society of Civil Engineers on December 5, 1888.

## LAURENCE FRANCIS McCOY, M. Am. Soc. C. E.[1]

DIED JANUARY 13, 1930

Laurence Francis McCoy was born on April 29, 1865, at Dumont, Iowa. He was the son of John and Anna (Coyle) McCoy, both of Irish extraction. His father was a Civil War veteran who engaged in farming after the war.

Mr. McCoy received his education in Iowa, having been graduated from Iowa State College in 1885. Following his graduation, he worked for three years on surveys in Illinois and Iowa. Becoming interested in the development of the Northwest, he went to Spokane, Wash., in 1888. Railroad location and construction were the phases of engineering he preferred, and his first position in the West was with the Seattle, Lake Shore, and Eastern Railway Company.

He worked on many of the D. C. Corbin lines, serving at various times as Locating and Chief Engineer. These railroads included: The Spokane Falls and Northern, in 1889 to 1891; the Nelson and Fort Shepherd, a Canadian continuation of the Spokane Falls and Northern, in 1893; the Columbia and Red Mountain, a line built in 1896 to facilitate the development of the Rossland mines; the Spokane International, in 1906; and the Flathead Valley, in 1910.

From 1891 to 1893 Mr. McCoy was employed by the San Francisco Bridge Company at Sandpoint, Idaho. During the time of slackened building construction in 1894 and 1895, he taught school in Whitman County, Washington.

From 1901 to 1904, he worked on several divisions of the Oregon Short Line Railroad. On the Boise, Nampa, and Owyhee Branch, he was in charge of both engineering and construction. In 1907, he was employed by the Idaho and Washington Northern Railroad Company; his work here continued for two years, during which time he served both as Locating and Chief Engineer.

Mr. McCoy went to Sudbury, Ont., Canada, in August, 1911, as Division Engineer for the Canadian Northern Railroad Company. The outstanding feature of this work was the great number of bridges and tunnels necessitated

[1] Memoir prepared by Edward G. Taber, M. Am. Soc. C. E.

by the rough and irregular nature of the country. On the completion of the work in 1914, he returned to the West where he accepted the position of Chief Engineer for the Blackwell Lumber Company at Cœur d'Alene, Idaho, a position that he held until the time of his last illness. For this Company, which was committed to a policy of railroad construction to get out its timber, a series of switchbacks on the side of a steep mountain was Mr. McCoy's first project. He later located and constructed many branch lines to the Company's scattered holdings. Subsequently, his duties grew to include the letting of all contracts and the determining of amounts to be paid. In consequence his reputation for honesty and accuracy was well established.

Although his work was in varying locations, Mr. McCoy was greatly interested in public affairs. He seldom failed to vote and frequently wrote articles on public questions for the newspapers.

He was accepted by all who knew him as a man of unquestioned integrity and the highest sense of honor. He was happy and proud of the fact that he numbered as firm friends the men who worked for him, as well as those for whom he worked.

He was married on November 23, 1893, to Crissie Rusch, who, with two sons, Robert F. and Joseph P., and two daughters, Anna and Marie, survives him.

His private life was governed by the best of ideals, and his genial and sympathetic nature made him loved as well as respected by all those with whom he was associated.

Mr. McCoy was elected a Member of the American Society of Civil Engineers on December 5, 1911.

## JOHN ALEXANDER McDONALD, M. Am. Soc. C. E.[1]

DIED JUNE 4, 1930

John Alexander McDonald was born in London, England, on January 10, 1856. As a young man he studied civil engineering for two years at King's College, London, and served as an articled pupil for three years to Messrs. Jessop and Appleby Brothers, of London and Leicester, England. He later held a position of responsibility in the Greenwich Works of this Company.

Subsequently, Mr. McDonald went to Australia and was appointed Assistant Engineer in the Roads, Bridges, and Sewerage Department, of the Public Works of New South Wales. Shortly thereafter he occupied the position of Chief Assistant Engineer and, later, that of Engineer in charge of the design and construction of all bridges. He was the sole patentee of "McDonald's Patent Expansion Rollers" for large bridges and received first awards in London, Chicago, Ill., Adelaide, South Australia, and Melbourne, Victoria, Australia.

[1] Memoir prepared from information on file at the Headquarters of the Society.

Mr. McDonald was again employed in the Roads, Bridges, and Sewerage Department of the Public Works of New South Wales, this time as Principal Assistant Engineer. After fourteen years of service, he resigned and sailed for a six months' trip to America.

On his return, he was appointed Assistant Engineer in the Public Works Department of Perth, Western Australia. Later, he became Resident Engineer on the Freemantle Harbor Works and Executive Engineer in charge of this work. He was then engaged as Assistant Engineer-in-Chief for the Colony of Western Australia and for nine months he served as Deputy Chief Engineer in full charge during the absence of the Chief Engineer on a trip to England. The construction work under his control included new and extensive railway workshops, with plant and machinery; the Freemantle Harbor construction, on which 1 000 employees were engaged; the water supply and sewerage systems, including artesian bores, for Perth and Freemantle; the Coolgardie Water Supply System which proved to be one of the largest in the world; roads and bridges throughout the Colony; water supplies for the gold fields; as well as the construction of all railways and all harbor and river works in the Colony.

When Mr. McDonald had spent four and one-half years in this service, he resigned and went to South Africa, where he was engaged in mine surveying and assaying in Rhodesia, and in the designing of electric light stations in Cape Town, Cape Colony. Finally, he established a private consulting practice in Durban, Natal.

Following this period, he was appointed Assistant Engineer in the Town Engineer's Department of the Johannesburg Municipality. He then became Deputy Town Engineer and for an interval of six months served as Acting Town Engineer. He controlled road and bridge construction, as well as sewerage, water supply, and tramway construction. This work included a large ferro-concrete power house and running sheds, refuse destructors, storm-water drainage, quarries, parks, swimming baths, fire stations, and concrete traffic subways. All these developments were undertaken for a town 81 sq. miles in area.

On his resignation from this position after five years of service, Mr. McDonald returned to Western Australia where he became Engineer for water conservation works. In 1912, he acted as Engineer to the Gisborne Harbor Board and, in 1918, was Resident and Consulting Engineer to the Gisborne Borough Council which position he held for five years.

He was a member of the Institution of Civil Engineers and of the Institution of Mechanical Engineers of London. Mr. McDonald died in his seventy-fourth year at Gisborne, New Zealand. He had been in failing health since 1923 and succumbed to a serious attack of erysipelas.

He is survived by his widow, Blanche de Warrenne McDonald, to whom he was married on December 24, 1919.

Throughout his life, Mr. McDonald showed marked organizing ability and much kindly consideration for all employees under his control and was respected by all with whom he came in contact. His opinion was frequently sought

when difficult problems were under discussion, and he was an expert witness in many cases relating to engineering matters. In many places, structures of unusual merit remain as a lasting monument to his memory.

Mr. McDonald was elected a Member of the American Society of Civil Engineers on February 5, 1890.

## ANSON BURLINGAME McGREW, M. Am. Soc. C. E.[1]

DIED FEBRUARY 26, 1931

Anson Burlingame McGrew was born at Scott Haven, Pa., on May 10, 1868. His early education was received in the public grade schools and the High School at West Newton, Pa., and at the Indiana State Normal School. He entered the Western University of Pennsylvania (now the University of Pittsburgh), Pittsburgh, Pa., in 1889, from which he was graduated in 1892, with the degree of Civil Engineer.

From 1892 to 1894 Mr. McGrew was engaged in private practice and was employed as Borough Engineer for various boroughs in the Pittsburgh District on municipal improvements. In 1894 he entered the Government Service, in the War Department, and, until 1918, was engaged as Assistant Engineer in the Cincinnati, Ohio, Wheeling, W. Va., and Pittsburgh Engineer Districts.

From 1918 to 1919, during and immediately following the World War Mr. McGrew was District Engineer in charge of the Nashville and Chattanooga, Tenn., Engineer Districts, in which capacity he supervised river improvement work on the Cumberland and Tennessee Rivers and their tributaries. In 1919, he returned to the Pittsburgh District and was employed first as Assistant and then as Associate Engineer in charge of the Navigation Division of the United States Engineer Office until his death, which occurred suddenly following a short illness at his home in Beaver, Pa., on February 26, 1931.

Mr. McGrew was a member of the Local Membership Committee, the Pittsburgh Section of the Society, a Registered Engineer in the State of Pennsylvania, a certified member of the American Association of Engineers, a member of the Society of American Military Engineers, the Engineers Society of Western Pennsylvania, and the Chambers of Commerce, of Pittsburgh and New Brighton, Pa. He was a member of the Federal Business Association, and, also, a Director in the Home Protective Savings and Loan Association, of New Brighton.

He was married, at Beaver, on January 1, 1895, to Jessie Galey, who, with one daughter, survives him.

In addition to his professional activities, Mr. McGrew found time to devote to public and community affairs. He was also untiring in his efforts to advance the Engineering Profession and to secure proper recognition for engineers. In his passing, his many friends and associates feel a distinct sense of loss.

Mr. McGrew was elected a Member of the American Society of Civil Engineers on June 4, 1902.

[1] Memoir prepared by Nicholls W. Bowden, M. Am. Soc. C. E.

## CLARK ROGERS MANDIGO, M. Am. Soc. C. E.[1]

DIED MARCH 25, 1930

Clark Rogers Mandigo was born in Sherwood, Mich., on February 13, 1884, the only son of William R. and Ada Idella (Rogers) Mandigo. His early education was received in St. Paul., Minn., where he was graduated from Central High School in 1902, and in Fargo, N. Dak. In June, 1907, he was graduated from Harvard University with the degree of Master of Civil Engineering, having previously obtained a Bachelor of Arts degree from Harvard College in June, 1906.

Previous to his entrance into Harvard College, Mr. Mandigo had served for several months as Rodman in the Engineering Department of the Northern Pacific Railway Company, and was similarly employed during the summer months of 1904 and 1905 as Rodman and Inspector for the same Company.

After his graduation in 1907, Mr. Mandigo re-entered the service of the Northern Pacific Railway Company as Inspector and Superintendent of Construction on 30 miles of track rebuilding and grade revision from Kalama to Vancouver, Wash., in which position he remained until March, 1908. At this time he was made Civil Engineer and Superintendent of Construction in the Quartermaster Department at Large, U. S. Army, War Department, at Fort Logan, Colorado, in charge of the design and construction of buildings, sewage disposal, and water supply. Later, he was with the same Department at Fort Riley, Kansas, engaged in building roads, paving, water-works, and sewers.

From February, 1911, until October, 1916, Mr. Mandigo served as Assistant City Engineer (for a time as Acting City Engineer), of Kansas City, Mo. He was appointed to this position as the result of a civil service examination. He had engineering charge of street and sidewalk construction, repair work and grades, retaining walls, small viaducts, bridges, subways, municipal wharf and wharf house, water supply, and sewers, as well as office and routine administration. From October, 1916, to March, 1917, he was Advisory Engineer with the Portland Cement Association at Kansas City, for which he compiled promotional statistical data and lectures on the various uses of Portland cement and examinations of defective structures.

For several months prior to his entrance into the Army Mr. Mandigo was Consulting Engineer for the Western Paving Brick Manufacturers Association. He entered the First Officers' Training Camp in May, 1917, and was commissioned a Captain in the U. S. Army, assigned to the 314th Engineers, 89th Division, Camp Funston, Kansas. He saw overseas service with the American Expeditionary Forces in France. He was promoted to the rank of Major, Corps of Engineers, in September, 1918, and was honorably discharged on November 30, 1918.

From December, 1918, until April, 1923, Major Mandigo again served with the Western Paving Brick Manufacturers Association as Chief Engineer, in which capacity he had charge of all technical and experimental work in the manufacture of paving brick and in the design and construction of brick

[1] Memoir prepared by Webster L. Benham, M. Am. Soc. C. E.

pavements. He wrote many technical papers on this subject and on the use of brick in construction work. He was recognized as a national authority generally on paving and road work. From April, 1923, to January, 1927, he was Secretary-Engineer with the Kansas-Missouri Contractors Association, and the Kansas Contractors Association, a branch of the Associated General Contractors Association.

In January, 1927, Major Mandigo was appointed Chief Engineer for the Oklahoma State Highway Commission. As such, he served with great credit to himself and the profession until April, 1929, when he resigned and accepted a position as Engineer with the Southern Surety Company of New York, with headquarters at Kansas City, which position he held until his death on March 25, 1930. He died at St. Luke's Hospital, in Kansas City, following a major operation.

Major Mandigo was a man of great ability, had a most pleasing personality, and was exceedingly popular with all with whom he came in contact. He was a Mason and a Shriner. He took a very active part in civic affairs and the Rotary Club in Kansas City, and was a Past-President of the Kansas City Engineers Club. He was active in the American Legion and was elected Grand Chef de Guerre of the "Forty and Eight", for the State of Missouri, a social organization of the American Legion. He belonged to several engineering societies, and was a member of the Kansas City Athletic Club.

He was married on December 31, 1907, to Gladys Irene Allen, of Worcester, Mass., who survives him. He leaves, also, two sons, James Allen and Robert Allen, and a daughter, Violet Barbara Allen, as well as his father and mother, Mr. and Mrs. William R. Mandigo, of St. Paul, Minn.

Major Mandigo was elected an Associate Member of the American Society of Civil Engineers on September 3, 1912, and a Member on January 20, 1920.

## MARSDEN MANSON, M. Am. Soc. C. E.[1]

DIED FEBRUARY 21, 1931

Marsden Manson, the son of Robert E. and Sophia A. (Smith) Manson, was a native Virginian, having been born at Leewood, on February 14, 1850. Most of his active life, however, was spent in California to which State he journeyed in 1877.

Mr. Manson was graduated from the Virginia Military Institute in July, 1870, and obtained his first engineering experience as a Rodman on preliminary and location surveys for the railroad lines from Bristol, Tenn., to Cumberland Gap. He was an Instrumentman on surveys for the Atlantic, Mississippi, and Ohio Railroad, from Bristol to Norfolk, Va., and, again, on a survey for a narrow gauge railroad from Liberty, Va., to Rocky Mountain, N. C.

Following some municipal work at Lynchburg, Va., he became, in 1874, an Assistant in the Corps of Engineers, United States Army, on surveys for the

[1] Memoir prepared by C. E. Grunsky, Past-President, Am. Soc. C. E., and Otto von Geldern and E. F. Haas, Members, Am. Soc. C. E.

extension of the James River and Kanawha Canal and on the making of plans for the locks of this canal from Chesapeake Bay to the Ohio River. The following year Mr. Manson served for some months as Assistant City Engineer of Lynchburg and, then, became Assistant Professor of Physics and Chemistry at the Virginia Military Institute, at the same time continuing his studies which brought him the degree of Civil Engineer.

On his arrival in California, he was, for a brief period, an Instructor at the Brewer Boys' School, at San Mateo, and then found employment to his liking in the newly created State Engineer Department of California. Under the State Engineer, William Hammond Hall, M. Am. Soc. C. E., it fell to Mr. Manson to make some special studies relating to the damage being done to the rivers and to farm lands by the debris from hydraulic mines. These studies included a determination of the amount of material carried in suspension by the Sacramento River and its tributaries—studies which could in large part be carried on by Mr. Manson at the University of California where he registered for and was granted the degree of Doctor of Philosophy.

In 1881, he again became, for a brief period, an Assistant in the U. S. Corps of Engineers, and was then made Chief Engineer of the California State Board of Harbor Commissioners which has jurisdiction over and operates the harbor and water-front facilities of San Francisco. After eleven years in this position, he was made a member of the San Francisco Sewer Commission which, however, had only a brief existence.

Private practice in San Francisco followed, which terminated, in 1896, with his appointment as a member of the State Highway Commission of California. Mr. Manson was made a member of San Francisco's first Board of Public Works in January, 1900. In connection with his experience on this Board, it is interesting to note that an unusual charter provision placed the responsibility for the condition of streets and sidewalks on the individual members of the Board and that, regardless of inadequate appropriations and the unreasonableness of such a provision, judgments were obtained against Mr. Manson and paid by him which, it is understood, in one year at least, exceeded his annual salary ($4 000).

During his three years in the City's service, from 1900 to 1903, Mr. Manson became deeply interested in San Francisco's endeavor to secure the right to store water on Tuolumne River and its tributaries. He resented the attempted abandonment of the Tuolumne River water supply project by the municipal authorities and at no small expense to himself spent much time at Washington, D. C., in the interest of the City of San Francisco, with the result that an adequate permit was granted to this City in 1908 by the then Secretary of the Interior, the Hon. James R. Garfield.

The later acceptance by the City of a modification of this permit, whereby the City made all her priority rights to river water subject to first call by the Turlock and Modesto Irrigation Districts and submitted to onerous requirements relating to water and power development, and to road building, was a great disappointment to Mr. Manson, upon whose recommendation the original

bond issue for a Tuolumne River Project (the so-called Hetch Hetchy Project) had been authorized and voted.

Mr. Manson was made City Engineer of San Francisco in 1908 and served in this capacity for four years. Thereafter, he remained active in private professional practice to the end of his days. "Dr." Manson, as his friends called him, died in San Francisco, on February 21, 1931.

He was married to Samuella L. Chase, at San Francisco, on September 12, 1883, and three years after her death, which occurred in August, 1913, he married Julia D. E. Wright, daughter of the late G. Alexander Wright, Architect, of San Francisco, who, with her two children, Julius A. and Marsden W., mourn his passing.

Mr. Manson had a strong leaning to the study of scientific problems and was particularly interested in meteorology and in the study of the earth's pre-glacial climate. This brought him into contact with scientists the world over. His was a pleasant and charming personality. His fund of scientific information was poured out to every interested listener. One of his friends has written:

"Maintaining his mental activity to the end, he loved to dwell upon the things that might be, and undoubtedly will be, done to make this Coast, especially California, with its marvellous scenic and climatic offerings the playground of the nation."

Another friend writes:

"He rendered invaluable service to the State and few engineers have been held in such high esteem by his contemporary members of the profession."

Mr. Manson was elected a Member of the American Society of Civil Engineers on September 6, 1882.

## CHARLES CYRIL MARTIN, M. Am. Soc. C. E.[1]

DIED JULY 11, 1903

Charles Cyril Martin was born on August 30, 1831, in Springfield, Pa., the son of James and Lydia (Bullock) Martin, and a descendant of John Martin who came from England about 1666 and settled in Swansea, Mass. On the distaff side he was descended from John Howland, a *Mayflower* passenger.

Mr. Martin's early years were spent on a farm in the wilderness of Northern Pennsylvania amid the difficulties and hardships of frontier life. He became familiar with the details of farming and lumbering before he was 20 years of age, and during this time also had availed himself of every opportunity for study and reading that came his way. Previous to his matriculation at Rensselaer Polytechnic Institute, at Troy, N. Y., he was an accepted local authority on land surveying and had taught in the local district school. Through private tutoring and teaching, he secured sufficient funds to maintain himself and complete his college course at Rensselaer from which he was graduated with high honors in 1856.

[1] Memoir prepared from information on file at the Headquarters of the Society.

During this year, Mr. Martin remained at the Institute as a teacher, but in 1857 he declined a further professorship and accepted employment as Rodman on the Brooklyn, N. Y., Water-Works then in course of construction. A steady advancement secured for him the position of Assistant Engineer in charge of the construction of three of the reservoirs and eight miles of the great conduit.

In 1860, on the completion of the Brooklyn Water-Works, he was engaged as Draftsman for the Trenton Locomotive and Machine Manufacturing Company of New Jersey, of which he was later made Superintendent. In this position he had charge of iron bridge building, car and locomotive construction, etc.

At the outbreak of the Civil War, Mr. Martin was engaged on the construction of an iron bridge across the Savannah River, on the Savannah and Charleston Railroad. This work was necessarily abandoned and the iron which was intended for use in its construction was melted into shot and shell for the Confederate Armies. After many vicissitudes Mr. Martin reached home *via* Nashville, Tenn. On account of the war, the character of the work at the Trenton Shops was changed to include the manufacture of ordnance, of which part Mr. Martin served as Superintendent and General Manager. Part of his work consisted in making experiments on combinations of metal for heavy guns.

In 1864, he was employed by the United States Government as an expert in a series of boiler experiments at the Brooklyn Navy Yard. Soon thereafter he was appointed Superintendent of the laying of the four 48-in. water mains along Atlantic Avenue to the Ridgewood Reservoir, through which the water supply of Brooklyn has since been largely obtained. In the spring of 1865 he was made Chief Engineer of Prospect Park in Brooklyn and brought to a successful completion the work on the landscaping, lakes, bridges, drives, and drainage, including the great Park Well, which at that time was the largest well in the world.

In January, 1870, Mr. Martin entered the employ of the New York and Brooklyn Bridge Company as Principal Assistant Engineer and Superintendent under Col. W. A. Roebling. Mr. Martin's former experience in bridge construction and foundations proved of the utmost value in this work. From the inception of the New York and Brooklyn Bridge until its completion, he had full charge of the execution of the work, the employment of men, the purchase of materials, and the auditing of bills. In his nineteen years of service as Chief Engineer and Superintendent of this bridge, Mr. Martin was active, industrious, and competent in every way. In 1902, when the office was abolished by the consolidation of the Department of Bridges, he was appointed Consulting Engineer to the new Department, and 1903, the year of his death, marked as complete thirty-three years of activity on behalf of the Brooklyn Bridge and more than forty years of professional service on public works in Brooklyn, a city he had most ably and faithfully served.

Mr. Martin had tact and ability which, with his integrity, exercised a beneficent effect on all his subordinates and associates and made friends of

every one with whom he came in contact. He performed a notable service in his frequent counsel and advice to young engineers and was able thereby to impart a self-confidence and encouragement to them seldom surpassed by any one man in his profession. Partly due to this fact he received the unanimous vote of the Alumni of the Rensselaer Polytechnic Institute for the head of that Institution—an honor he reluctantly declined.

He was married to Mary A. Read, the daughter of Brig.-Gen. Jonathan Read, of Rensselaer County, New York, on August 9, 1859. They had two sons, Charles B. and Kingsley L. Martin, and two daughters, Mrs. John J. Hopper and Mrs. George Blatchford.

Mr. Martin's death occurred from heart failure at the summer home of his son, Kingsley L. Martin, at Far Rockaway, Long Island, on July 11, 1903. In reporting his death to the Mayor, the Commissioner of Bridges said:

"In the death, on Saturday, July 11th, 1903, of Mr. Charles Cyril Martin, Consulting Engineer of the Department of Bridges, the City of New York has sustained the loss of an eminent engineer, an able public officer, a wise counsellor, an honored citizen, and a man of unimpeachable integrity.

"Identified with the public works of the City of Brooklyn for over forty years, he was intimately connected with the New York and Brooklyn Bridge from its conception. Entering its service on January 2d, 1870, as First Assistant Engineer under Colonel W. A. Roebling, he held that office until the Bridge was completed in 1883, when he was appointed Chief Engineer and Superintendent of the New York and Brooklyn Bridge. This office he held until January, 1902, when he was appointed Consulting Engineer to the Department of Bridges.

"He served in each position with such faithfulness and success as to confer honor upon himself and dignity and distinction upon his profession."

Mr. Martin was elected a Member of the American Society of Civil Engineers on July 10, 1872, and served as Vice-President of the Society from 1894 to 1895. He was also an Honorary Member of the Brooklyn Engineers Club.

---

## SHELDON ELTON MINOR, M. Am. Soc. C. E.[1]

---

DIED FEBRUARY 19, 1931

---

Sheldon Elton Minor was born in Northfield, Conn., on September 14, 1860, the son of Henry and Amelia (Heaton) Minor. His early life was spent in Litchfield, Conn., until the death of his father. The family then moved to Thomaston, Conn., where he attended High School. He afterward entered the Sheffield Scientific School of Yale University, New Haven, Conn., from which he was graduated with the degree of Bachelor of Philosophy in 1882, winning the prize in Civil Engineering.

Immediately after his graduation, Mr. Minor started his career as Rodman for a proposed South Pennsylvania Railroad, on which work he was engaged

[1] Memoir prepared by W. R. Devaul, Assoc. M. Am. Soc. C. E.

until July, 1883. He then went to Santiago, Cuba, from September, 1883, to September, 1884, as Instrumentman for the Juragua Iron Company, on the construction of railroads to mining property. From April, 1885, to November, 1886, he was employed as Instrumentman and Inspector on United States River and Harbor Improvements on Long Island Sound and Gedney's Channel.

In February, 1887, Mr. Minor entered into private civil engineering practice in Greenwich, Conn., thereby realizing the ambition of every young engineer who has been working in various branches of the profession in order to gain the experience necessary to achieve his particular niche in the scheme of life. Starting his business career on a small scale in Greenwich, he advanced rapidly, due to his efficiency and close attention to detail, as well as to his honest business dealings with his fellow men. He became the Engineer for both the Town and Borough of Greenwich, having charge of the design of all highways, bridges, and sewers, in addition to private subdivision work and the laying out of large estates. From 1921 until Mr. Minor's death, the business was continued under the name of S. E. Minor and Company, Incorporated, with Mr. Joseph W. Cone as a partner.

Mr. Minor served for many years as Clerk and Treasurer of the Borough of Greenwich, was a member of the Board of Appeals of the Zoning Commission, and, for thirty-five years, acted as Engineer for the Greenwich Water Company and Port Chester Water-Works.

The passing of Mr. Minor is an occasion for deep regret on the part of a host of associates and friends throughout the State of Connecticut. All that is best in a sturdy New England heritage was typified in him; his integrity was unquestioned; his dealings with all were patient, fair, and sympathetic. As an Engineer, he ranked high in the profession, and strengthened his scientific training with practical judgment. He was always cheerful and even tempered; irritability and needless worry were foreign to his nature. Few men have had the unqualified esteem and respect of their friends that Sheldon E. Minor enjoyed.

In May, 1930, while still actively engaged in his work, a slight heart attack caused him to enter a private hospital in the Hotel Pennsylvania, New York City. He left the hospital after two weeks' treatment, in good spirits, and continued to devote himself to his work. Another attack caused him to return to the hospital on February 12, 1931, and, after seeming to improve, he suddenly grew worse and passed away on February 19, 1931.

Mr. Minor had served as a member of the Connecticut State Board of Civil Engineers as a Consultant on Dams since 1917; he had also been a member of the Connecticut Society of Civil Engineers since 1886 (President in 1913), the Yale Engineering Society, Chi Phi Fraternity, and of the Masonic Order.

He was married on December 6, 1887, to Mary E. Pierpont, of New Haven, who, with his son, Pierpont L. Minor, survives him.

Mr. Minor was elected a Member of the American Society of Civil Engineers on June 3, 1915.

## HENRY MITCHELL, M. Am. Soc. C. E.[1]

DIED DECEMBER 1, 1902

Henry Mitchell, the son of William and Lydia (Coleman) Mitchell, was born at Nantucket, Mass., on September 16, 1830. He received his education in private schools and at home, the atmosphere of the latter being especially conducive to study. His mother had been a school teacher prior to her marriage; his father, a teacher and later a bank official and one of the Overseers of Harvard College, was an able astronomer who enjoyed a wide acquaintance among American men of science; a sister, twelve years his senior, was the well-known astronomer, Maria Mitchell, who during her brother's youth was busily engaged on astronomical work at home.

In 1849, Henry Mitchell entered the United States Coast Survey, his first assignment being in connection with triangulation. Later, he was transferred to the Hydrographic Branch, in which field his abilities soon became manifest. In 1854, entrusted with carrying out a tidal survey of Nantucket and Vineyard Sounds, he devised a tide-gauge for use on the open coast. During the next thirty-four years he was engaged in harbor surveys and in investigations in physical hydrography, the results of his investigations appearing in numerous papers, published principally in the Annual Reports of the Coast Survey between the years 1854 and 1888. He also served as Chief of the Department of Physical Hydrography.

In his harbor investigations Mr. Mitchell was concerned principally with studying the tide and current régime as related to hydrographic features. In these studies he was successful in elucidating the complex forces at work in maintaining or changing the channels or shore lines of the harbors in question. His principal publications are: "Tides and Tidal Phenomena" (1868); "On the Reclamation of Tide Lands and Its Relation to Navigation" (1869); "Hints and Suggestions upon the Location of Harbor Lines" (1871); "On a Physical Survey of the Delaware River in Front of Philadelphia" (1878); "Physical Hydrography of the Coast of Maine" (1879); "Monomoy and Its Shoals" (1886); "The Circulation of the Sea Through New York Harbor" (1886); and "The Under-Run of the Hudson" (1888).

While still in his thirties, Mr. Mitchell became recognized as a leading Hydrographic Engineer and his services were utilized by various Government commissions. In 1866, he was directed by the Secretary of the Treasury at the nomination of the late Julius Erasmus Hilgard, M. Am. Soc. C. E., then in charge of the Coast Survey Office, to take the place of the late Alexander Dallas Bache, Hon. M. Am. Soc. C. E., on the United States Commission on Boston Harbor; and, subsequently, on application of the Massachusetts Board of Harbor Commissioners Mr. Mitchell became a member of its Advisory Council. In 1868, he was sent to Europe to investigate hydrographic and engineering progress, and while there he made a detailed inspection of the Suez Canal, upon which he prepared a report.[2]

[1] Memoir prepared by H. A. Marmer, M. Am. Soc. C. E.

[2] *North American Review*, October, 1869.

As Consulting Engineer, he served on various harbor boards in the United States. In 1874, he was appointed a member of the Commission on the Construction of an Oceanic Ship Canal, making a report of his inspection and investigation of the proposed routes through Nicaragua and the Isthmus of Darien.[3] That same year, President Grant appointed him a member of the Board of Engineers to survey the mouth of the Mississippi River, and in the following year, at the request of the late James B. Eads, M. Am. Soc. C. E., he served as a member of an Advisory Board in connection with the construction of the Mississippi Jetties. From 1875 to 1877 he served on the Advisory Board to the Harbor Commissions of Virginia and Rhode Island, and in 1879 he was appointed a member of the Mississippi River Commission by President Hayes.

In the world outside his chosen profession Mr. Mitchell's attainments likewise received wide recognition. Various scientific societies honored him by election to membership; in 1867, Harvard College conferred upon him the degree of Master of Arts; in 1869, he was offered the Professorship of Physical Hydrography at the Massachusetts Institute of Technology; and, in 1873, he was obliged on account of official duties to decline the same Chair in the Agassiz School of Science. In 1875, he was elected to the National Academy of Sciences.

In 1888, after thirty-nine years of service, Mr. Mitchell resigned from the Coast Survey. The following year, President Harrison offered him the Superintendency of the Survey, but his health did not permit him to assume the burdens of the office, and he declined the offer. Leading a retired studious life, he spent his summers in Nantucket and his winters near Boston, Mass. In 1890, he served as a member of the Commission of the Annual Assay of the Mint; in 1893, he was appointed a member of the Advisory Council of the World's Columbian Water Commerce Congress; and, in 1896, he published in the *Proceedings* of the American Academy of Arts and Sciences a biographical sketch of Ferdinand de Lesseps.

Mr. Mitchell was married three times. His first wife was Mary Dawes, of Boston, to whom he was married in his early twenties and who left him a widower after twelve years. In 1873, he was married to Margaret Hayward who died in 1875, about five months after the birth of a daughter, his only child. Two years later, he married his deceased wife's elder sister, Mary Hayward, who died in March, 1902. Mr. Mitchell died about nine months later at the home of his daughter in New York City.

Mr. Mitchell was elected a Member of the American Society of Civil Engineers on January 7, 1880.

---

## JOHN MITCHELL MONCRIEFF, M. Am. Soc. C. E.[1]

---

DIED JANUARY 10, 1931

---

John Mitchell Moncrieff was born at South Shields, Durham, England, on March 8, 1865, the son of the late Mitchell Moncrieff. He was educated

[3] Coast Survey Report, 1874.

[1] Memoir prepared from information supplied by Thomas C. Finlay, Esq., London, England, and on file at the Headquarters of the Society.

privately and served his apprenticeship at Messrs. Rennoldson's Engineering Works in South Shields.

After his apprenticeship Mr. Moncrieff entered the office of the late Mr. J. Watt Sandeman, of Newcastle-on-Tyne, England, as a pupil. Later, he became an Assistant in the same office, and, subsequently, joined Mr. Sandeman in partnership.

In 1906, this partnership was dissolved and, for many years, Mr. Moncrieff carried on an extensive practice by himself, at Newcastle-on-Tyne, specializing in bridges, docks, harbors, shipping facilities, and river-side improvements, generally.

One of his earlier works was the important undertaking of the new Redheugh Bridge across the River Tyne, at Newcastle, which was constructed according to his designs and under his supervision from 1899 to 1901, and which is considered to be one of the most difficult feats of bridge engineering ever achieved in England.

In 1907, when the Blackfriars Bridge disaster occurred Mr. Moncrieff was called in by Messrs. Sir William Arrol and Company to investigate and advise the Company concerning the causes of the accident. He frequently figured in other important cases of litigation and arbitration when he was called in to give expert engineering opinion, and also to advise in support of, or in opposition to, private bills before Parliamentary Committees of the House of Lords and the House of Commons.

In 1925, Colonel Moncrieff was invited by the Society for the Protection of Ancient Buildings to express his opinion for submission to the proper authority, on the question of the practicability of saving the structure of Waterloo Bridge over the Thames River. At this time he definitely expressed the opinion that the complete reconstruction of the damaged bridge piers was an absolute necessity and that this could be done only by taking down the bridge as a whole and likewise reconstructing it as a whole.

He was also associated with many other bridge undertakings during his career and was engaged on the design and construction or improvement of many large shipbuilding yards and graving docks in various parts of England. He was interested in railways, harbor developments, steel, timber, and reinforced concrete coaling staiths and their equipment, land development projects for industrial purposes, and the erection of large factories in steel and reinforced concrete, etc.

In June, 1917, he was appointed Director of Engineering Work in the Department of the Controller-General of Merchant Shipping at the Admiralty with the rank of Lieutenant-Colonel, Royal Engineers, and, in 1918, he had the honor of having the order of Commander of the British Empire conferred on him for his services.

In 1918, by permission of the Admiralty, Colonel Moncrieff resumed his practice for the purpose of designing important dock and harbor improvements at Falmouth, England, after which date he made London his headquarters.

In 1919 he took into partnership Mr. John W. Goldson, and his own son, Mr. Alan Moncrieff, with offices at Newcastle-on-Tyne and in London, and

although this partnership was later dissolved, he continued to practice in London to the time of his death.

Colonel Moncrieff was a well-known member of many engineering societies in England and in other countries, among which are included the Institution of Civil Engineers, by which he was awarded the Telford Premium, 1893-94, and for which he was sometime Examiner in Theory of Construction; a sometime member of Council of the Northeast Coast Institution of Engineers and Shipbuilders, by which he was awarded the Engineering Gold Medal, 1905-06; a member of the Association of Consulting Engineers, serving as Chairman in 1924; and Immediate Past-President of the Institution of Structural Engineers, having held office in 1928-29 and 1929-30. At the time of his death, he was President of the British Section of the French Society of Civil Engineers, and a Vice-President of the newly formed International Association for Bridges and Structural Engineering, the administrative offices of which are at Zurich, Switzerland.

Colonel Moncrieff served on the Steel Research Committee formed by the Department of Scientific and Industrial Research, as well as many other committees and panels organized for research work. He wrote numerous engineering papers and contributed to the discussions on many others, all of which have appeared in the publications of the various engineering societies and in the engineering press. He was the author of "The Practical Column under Central or Eccentric Loads", which was published by the Society.[2]

At one time he was External Examiner in Civil Engineering to Sheffield University. As President of the Institution of Structural Engineers, Colonel Moncrieff was invited by the Ministry of Transport to organize the British Section of the International Congress for Reinforced Concrete which was held at Liege, Belgium, in September, 1930.

On June 4, 1890, he was married to Elizabeth, daughter of the late Mr. P. Allan, of South Shields, and is survived by his widow, two sons, and two daughters.

Colonel Moncrieff was elected a Member of the American Society of Civil Engineers on November 3, 1897.

---

## GUY MOULTON, M. Am. Soc. C. E.[1]

---

DIED DECEMBER 3, 1929

---

Guy Moulton, the son of Emery and Mary J. (Churchill) Moulton, was born on February 25, 1861, in Cicero, N. Y.

He received his early education in Cicero, later enrolling at Cornell University, in Ithaca, N. Y., from which institution he received the degree of Bachelor of Science in 1881. Following his graduation, Mr. Moulton was employed by the Buffalo, Rochester, and Pittsburgh Railroad Company, serving as Stakeman, Draftsman, Transitman, and Leveler until the autumn of 1883.

[2] *Transactions*, Am. Soc. C. E., Vol. XLV (June, 1901), p. 334.

[1] Memoir prepared by Glenn D. Holmes, M. Am. Soc. C. E.

In the early summer of that year, he held the position of Assistant Engineer on location for the Pittsburgh and Allegheny Railroad.

From the autumn of 1883 to the spring of 1889, Mr. Moulton was engaged in other business, but returned to the Engineering Profession when he accepted the position of Transitman for the Lizard Creek Branch of the Lehigh Valley Railroad. In July, 1889, he was promoted to be Assistant Engineer in charge of construction on the Buffalo Extension under the late Paul S. King, M. Am. Soc. C. E., Chief Engineer.

Mr. Moulton left the service of the Lehigh Valley Railroad Company in December, 1892, to design and supervise the construction of an addition to the sewerage system at Watkins, N. Y., which work was successfully completed in the spring of 1893. Following a brief engagement with the New York and New England Railroad Company as Assistant Engineer, a similar position was accepted with a survey party for a private railroad in Tennessee during the summer of 1894. During the succeeding year he acted as Superintendent and General Manager for Charles McFadden in mining bituminous coal in Pennsylvania.

During the winter and spring of 1895-96 Mr. Moulton served as Assistant Engineer in charge of construction of the Jackson and Saginaw Railroad, in Michigan. In September, 1896, he assumed charge as Engineer and General Manager for McDonald and Sayre, General Contractors, on construction work of the Erie Canal Improvement. In November of the following year, he resigned to accept an appointment as First Assistant Engineer for the State of New York. He was in charge of the work from Syracuse, N. Y., to the Oneida County line during the "$9 000 000 Improvement", and after its completion, he was given charge of the entire Middle Division.

In 1904, as Resident Engineer, Mr. Moulton had charge of Residences 6 and 7, and a part of Residence 5, of the Barge Canal System. In 1909, he was appointed Division Engineer and, in 1911, First Resident Engineer of the System. In 1915 he was again made Division Engineer of the Barge Canal which position he held until his retirement in 1922.

From 1923 until his death he was engaged in consulting practice, maintaining an office in Syracuse. Mr. Moulton had been in failing health following a major operation in the summer of 1929, but continued his usual activity to the end. Death came to him as he was leaving his son's automobile on the way to his office, the result of a heart attack.

Mr. Moulton was known among the members of the Engineering Profession as a capable engineer of scrupulous integrity; to the public, as a trustworthy servant; among his associates, as a constant and unchanging friend; and to his family, as a devoted and generous husband and father.

He was a member of the First Universalist Church, which he served in many ways. He was affiliated with the Masonic bodies and was a member of the Citizens' Club of Syracuse. As an active member of the Syracuse Technology Club, he served as Director, Vice-President, and President, and on many of its committees. Mr. Moulton ably served his city upon two Flood Prevention Committees when appointed in 1915 and 1925 to study flood hazards and remedies in Syracuse.

He was a great lover of Nature. During the early morning and evening hours he took especial delight in his garden and the growing of roses, dahlias, gladioli, and other flowers.

He was married on March 16, 1887, to Sarah Adeline Wright, of Clay, N. Y., who, with three sons, Webster C., Lloyd W., and Guy W. Moulton, survives him.

Mr. Moulton was elected a Member of the American Society of Civil Engineers on March 1, 1905.

---

## ANDREAS WENDELBO MUNSTER, M. Am. Soc. C. E.[1]

DIED MAY 13, 1929

Andreas Wendelbo Münster was born in Bergen, Norway, on December 26, 1853, the son of Lt.-Col. Frederik Julius Münster, of the Norwegian Army, and Grete Bull Münster, a sister of the famous violinist, Ole Bull. Mr. Münster received his technical education at the Chalmarske Institute at Gothenborg, Sweden, from which he was graduated in 1873.

In August following his graduation, Mr. Münster entered the service of the Norwegian Government Railroads, where he remained for eight years, holding, successively, the positions of Assistant Engineer on location until the fall of 1876; Assistant Engineer on construction until 1880; and Resident Engineer on construction until his resignation in May, 1882.

On his arrival in the United States in 1882, Mr. Münster went West and in July accepted the position of Assistant Engineer on the Rocky Mountain Division of the Northern Pacific Railroad Company, with headquarters in Helena, Mont. After the completion of the road in 1883, he spent the following winter and spring as Draftsman in the Office of the Surveyor-General of Montana and, in August, 1884, was appointed Bridge Engineer in the City Engineer's Department at St. Paul, Minn. Among the more important structures which were designed by him and erected under his supervision were several bridges across the Mississippi River in St. Paul, Minn., including the Robert Street Bridge, an iron bridge, 1 540 ft. long, which was completed in 1886; High Bridge, an iron structure, 2 770 ft. long; and the Wabasha Street Bridge, also an iron structure; also, the Third Street Viaduct, an iron and masonry structure, 1 900 ft. long, completed in 1887; and the Colorado Street Stone Arch Bridge, a skew arch of 70 ft. span.

Mr. Münster had charge of the many artesian wells owned by the City of St. Paul as a part of its water supply and he also built the Aberdeen Hotel, on the corner of Dayton and Western Avenues, which, at one time, was considered one of the finest buildings in that city.

In April, 1904, he was appointed Chief Engineer of the Great Western Railway Company. He continued in that capacity until his resignation in July, 1906. During his connection with this Company, Mr. Münster designed and supervised the construction of the following: Grain Terminals and Independent Elevator at Omaha, Nebr.; the Red Wing, Minn., Depot; the Great

[1] Memoir compiled from information supplied by Charles F. Loweth, Past-President, Am. Soc. C. E., B. Thomas, Civ. Engr., Seattle, Wash., and on file at the Headquarters of the Society.

Western Elevator at Kansas City, Mo.; the Fort Dodge, Iowa, Depot; shops, store rooms, and a forty-stall round-house, at Oelwein, Iowa, etc. He also was in charge of the double-tracking of the Chicago Great Western Railroad from Stockton to Galena Junction, Ill.

In 1906, Mr. Münster engaged in private practice as a Consulting Engineer with offices in Seattle, Wash., which he continued until his death. Because of his enviable record in St. Paul, his services were soon sought throughout the West. He was Consulting Engineer for the Chicago, Milwaukee, and St. Paul Railway Company during the construction period of the Western Extension to Seattle (1908 to 1911), and designed several of the railway terminals and division structures in Washington and Idaho, which included docks, wharves, and freight houses in Seattle and Tacoma. He was also Consulting Engineer for the Great Northern Railway Company, and among the many structures which he designed for this road was the reinforced concrete dock in Vancouver, B. C., Canada.

From 1914 to 1923 Mr. Münster served as Consulting Engineer for the City of Seattle, on the design and construction of several of its bridges, notably those at 15th Avenue West, Fremont Avenue, Eastlake Avenue, and West Spokane Avenue. From 1923 until his death, he also acted as Chief Engineer of the Bridge Department for that city. The Montlake Bridge, over the Lake Washington Ship Canal, is an outstanding structure which was designed and constructed under Mr. Münster's supervision. On its completion his friends in Seattle arranged a celebration in his honor.

A nobleman by birth, Mr. Münster was a quiet and dignified gentleman, who commanded the admiration of all who knew him. Through him as a man of eminence in his profession is added greater renown to those engineers of Norwegian birth who have practiced their profession in the United States. His work which was of high quality prompted by a noteworthy pride in professional achievements, was ever conscientiously performed. Many of the bridges that he designed forty years or more ago are still giving satisfactory service. They are models of fine design which will stand as monuments to his unusual skill and ability as an engineer. The character of his work is a tribute to him and accounts for the esteem in which he was held by the City of Seattle.

On September 17, 1926, Mr. Münster was married to Clara von Tangen Sullivan who survives him, together with a sister, Mrs. Storm Bull, of Madison, Wis.

Mr. Münster was elected a Member of the American Society of Civil Engineers on May 1, 1889.

## RALPH WALDO NICKERSON, M. Am. Soc. C. E.[1]

DIED MAY 13, 1929

Ralph Waldo Nickerson, of an old New England family, was born on November 26, 1881, at Tiverton, R. I. His father was Capt. George Ferdinand

[1] Memoir prepared by J. E. Wadsworth, J. B. French and H. G. Balcom, Members, Am. Soc. C. E.

Nickerson, and his mother, Marie (Springer) Nickerson, was a lineal descendant of Knight Springer of Revolutionary Service.

Mr. Nickerson prepared for college in the public schools of Tiverton. He entered Worcester Polytechnic Institute, Worcester, Mass., in the fall of 1899 and was graduated in 1903 with the degree of Bachelor of Science. Immediately after his graduation he entered the employ of the American Bridge Company as a Structural Draftsman in the East Berlin, Conn., Plant. He was promoted to the position of Squad Leader in 1906, and had supervision of a squad of draftsmen preparing detail drawings of bridges and buildings. In 1911 he was again promoted, this time to the position of Designing Engineer in the New York Office of the Company.

As a Detail Draftsman he had charge of the detailing of some of the most important structures fabricated by the Company, and as a Designer he designed the steel framework for many large manufacturing plants, among which were the new plants of the American Brass Company at Waterbury, Ansonia, and Torrington, Conn., and Kenosha, Wis. He also had general supervision of the detailing of his own designs.

During his connection with the American Bridge Company Mr. Nickerson was released to do special work for H. G. Balcom, M. Am. Soc. C. E., Consulting Engineer of New York City, under whose direction he prepared designs for several large office buildings there.

In December, 1924, he resigned his position with the American Bridge Company and opened an office in New York City, as Consulting Engineer, making a specialty of structural steel, reinforced concrete, and foundations. While in private practice Mr. Nickerson designed the structural steelwork and foundations for a large number of theatres, office buildings, and miscellaneous structures, in various parts of the country, and established a reputation for conscientiously thorough and high-class work.

In 1928 Mr. Nickerson entered the Engineering Department of the George A. Fuller Company and remained with that Company until his death on May 13, 1929. During this period he had direct supervision of the work of the Company on the No. 400 Madison Avenue Building, the Beaux Arts Apartments (312 and 313 East 44th Street), and the Astor Apartment (520 East 86th Street), all in New York City.

Mr. Nickerson was a man of sterling character and of indisputable integrity. He was an indefatigable worker and a man of unquestioned reliability. He had the confidence of the companies by which he was employed and of his clients for whom he acted as a Consultant.

He was a member of the Union County (New Jersey) Chapter of the Society of Professional Engineers and Land Surveyors, the Sons of the American Revolution, Elizabethtown, Pa., Chapter; and the Architects and Engineers Square Club. He was also a member of Hillside (N. J.) Lodge No. 241, F. and A. M., and an Elder in the Hillside Presbyterian Church.

He is survived by his widow, Edith North Nickerson, and two sons, Ralph Waldo and Stanley North Nickerson.

Mr. Nickerson was elected a Member of the American Society of Civil Engineers on April 20, 1925.

## GEORGE H. NORMAN, M. Am. Soc. C. E.[1]

DIED FEBRUARY 4, 1900

George H. Norman was born in Newport, R. I., on January 1, 1827, the son of George W. and Hannah Norman, and maintained his home there throughout his life.

His education was limited to that provided by the common schools of Newport. He left school at an early age and began work in a shoe store. Before he was twenty years old, he had acquired the business, on the death of his employer, and continued it successfully for some time.

In 1849, Mr. Norman, in partnership with Mr. William H. Cranston, purchased the *Newport Daily News*, which they continued to publish until 1856. A gas company was started in Newport early in the Fifties and the promoter, desiring to secure the aid of the newspaper, interested Mr. Norman in the matter to such an extent that he took some stock in the Company, became its Secretary, and acted for some time as its Bookkeeper and Cashier. This was his introduction to public utilities.

Mr. Norman's first venture in the construction field, in which he afterward became so successful, was the installation of gas-works at Waterbury, Conn. With the experience gained on this work, and in company with a fellow townsman, Mr. William Fludder, Mr. Norman in 1857 undertook the construction of a gas plant in Cuba—the St. Fago de Cuba Gas-Works. He went to England to purchase pipe and other material, and thence to Cuba to construct the works. Later, Mr. Norman entered the field of general engineering contracting. The construction of sewers in Manchester and Nashua, N. H., was among his earlier works.

Subsequently, he turned his attention to the construction and operation of water-works. About 1876, he began the Newport Water-Works, organizing a corporation to build and operate the plant. He continued in control of this Company until his death, and the ownership remained in his family until about 1929.

After building the water-works at Newport, Mr. Norman organized water companies and built works in many other places, and, also, as contractor, constructed extensions to a number of existing municipal water-works. Most of this work was done between 1880 and 1890, although some of it was continued as late as 1898. Among the places for which works were built or extended, may be mentioned the following: Manchester, N. H.; Newburyport, Lowell, Beverly, Gloucester, Lynn, and Franklin, Mass.; Bristol, Warren, and Jamestown, R. I.; Middletown, Conn.; Seneca Falls and Hoosick Falls, N. Y.; Frankfort, Ind.; and Green Bay and Fort Howard, Wis. During this period he was also engaged in railroad construction, both in New England and in Texas.

A large proportion of the distribution pipe in these water-works systems was of sheet iron, lined and surrounded with cement mortar, a type of con-

[1] Memoir prepared by Charles W. Sherman, M. Am. Soc. C. E., chiefly from information furnished by Bradford Norman, Esq., Newport, R. I.

struction which was then at the height of its popularity. Mr. Norman's skill in construction and laying pipe of this type at comparatively low cost, and his business acumen in establishing water companies in growing towns and retaining the control of them until they could be sold at a good profit, were probably responsible in large measure for the financial success which he achieved.

Mr. Norman was married on May 23, 1859, to Abby Durfee Kingsley, daughter of Rufus B. Kingsley, of Newport. He had six sons and three daughters.

Shortly after the re-organization of the American Society of Civil Engineers, Mr. Norman was elected a Member on February 17, 1869; and on March 23, 1870, he became a Fellow, by contributing a substantial sum to the permanent funds of the Society. In 1872, he endowed the first prize established by the Society, the Norman Medal, which is awarded annually for a paper by a member of the Society, "which shall be judged worthy of special commendation for its merit as a contribution to engineering science."

## GEORGE HARVEY NORTON, M. Am. Soc. C. E.[1]

DIED MARCH 4, 1930

George Harvey Norton, the son of George Harvey Norton, M. D., and Martha Graves Norton, was born in East Pembroke, N. Y., on October 24, 1863. In 1887, he was graduated from Cornell University, at Ithaca, N. Y., with the degree of Civil Engineer.

In his early life, during 1887 and 1888, Mr. Norton was engaged in survey work on the Duluth, South Shore, and Atlantic Railroad and the Chicago and West Michigan Railroad. While thus engaged, he went to Buffalo, N. Y., on a vacation and obtained a position as Substitute Draftsman with the Grade Crossing Commission. Within six months, he was appointed Assistant Engineer, under the late George E. Mann, M. Am. Soc. C. E., who for years served both as Engineer for the City of Buffalo and the Grade Crossing Commission. Mr. Norton entered the service of the City of Buffalo on November 1, 1888, and was closely associated with all its more important engineering projects from that time until his death.

Among his notable accomplishments, were the improvement of Scajaquada Creek and, coincident with this, the improvement of the Buffalo River and Cazenovia Creek, for relief from floods. From 1889 to 1895, as Assistant Engineer, he also constructed and operated a temporary sewage pumping plant, made paving plans, and had charge of the underground construction preceding paving, on about 150 miles of streets. During 1896 and 1897, he was engaged in paving construction.

From 1898 to 1908, Mr. Norton, as Assistant City Engineer, was in immediate charge of all bridge, harbor, and hydraulic work of the city (except grade-crossing elimination), covering both construction and maintenance, including the maintenance of many grade-crossing structures after comple-

[1] Memoir prepared by Edward P. Lupfer, M. Am. Soc. C. E.

tion. He was in charge of the design and construction of several fixed bridges, having spans of from 40 to 150 ft., and the general location, design, and construction of temporary structures and foundations for two bascule bridges, one of 110-ft. span and the other of 166-ft. span, together with the supervision of the construction and operation of these bridges.

His name is likewise outstanding in the development of Buffalo's waterfront. He had immediate supervision of the plans and the dredging of Buffalo's Inner Harbor, this project costing approximately $900 000, and, during 1908, he was engaged in survey and engineering work in negotiations for the improvement of a large part of Buffalo's Outer Harbor, as well as in making hydraulic studies and plans for flood abatement and extending the navigable channel in Buffalo River, at a total cost of about $1 000 000.

From 1909 to 1923, as City Engineer, Mr. Norton was in charge of all street, sewer, sidewalk, and bridge construction and maintenance, all city harbor deepening and extension, land surveys, the supervision of franchise, occupation of streets, and valuation of physical properties therein, as well as a great variety of other engineering work arising in a large city. Some of the larger projects included the improvement and extension of navigation; the beginning of the Scajaquada Creek drain, one of the largest of such projects for placing streams below ground; water-front improvements; studies of sewage treatment; and the settlement of long disputed water-front rights and titles. Expenditures in this work, under the City Engineer, averaged about $3 000 000 per year.

As City Engineer, Mr. Norton also was made Chairman of the City Planning Committee, and served as such until the spring of 1926. During this time there was developed a general City Plan, including the location of public buildings and the adoption of a zoning ordinance. He was also a Director of the Buffalo City Planning Association and Niagara Frontier Association, and was deeply interested in general city planning.

In 1923, Mr. Norton became Chief Engineer of the Grade Crossing and Terminal Station Commission, and served in this capacity until his death. His career in this office was a notable one, and as Chief Engineer of the Grade Crossing Commission, his services in connection with the location and design of the New York Central Terminal at Buffalo were, perhaps, the crowning achievement of a distinguished career.

His interests and activities were many and varied, and in addition to his civil life, he had an honorable military record. He enlisted in the Sixty-fifth Infantry, New York National Guard, in 1889, advancing to Corporal, Sergeant, Second and First Lieutenant, and, in May, 1898, he received his Commission as Captain, in which rank he served throughout the Spanish-American War. He was placed on the Reserve List in 1918, re-assigned to the Sixty-fifth Field Artillery in 1919, and appointed Major of Field Artillery and placed on the Retired List in 1920.

Major Norton's services to the Buffalo Chamber of Commerce as Vice-President and as member of the Board of Directors for two consecutive terms, were long and useful. He was particularly active on the City Planning and

Marine Airport Committees, and developed the first plans for the landing area at the foot of Georgia Street, Buffalo.

He was the author of various articles for technical papers and social publications. He was a Past-President of the Buffalo Section of the American Society of Civil Engineers, the Engineering Society of Buffalo, and the American Society for Municipal Improvements. He was a member of the City Planning Institute and the Cornell Society of Engineers.

In civil and social organizations of the city Major Norton also was active. He was a member of many prominent groups, some of which are as follows: The Automobile Club of Buffalo, the Scottish Rite Masons, the Shrine, the Rotary Club, the Torch Club, the University Club, the Buffalo Athletic Club, and the Hook and Axe Club. He was a member of the Central Presbyterian Church.

Major Norton's life was cut short at the crest of his active career, when he passed away on March 4, 1930. He was one of the finest of men, a worker who loved his work and who sought no ostentatious praise. He was filled with the spirit of service to the community, and possessed a kindly, gentle character that endeared him to all who knew him. He was a highly esteemed gentleman, and, in his death, Buffalo has lost one of its great builders. He was deeply beloved by all and his passing leaves a void that can not easily be filled.

At the time of his death, fitting testimonials to Major Norton's sterling qualities appeared in many publications in his own section of New York State, typical of which is the following from the *Buffalo Evening News:*

"The death of Major George H. Norton removes a man who has had a part in nearly every big public improvement that has been carried out in Buffalo during the last forty years. In many of them he was the directing mind. As City Engineer and, later, as Engineer for the Grade Crossing Commission, he had responsibilities far beyond any credit which his modest mind ever thought to claim.

"Moreover, it may be said for him that in a long lifetime of public employment, he retained the confidence and the friendship of those with whom he was associated to such a degree that even dissent from his plans never meant personal criticism. Closely associated as he was with government, he was regarded by everybody as distinctly an engineer, not a politician."

He is survived by his widow, Mrs. Elvina Margaret Schiferle Norton, and a son, George H. Norton, Jr.

Major Norton was elected a Member of the American Society of Civil Engineers on April 7, 1915, and at the time of his death was serving on the Board of Direction.

---

## CHARLES WELLMAN PARKS, M. Am. Soc. C. E.[1]

---

DIED JUNE 25, 1930

---

Charles Wellman Parks was born at Woburn, Mass., on March 22, 1863, the son of Granville and Elizabeth Augusta (Carter) Parks. His ancestors

[1] Memoir prepared by Glenn S. Burrell, Capt. (C. E. C.), U. S. N., M. Am. Soc. C. E.

were of early Colonial New England stock. He was graduated from the Woburn High School in 1879, and, in 1929, he attended the Fiftieth Anniversary re-union of his class. Entering Rensselaer Polytechnic Institute, at Troy, N. Y., in 1879, he was graduated in 1884 with the degree of Civil Engineer. In 1899, he was graduated from the Columbian University, (now George Washington University) with the degree of Bachelor of Laws.

Mr. Parks' first practical engagement was in the fall of 1881 as Instrumentman on the Missouri River Survey with headquarters at Council Bluffs, Iowa. From December, 1881, to April, 1882, he was Leveler on the Arkansas Northern Railroad, and from April to August, 1884, he served as Engineer with the Denver, Memphis, and Atlantic Railway Company in Kansas. For the next four months he was employed as Engineer on railroad work in Colorado. In 1885 he was engaged in designing street railway equipment in Boston, Mass.

In September, 1885, Mr. Parks became Assistant to the Director of the Rensselaer Polytechnic Institute, and Engineer with the Electric Manufacturing Company of Troy, the first company in the United States to manufacture electrical testing instruments. From September, 1886, to September, 1894, he was the head of the Department of Physics at Rensselaer Polytechnic Institute.

From November, 1888, to March, 1890, Mr. Parks served under United States Government appointment as Superintendent of Liberal Arts at the Paris Exposition of 1889. The exhibit of the Rensselaer Polytechnic Institute under his charge was awarded the Grand Prix. He was made Officier de l'Instruction Publique of France, and awarded the decoration with golden palms. He also served under Federal appointment as Special Agent to the World's Columbian Exposition in Chicago, Ill., in 1893. As Special Agent of the United States Bureau of Education, he visited and reported on the educational exhibits at the expositions at Antwerp, Belgium, Lyons, France, Genoa, Italy, and Zurich, Switzerland, and investigated and reported on forestry schools and systems in various European countries.

In 1895 and 1896 he was engaged on the New York State Land Survey. In July, 1896, Mr. Parks became an Examiner in the United States Patent Office and, at the same time, pursued the course in law at Columbian University. In the summer of 1897, yielding to the persuasion of the late Rear-Admiral Mordecai T. Endicott, C. E. C., U. S. N., Past-President, Am. Soc. C. E., then Chief of the Bureau of Yards and Docks, United States Navy Department, Mr. Parks took the competitive examination for entrance into the Corps of Civil Engineers, United States Navy. Commissioned a Civil Engineer with the rank of Lieutenant (Junior Grade) in July, 1897, he was promoted to the rank of Lieutenant in February, 1901, Lieutenant Commander in October, 1909, Commander in August, 1913, Captain in July, 1917, and Rear-Admiral in January, 1918.

From July, 1897, to February, 1898, Lieutenant Parks was on duty at the Navy Yard, Norfolk, Va. From that time until the spring of 1899 he was on duty in the Bureau of Yards and Docks, Washington, D. C. During

the major part, if not all, of this period he was the only commissioned Assistant to the Chief of the Bureau. This covered the period of stress incident to the Spanish-American War. During this period he designed the naval dry docks for Portsmouth, N. H., and Boston, Mass., including the first electric pumping plants used for United States Naval dry docks.

Thereafter, he served as Officer-in-Charge of the design, construction, and maintenance of public works at various stations as follows: San Juan, Porto Rico, 1899-1902; the Navy Yard, Boston, 1902-1905; and the Navy Yard, Portsmouth, 1905-1908. At Portsmouth he was charged with making the material preparations for the Russo-Japanese Peace Treaty sessions, for which he earned high commendation.

In May, 1908, Lieutenant Parks was selected by the Secretary of the Navy to take charge of the development of Pearl Harbor, Hawaii, for Naval purposes. Surveys, triangulation, soundings, and borings were undertaken at once. At the time of his detachment in February, 1910, the dredging of the 4½-mile entrance channel had been under way for about a year and excavation for the dry dock was also well along. He was subsequently detailed, 1910 to 1912, as Inspector of material and apparatus for the Navy at the works of the General Electric Company, at Schenectady, N. Y. Following this, he was Public Works Officer at the Navy Yard, Philadelphia, Pa., from 1912 to 1914.

In December, 1914, Commander Parks was again selected by the Secretary of the Navy as Public Works Officer for the Naval Station, Pearl Harbor. A very important part of the assignment was the resumption of the construction of the 1 000-ft. dry dock by contract, with radical changes in the design and method of construction. Concurrently, there was active development of the remainder of the station, including shops, storehouses, roads, railroads, coaling plant, fuel oil plant, radio station, ammunition depot, water-front, hospital, etc. The dry dock was brought to practical completion by the time of his detachment in January, 1918.

In the meantime, he had been promoted to the rank of Captain. In January, 1918, in the great stress of the wartime building program, he was commissioned Chief of Bureau of Yards and Docks (and Chief of the Corps of Civil Engineers), with the rank of Rear-Admiral. Some conception of the magnitude of the work handled by the Bureau in 1918 may be had from the fact that the expenditures for construction work were about forty times as great as in peace time preceding the war.

There was a vast expansion of industrial and storage facilities, of dry docks and shipbuilding facilities, of training stations, air stations, submarine bases, hospitals, and ammunition depots. In the meantime the Bureau was carrying on a vast amount of construction work in Europe, including air stations in Great Britain and France, and the world's greatest radio station at Croix de Hins, France. In addition, the Bureau was assisting many commercial shipbuilding and repair plants in the expansion of their facilities to do Navy work.[2]

[2] For a full account of this work the interested reader is referred to the book, "Activities of the Bureau of Yards and Docks in the World War", of which Admiral Parks was Editor-in-Chief.

On the conclusion of the World War, Admiral Parks was confronted with another difficult task, that of slashing budgets, reducing construction programs, and decreasing forces at the Bureau and at various stations. It is one thing to go with the tide, but another to check it. This task he performed vigorously with a great saving of taxpayers' money.

During his career, Admiral Parks served on numerous boards of officers making investigations and reports on important Naval projects, including dry docks, coaling stations, the layout of the Pearl Harbor Station, power plant consolidations, and similar construction work. He was a member of various boards on the admission and promotion of officers in the Corps of Civil Engineers. In 1905, he was ordered to Europe to make an investigation and report on progress in the manufacture of direct-current turbo-generators.

In recognition of Admiral Parks' outstanding service as Chief of Bureau during the war he was awarded the Distinguished Service Medal (Navy) by the United States Government. The Republic of France made him a Commandeur Legion d'Honneur, this reward being conferred by General Nivelle. The degree of Doctor of Laws was conferred upon him by George Washington University, on February 22, 1921.

In December, 1921, Admiral Parks was found to be suffering from chronic heart disease, and he was thereupon retired for disability incident to the service, with the rank of Rear-Admiral. In 1922, he gave his services to the United States Department of Justice, assisting with the handling of cases growing out of war-time construction contracts. He continued in this work for nearly eight years until shortly before his death. His long and broad experience at the Bureau and various stations, coupled with his legal and engineering education, especially fitted Admiral Parks for this work. With his keen analytical mind he was of the greatest assistance to the Department of Justice in handling the various cases. He was offered active duty for this work, but preferred to carry on in his retired status with no increase in compensation.

Admiral Parks was a Fellow of the American Institute of Electrical Engineers, and a member of the following societies: the Rensselaer Society of Engineers; the American Society of Naval Engineers; the Society of American Military Engineers; the National Geographic Society; the American Geographical Society; the American Association for the Advancement of Science; and the New England Genealogical and Historical Society.

During the latter forty years of his life Admiral Parks was deeply interested in genealogy, and made exhaustive studies of the Parks family in America and in England. This may be said to have been his one hobby.

He was also a member of the following clubs: The Algonquin (Boston), the Cosmos and Army and Navy (Washington), and the Army and Navy of America (New York). He was a member of the Presbyterian Church for fifty years.

Admiral Parks was married in Troy, on April 14, 1887, to Martha Bessac Frear, of Coxsackie-on-the-Hudson and Troy, who survives him. He is also survived by three brothers, Granville H. and Karl E., of Washington, and Albert F. Parks, of South Norwalk, Conn.

On June 25, 1930, Admiral Parks died of pneumonia and heart trouble at the Naval Hospital in Washington, after an illness of several months. He was buried at the National Cemetery at Arlington, Va., with full Naval honors for his rank.

In the death of Admiral Parks the Society has lost an illustrious member. His patriotism, all-round professional ability, untiring zeal, and executive ability combined to make him a most valuable public servant in peace and in war. He always maintained the courage of his convictions and was indefatigable in protecting the Government's interest. He was ever ready with counsel for those who sought his advice.

Admiral Parks was elected a Member of the American Society of Civil Engineers on October 3, 1906.

## JAMES SUYDAM POLHEMUS, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 29, 1930

James Suydam Polhemus was born in Astoria, N. Y., on March 26, 1852. He was the fifth to bear the same name, born in direct succession in the United States, the family having originally come from Holland. His father was engaged in the shipping and commission business in New York, N. Y.

Mr. Polhemus' boyhood was spent very largely on the waters of the East River and Long Island Sound and his interests naturally followed along marine lines. After the usual preliminary school education, he attended Lehigh University, from which institution he was graduated in Civil Engineering in 1872. He was a classmate of Dr. Drinker, President Emeritus of the University.

As a young man, Mr Polhemus was somewhat delicate and at the end of his Junior year at the University, in June, 1870, his father sent him on a trip around the world. He sailed from New York in one of the old-style Pacific Mail steamers of that time, and proceeded by way of the Mediterranean and Suez Canal to China. His account of the voyage made in those early days was most interesting, as he was a close observer and possessed of a most retentive memory. On his arrival in China, after stopping in Japan, he was advised of his father's death, and he returned directly to New York by way of San Francisco.

Shortly after his arrival in New York, Mr. Polhemus was employed on the construction of the Albany Water-Works. He re-entered Lehigh University in the Class of 1872, and after graduating he became connected with river and harbor work under the Corps of Engineers, United States Army. His first duty was at Galveston, Tex., later at New Orleans, La., and his work consisted principally in surveying the many bays and bayous adjoining the Gulf of Mexico in Texas and Louisiana. The conditions under which he carried out his work were most strenuous, for everything in that section was very primitive in those days when one found himself away from the cities or regular settlements.

[1] Memoir prepared by Frederick C. Schubert, M. Am. Soc. C. E.

After three years in the Gulf region, Mr. Polhemus was transferred to the United States Lake Survey, which was then making the first hydrographic survey of the Great Lakes. He was more particularly connected with the Computing Section of the Astronomical Division, which was determining the precise latitude and longitude of the various stations. Leaving the Lake Survey in 1877, he was assigned to the Wheeler Survey, then doing exploration work in California. He returned to Galveston in 1878, where he remained until 1880, when he was transferred to Portland, Ore.

After his arrival in Oregon, Mr. Polhemus was intimately connected with many river and harbor improvement works, more especially at Yaquina and Coos Bay, where he initiated and carried on the work on the jetties at the entrances to these harbors. He was a pioneer in this class of work, as the jetties at Yaquina Bay were the first of the kind on the Pacific Coast.

Mr. Polhemus retired from active work on March 25, 1924, after a long and honorable record of fifty-two years of continuous Government service. His opinion and judgment were highly valued by all. No single individual possessed a greater knowledge or fund of information regarding the entire Western Coast. His information was not confined to engineering matters, and he could discuss almost any subject. He was a great reader and kept himself fully abreast of the world's progress along every line of effort.

Mr. Polhemus had suffered from heart trouble for several years, and a recurrence of this trouble caused his death after a week's severe illness. He died at his home in Portland on September 29, 1930.

Personally, he was a most lovable character, even tempered, and kindly. News of his passing was heard with the greatest regret up and down the entire Western Coast, for it is safe to say that no one possessed more friends in all walks of life.

Shortly after his arrival in Oregon, Mr. Polhemus was married to Mary Clark Daly, daughter of the late W. A. Daly. Mrs. Polhemus died in 1922. A son, James H. Polhemus, now Manager of The Port of Portland, and a daughter, Harriette, survive their father.

Mr. Polhemus was elected a Member of the American Society of Civil Engineers on October 3, 1894.

## JAMES BOND POPE, M. Am. Soc. C. E.[1]

DIED JULY 13, 1928

James Bond Pope, the son of Algernon R. and Nannie L. (Walker) Pope, was born on January 29, 1866, in Macon, Mo.

Mr. Pope began his engineering career in the early Eighties on the construction of the St. Louis-San Francisco Railroad and, in 1887, was employed by the California Southern Railroad Company. In 1889 and 1890, he located and built roads and railroads for lumber companies and, in 1891 and 1892, was Locating Engineer for the Arrowhead Reservoir Company.

[1] Memoir prepared by George W. Rear, J. L. Campbell, and H. M. Mitchell, Members, Am. Soc. C. E.

In the fall of 1892 until the spring of 1902, Mr. Pope was engaged in private practice at San Bernardino, Calif. At this time he had charge of the location, design, and construction of several water supply systems for irrigation and domestic use. Among these were the extension of Bear Valley Irrigation System, the Highland Domestic Water Company, and the domestic water supply and irrigation system of Colton, Calif.

In 1902, Mr. Pope entered the service of the Southern Pacific Railroad Company and until June, 1907, he was engaged in reconnaissance and office work under the late William Hood, M. Am. Soc. C. E., Chief Engineer. In June, 1907, Mr. Pope took up the work of physical valuation of railroad properties, devoting two years to those of the Oregon Railroad and Navigation Company which at that time was affiliated with the Southern Pacific Company as part of the Harriman Lines. He became Valuation Engineer on the Southern Pacific Railroad Company's own properties in the fall of 1909, continuing as such until September, 1922, when he became Consulting Engineer of Valuation.

In June, 1926, Mr. Pope resigned his position with the Railroad Company and opened an office as a Consulting Valuation Engineer. He was one of the pioneers in railroad valuation and had a prominent and important part in the development of its theories and in the organization of valuation forces as required by a large railroad company. He was peculiarly fitted to help solve the many complicated and difficult problems which arose from day to day in this new phase of railroad engineering work, and his passing has been keenly felt by those associated with him for so many years.

He was a member of several engineering societies and clubs and an active member of the Masonic Fraternity.

He was married in 1890 to Annie Florence Bannon, a native of England, who survives him. He is also survived by his son, Fred B. Pope, and a grandson, James B. Pope, of Stockton, Calif.

Mr. Pope was elected a Member of the American Society of Civil Engineers on February 4, 1914.

## GEORGE FREDERICK PORTER, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 19, 1930

George Frederick Porter, the son of Frederick B. and Helen C. (Perry) Porter, was born at Detroit, Mich., on October 7, 1862.

His education was received in the public schools of Detroit; from training in general engineering work in the office and employ of Mason L. Brown, Civil Engineer and Surveyor, in Detroit, from 1885 to 1894; as Draftsman and, later, as Engineer in the employ of the Detroit Bridge and Iron Works, 1894 to 1896; with the Keystone Bridge Company of Pittsburgh, 1896 and 1897; with the Detroit Bridge and Iron Works again from 1897 to 1900; and from his own unwearying study of engineering matters in his chosen field.

[1] Memoir prepared by the following Committee of the Detroit Section: C. M. Goodrich, F. C. McMath, Willard Pope, and C. W. Hubbell, Members, Am. Soc. C. E.

In the main, self-educated, his outstanding ability was fittingly recognized in October, 1921, when McGill University conferred upon him the honorary degree of Doctor of Laws.

In 1900, The Canadian Bridge Company, Limited, of Walkerville, Ont., Canada, was formed, and Mr. Porter was one of the small group which launched this enterprise, himself taking charge of the planning and construction of the plant. His connection with this Company was unbroken until 1909 when, because of his outstanding ability in the detail planning of large structures, his services were demanded by the Board of Engineers appointed by the Government of the Dominion of Canada to design and supervise the construction of the Quebec Bridge, which now spans the St. Lawrence River near the City of Quebec, Que., Canada.

Shortly after the completion of the official design by the Dominion Board of Engineers in June, 1910, The Canadian Bridge Company, Limited, and the Dominion Bridge Company, Limited, of Montreal, Que., Canada, formed the St. Lawrence Bridge Company to tender bids upon the Quebec Bridge, and Mr. Porter was given charge of working out the detail plans for a new design for this structure. The contract was awarded upon the basis of this alternative design, and Mr. Porter was made Engineer of Construction, which position he held, supervising not only the work of detail design and fabrication, but that of erection as well, until the completion of the structure in 1918 and the dissolution in 1919 of the Company formed to undertake it. He is entitled to a large share of the credit for the success of this huge engineering feat.

Mr. Porter, G. H. Duggan, M. Am. Soc. C. E., and the late Phelps Johnson, M. Am. Soc. C. E., were joint authors of the paper entitled "The Design, Manufacture and Erection of the Superstructure of the Quebec Bridge", presented in 1919 to the Engineering Institute of Canada,[2] a paper the unusual merit of which was rewarded by the award of the Gzowski Medal.

In 1919, Mr. Porter returned to the Canadian Bridge Company, Limited, as Chief Engineer, subsequently becoming Consulting Engineer. During this period many interesting and important engineering problems came under his immediate supervision. Among these should be mentioned the fabrication and erection of six of the 200-ft. lift spans over the Welland Ship Canal, and the fabrication and launching of the nine steel tubes, each 31 ft. in diameter and 248 ft. long, for the Detroit and Windsor Vehicular Tunnel under the Detroit River. With the close of 1929, he retired from active service with this Company, retaining, however, the keen interest in the engineering world which he had always shown. Happily his later years were marked by sufficient leisure to enable him to tour extensively on the American Continent, to visit the Hawaiian Islands, and to visit and examine the works of the Panama Canal.

Mr. Porter's interests were by no means confined to engineering. He was a wide and careful reader of literature in many fields. He was an unassuming, but most useful member in the Church to which he belonged. His character matched his abilities; he was as patient as thorough, as cautious as courageous, and as kindly as he was firm. He was possessed of remarkable self control and,

[2] *Transactions*, Eng. Inst. of Canada, Vol. XXXII, 1919, Pt. 1, "The Quebec Bridge," p. 63; see, also, Pt. A (plates to accompanying text of Pt. I).

under any adverse circumstances, his serenity and poise, founded on a deep-seated courage, became evident. A great number of young engineers, many of them to-day with established reputations, profited by the instruction which he delighted to give them. This instruction was specific, thorough, untiring, and was given generously and unassumingly. He possessed the faculty of making friends, as well as admirers, of those with whom he came in contact.

In erection work Mr. Porter was always interested. Derrick cars of a then new type were devised and built by him in the first years of his work in Canada, and are still in use. A recent device of his suggesting, put in place a long series of deck girder spans, completely assembled and field-painted, in a high viaduct, some of the spans running to 112 ft. in length, and this in a period of only about two hours for removing the old and placing the new span. Another of his devices erects lift bridges by moving itself vertically up the tower, and then horizontally along the bridge, erecting as it goes. The bridges and buildings with which he was connected are, of course, of great number. Various patents were granted him, and applied for by him—some of great ingenuity and value.

In the case of any active contracting bridge company it frequently happens that a noteworthy design may be made for a structure the contract for which, for various competitive reasons, is secured by another company, and the design, excellent as it may be, is not used. A striking example of this, in Mr. Porter's case, was the important Sydney Harbor Bridge, in Australia. In commenting on the Canadian Bridge Company's design on which its unsuccessful tender for this great bridge was based, Dr. J. J. C. Bradfield, Chief Engineer, made the following remarks in his report:

"The methods of stress analysis are beyond criticism, and full and accurate details of deflection, secondary stress problems, and intricate connection lay-outs were submitted. * * * Discussion of many intricate secondary phenomena is given in the calculations submitted with the tender. These calculations show a masterful knowledge of statical principles and practice of bridge design."

Mr. Porter was a member of the Engineering Institute of Canada, the American Railway Bridge and Building Association, the Detroit Engineering Society, and also of the Detroit Athletic Club, the Grosse Ile Golf Club, and the Detroit Automobile Club.

He was married in June, 1894, to Florence E. Murray, who, with one daughter, Mrs. Bertram S. Perham, survives him.

Mr. Porter was elected a Member of the American Society of Civil Engineers on October 1, 1913.

## WILLIAM ABBOTT PRATT, M. Am. Soc. C. E.[1]

DIED MARCH 16, 1930

William Abbott Pratt was born on June 16, 1850, in Richmond, Va. His father was William A. Pratt and his mother, Eveleen (Ginevan) Pratt. On

[1] Memoir prepared from information on file at the Headquarters of the Society.

the paternal side, his grandfather, who was also William Abbott Pratt, came from England and settled in Virginia in 1832. His mother's family made their home in what is now West Virginia many years before the Revolutionary War.

Mr. Pratt received his early education and spent his childhood at the University of Virginia near Charlottesville in that State, his father being for many years Superintendent of the University. Mr. Pratt also attended private schools in Charlottesville, prior to his matriculation at the State University.

On leaving college he entered the employ of the Chesapeake and Ohio Railroad Company as Rodman in the Engineer Corps. Subsequent to this primary course in practical engineering experience, Mr. Pratt received the degree of Civil Engineer at the University of West Virginia. During the period between 1874 and 1876, he studied at Drexel Institute in Philadelphia, Pa., and was graduated as an Electrical Engineer.

Prior to this period, in 1869, however, Mr. Pratt was connected with the Chesapeake and Ohio Railroad Company in the Engineer Department during the location and construction of the road throughout West Virginia. In this capacity, he occupied the various positions from Rodman to Resident Engineer. In 1873, he transferred his interests to the Baltimore and Ohio Railroad Company as Resident Engineer on the construction of the Chicago Extension of that road. After an interval spent in the Maintenance-of-Way and Traffic Department, he accepted, in 1877, a position in the Engineer Department of the City of St. Louis, Mo., subsequently being made District Engineer of the District above Chouteau Avenue and between Grand Avenue and the Mississippi River.

In 1881, Mr. Pratt again entered the employ of the Baltimore and Ohio Railroad Company in charge of the location and construction of lines in Western Pennsylvania. From 1883, he was Chief Engineer on the location, construction, and operation of several short lines in West Virginia. From 1886 until 1896, he served as Division Engineer of the Philadelphia Division of the Baltimore and Ohio Railroad Company and, during this period, and until 1898, he also served as President of the Street and Sewer Directors of Wilmington, Del.

From this latter date until 1902, Mr. Pratt was Professor of Mechanical and Electrical Engineering in Delaware State College, at Newark, Del., and was also engaged in consultation practice. While in this field, he made a survey for a railroad in Alaska, by the Yukon route, from Juneau to Lake Teslin, the head of the Yukon River, extending over a distance of 150 miles. This was the first extended railroad survey in Alaska.

At the outbreak of the Spanish-American War, Professor Pratt obtained a leave of absence from Delaware State College and was commissioned Captain of Company M, First Delaware Volunteer Infantry. His service continued throughout the war and after the signing of the peace treaty, he returned to his college work.

In the summer of 1901, Captain Pratt again visited Alaska in charge of an expedition to Unalaska Island. The following year he resigned from the College Faculty to assume charge of the Baltimore and Ohio Railroad Company's

interests in New York and Staten Island. Later, he resigned this position to become Chief Engineer of the New York Westchester, and Boston Railway Company.

In May, 1909, because of his failing health, Captain Pratt gave up business in New York City and retired to the family home at Waynesboro, Va. In January, 1910, he organized the Riverside Light and Power Company of Waynesboro and served as its President and Manager until January, 1920. This Power Company was purchased by the Virginia Public Service Company, and it was as Consulting Engineer for the latter that Captain Pratt served until his death which occurred from pneumonia after an illness of only a few days.

Captain Pratt had been a very active citizen of Waynesboro. He was a member of the Board of Directors of the Citizens-Waynesboro Bank and Trust Company; a Charter Member of the Waynesboro Rotary Club; a member of the City Council; Chairman of the Zoning Board of Appeals; President of the Library Board; President of the Waynesboro Welfare Alliance; and a member of the Waynesboro Literary Club. He was Senior Warden and Registrar of St. John's Protestant Episcopal Church, and a member of the Vestry, having also served as Treasurer of the Church. He was further affiliated with the Railway Signal Association and the Society of the "Virginians". Outside of his home, Captain Pratt was known to have had two great interests—his profession and St. John's Church.

He was married on February 25, 1873, in Trinity Church, in Waynesboro, to Rebecca Porterfield Kinney, of Stanton, Va. He is survived by his widow and by several nieces and nephews.

Captain Pratt was elected a Member of the American Society of Civil Engineers on July 5, 1882.

## MARSHALL ROGERS PUGH, M. Am. Soc. C. E.[1]

DIED NOVEMBER 22, 1930

Marshall Rogers Pugh was the son of John B. and Elizabeth (Fox) Pugh and came of a family which numbered among its members the Rev. J. Dickinson, the first President of Princeton University, Edward Fox, the first Secretary and Treasurer of the University of Pennsylvania, soldiers of the Revolutionary War, and a judge who served in the War of 1812. He was born on December 31, 1863, at Doylestown, Pa., about 20 miles north of Philadelphia, Pa., and followed an engineering career which took him to far corners of the United States, outside its borders, and to France where he served with distinction in the World War, and it brought him finally again to Philadelphia for many years of activity in consulting practice and in civic affairs.

Mr. Pugh attended the Towne Scientific School of the University of Pennsylvania from 1881 to 1886 receiving, in June, 1886, the degree of Bachelor

[1] Memoir prepared by Stephen Harris, M. Am. Soc. C. E., and Charles A. Howland, Assoc. M. Am. Soc. C. E.

of Science and in June, 1887, the degree of Mining Engineer. He stood at or near the head of his class during the entire college course. In August, 1886, his engineering work began with the Northern Pacific Coal Company in the far Northwestern United States. Until October, 1887, he was engaged as Engineer in Charge of railroad location and construction, mining engineering, mapping, construction of tipples, saw-mills, etc., at Sims, N. Dak., Timberline, Mont., and Roslyn, Wash. His work at Roslyn included the design and layout of the town.

Returning, in 1887, to the University of Pennsylvania, he instructed for two years in Engineering but, in June, 1889, he journeyed again to the Northwest and was engaged for more than four years in private practice at Denver, Colo., as a member of the firm of Lang and Pugh. April of 1894 brought Mr. Pugh to Philadelphia to take up the work of Assistant Engineer in the City's Bureau of Surveys, Department of Public Works. The surveys, street layouts, sewer planning and construction, rebuilding of storm sewers, paving, and other municipal engineering work of this Bureau engaged him for more than five years.

He resigned, in 1900, from the Philadelphia Bureau of Surveys to accept the position of Construction Engineer with the organization of Charles McCall, then one of the largest contracting firms in the Eastern United States. When Mr. McCall died in 1901, Mr. Pugh entered into partnership with Mr. Hugh T. Downing for the practice of engineering and architecture. In 1903, this firm was succeeded by that of Pugh and Hubbard, of which the latter was the late Isaac Wendell Hubbard, M. Am. Soc. C. E.

During the seventeen years that Mr. Pugh was associated with Mr. Hubbard he was engaged in a variety of work in many parts of the United States and abroad. The firm designed and constructed water-works for Georgetown and Newport, in Delaware, for Manasquan and Cranberry, in New Jersey, and for Boyertown and Enola, in Pennsylvania. Sewers and sewage disposal plants were designed and constructed for seven towns in New Jersey, two towns in Delaware, four towns in Pennsylvania, for Haverford College, and for Ocean City, Md. The firm located 6 miles of trolley line in Williamsport, Pa., did the preliminary work upon 10 miles of railroad in Kentucky, and mapping and preliminary work for 45 miles of railroad in Honduras to reach mining and timber concessions. Location plans and details of 40 miles of interurban railroad in Ohio, from Wooster to Mansfield, were the firm's work. Other important trolley lines were surveyed and constructed in New Jersey, and 10 miles of narrow-gauge, interplant railroad were built for the Alan Wood, Iron and Steel Company in Pennsylvania. Among the largest of the firm's undertakings were the development of Queen Lane Manor, in Philadelphia, for the Warden Estate, and the surveying, designing, and construction, on a percentage basis, of the industrial Town of Enola, for the Pennsylvania Railroad Company.

When the United States entered the World War, Mr. Pugh offered his services and, in June, 1917, entered the army as Major, Corps of Engineers. He commanded the 1st Battalion, 21st Engineers, on the construction of light or combat railways in the Toul-St. Mihiel Sector in France and, after the

Armistice, was Post Engineer at the Bordeaux Embarkation Camp in charge of water-works, sewers, roads, and building construction. Returning to the United States, Major Pugh was retained in service by the U. S. Shipping Board, Emergency Fleet Corporation, to handle the cancellation of water contracts.

After his release from service in 1921, with the title of Lieutenant-Colonel, Engineer Reserve Corps, Colonel Pugh resumed practice as a Consulting Engineer in Philadelphia and continued his work in sewerage and sewage disposal, water supply, flood control, and highway engineering. With George L. Watson, M. Am. Soc. C. E., he founded the firm of Watson and Pugh. Some of the larger work executed by the firm included a sewerage system for Clifton, N. J., a sewage disposal plant for the Perkasie Sewage Company, sewers and sewage disposal for Neptune Township, New Jersey, storm sewers and flood control at Passaic, N. J., and also at Clifton, and sewage disposal for Ocean City, N. J.

His active interest in civic betterment engaged Colonel Pugh in many undertakings for the improvement of his city. In 1913 and 1914, he was a member of the Pennsylvania Suburban Metropolitan Planning Commission and as Chairman of its Survey Committee made studies for a comprehensive regional plan for the Philadelphia Metropolitan Area. The Commission went out of existence, but when the Regional Planning Federation of the Philadelphia Tri-State District was formed later, Colonel Pugh became a member of its Technical Advisory Committee. As a member of the Boards of the Philadelphia Housing Association and the Pennsylvania Housing and Town Planning Association, he actively promoted better housing and sanitary conditions in Philadelphia and elsewhere. When the Philadelphia Chamber of Commerce sponsored a hospital and health survey of the city, Colonel Pugh served on a Committee to co-operate in the work of sanitation. This record might be extended at great length to include activities with civic groups of the Engineers' Club of Philadelphia, the Philadelphia Conference on City Government, and many others. Where active work for civic betterment was to be done, Colonel Pugh was found in the front rank.

In 1890, Colonel Pugh was married at Doylestown, to Helen Darlington, who, with their three children, Edward John Pugh, Henry Darlington Pugh, and Elizabeth (Pugh) Welpley, survives him.

He was a member of the Protestant Episcopal Church. He was also a member of the American Waterworks Association, the Society of American Military Engineers, a Thirty-Second Degree Mason, and a member of the Engineers' Club of Philadelphia. During his active life Colonel Pugh found time to contribute articles and papers to the technical journals and to engage in the discussions of engineering societies.

No truer or more impressive account can be given of the life of Colonel Pugh than the recounting of his many achievements. By his works he is known. Thousands live in greater comfort, travel more safely and rapidly upon their business, and are secure in the enjoyment of adequate public works, because of his labors.

Mr. Pugh was elected an Associate Member of the American Society of Civil Engineers, on December 7, 1904, and a Member on November 2, 1908.

## JOHN WILLIAM RAITT, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 27, 1930

John William Raitt, the son of Nathan E. and May (Hall) Raitt, was born at Shawneetown, Ill., on March 21, 1880. When he was six years of age the family moved to Cincinnati, Ohio, where he lived until he reached manhood. He received his education in the Cincinnati High School and the Nelson Business College of Cincinnati, and was graduated from both institutions. Later, he continued his engineering studies through correspondence courses.

The first active work undertaken by Mr. Raitt was from 1898 to 1901, when he was employed on the construction of the Cincinnati Belt Line Railway, a part of the Cincinnati, Portsmouth and Virginia Railway (now the Cincinnati District of the Norfolk and Western Railway), successively, as Axeman and Rodman. When the Cincinnati, Portsmouth, and Virginia Railway was taken over by the Norfolk and Western Railway Company, Mr. Raitt was moved to Radford, Va., in the office of the Engineer of Branch Lines where he served as Draftsman. Following this engagement he was transferred to Kenova, W. Va., where he held a similar position from 1902 to 1905.

From 1905 to 1906 Mr. Raitt was employed in the office of the Superintendent of Construction of the Cleveland, Cincinnati, Chicago, and St. Louis Railway Company. He resigned this position and, in 1907, returned to the Norfolk and Western Railway Company, at Roanoke, Va., as Draftsman. His work in this position included all classes of drafting incidental to branch-line construction, such as mapping, right-of-way plans, track, bridge design, etc. Subsequently, Mr. Raitt was promoted to be Assistant Engineer in the office of the Engineer of Branch Lines, and, in 1918, was made Chief Draftsman in the office of the Chief Engineer at Roanoke, advancing to the position of Office Engineer in 1919.

On January 1, 1924, he was appointed Assistant Engineer at Norfolk, Va., in which position he had field charge of maintenance of way, construction, etc. This work also covered field supervision of the terminals at Lamberts Point, Va., where the Norfolk and Western Railroad Company's coal piers and warehouses are situated. Due to his experience in branch-line work, he was placed in charge of the preliminary surveys and location of the Big Sandy and Cumberland Railroad, in Buchanan County, Virginia, which road is controlled by the Norfolk and Western Railroad Company. His work here covered the preliminary surveys, location, and purchase of right of way for about 40 miles of mountain line.

In 1926, Mr. Raitt was transferred to Bluefield, W. Va., as Assistant Engineer, where he had charge of engineering on the Pocahontas Division of the Norfolk and Western Railroad. The construction of the Big Sandy and Cumberland Railroad was also under his direct charge, but, unfortunately, he did not live to complete this work.

Mr. Raitt was a man of fine character, well liked by every one with whom he came in contact, a man who was never known to have an enemy. He was

[1] Memoir prepared by W. P. Wiltsee, M. Am. Soc. C. E.

a conscientious worker and was devoted to the profession which he had chosen for his life work.

He was married in June, 1903, to Emma Tschudi. They had three children: Nathan C., Elton W. (deceased), and John Hall Raitt. Mrs. Raitt died on February 2, 1915, and in September, 1917, Mr. Raitt was married to Mrs. Cora Carpenter Moss who, with his two sons, survives him.

Mr. Raitt was elected a Member of the American Society of Civil Engineers on May 19, 1924.

## WILLIAM BOARDMAN REED, M. Am. Soc. C. E.[1]

DIED JUNE 19, 1930

William Boardman Reed was descended from several families that emigrated to the United States from England in the early part of the Seventeenth Century. He was the oldest son of Henry A. and Alice Boardman Reed, and was born in Poughkeepsie, N. Y., on May 27, 1860. His father was one of the pioneer telegraphers, a friend of Professor Samuel Finley Morse, and assisted the latter in many of his experiments, being the first person to test for faults by the galvanometer.

Mr. Reed was prepared for college at private schools and, in 1878, entered Union College at Schenectady, N. Y., from which he was graduated in 1882 with the degrees of Bachelor of Arts and Civil Engineer. On his graduation he was appointed Chief Engineer of the Lake Champlain and Moriah Railroad Company; Witherbee, Sherman and Company; and the Port Henry Iron Ore Company, the latter two companies being engaged in mining magnetite, known as Lake Champlain ore. He retained this position until 1891, and during this period was also consulted by various other mining companies, making one trip to the Island of Cuba to inspect iron ore properties there.

In 1891, Mr. Reed formed a partnership with Mr. William Gifford, of Schenectady, and carried on a general engineering practice with headquarters in that city. During this time he had charge of the construction of waterworks for the Village of Northville, N. Y. He was Chief Engineer of construction for the Cayadutta Electric Railroad, running from Fonda to Gloversville, N. Y. The Cayadutta Line was a pioneer freight and passenger electric road, and the first of its kind to carry freight. It was built over private right of way, and was operated successfully for some years, after which it was bought by and consolidated with its steam rival, the Fonda, Johnstown and Gloversville Railroad Company.

On the completion of the Cayadutta Railroad in 1894, Mr. Reed went to New York, N. Y. The Metropolitan Street Railroad Company was then in formation, and he was immediately engaged as Engineer of Maintenance. As organized by Mr. Reed, the Maintenance-of-Way Department became one of the most efficient in the country. The difficulties entailed in maintaining a conduit electric structure, in view of the extraordinary traffic and other con-

[1] Memoir prepared by H. Burdett Cleveland, M. Am. Soc. C. E.

ditions peculiar to New York City, called for engineering and executive ability of a high degree. Through handling these problems Mr. Reed became an authority on urban electric construction and maintenance. He was instrumental in designing the section of girder rail which is the standard of Greater New York and which is much used in other cities. During his connection with the street railways of New York City, Mr. Reed was widely consulted by those about to build or reconstruct electric lines in other cities.

While he was acting as Maintenance Engineer for the New York City Railways, Mr. Reed was also Vice-President of the Bishop Gutta Percha Company, of which his father, Henry A. Reed was President. When the latter wished to withdraw from active work, Mr. Reed felt it necessary to retire from engineering and give his attention exclusively to this Company, which afterward became the Bishop Industries, Inc. For several years Mr. Reed continued to act as Consulting Engineer, but for about ten years before his death, he had been unable to devote any time to this work.

Mr. Reed was Vice-President of the Graduate Council of Union College at the time of his death, and had served for several years as President of the Board of Trustees of The Arietta Crane Reed Home for Convalescents, at Brewster, N. Y. He was a member of the Delta Phi Fraternity, the Engineers Club, and the New York Railroad Club, and had been President of the Union College Engineers Club since its organization.

He is survived by his widow, Sarah (Parks) Reed, to whom he was married in 1896, by Edith Harlan (Reed) Robinson, a daughter by an earlier marriage, by Marion Boardman (Reed) Hitchcock, and by his son, Henry Hazen Reed.

Mr. Reed was a thorough-going American gentleman of wide sympathies, with an unswerving loyalty to his professional colleagues, to his college, and to the many and varied interests that claimed his attention. In his own circle of friends and acquaintances the memory of his upright character, his kindly temperament, and his whole-souled devotion to any duty that lay before him, will persist.

Mr. Reed was elected an Associate Member of the American Society of Civil Engineers, on February 6, 1895, and a Member on May 1, 1901.

## CLAUDE IRVIN RHODES, M. Am. Soc. C. E.[1]

DIED MAY 11, 1930

Claude Irvin Rhodes, the son of Luther Graham and Sarah (Irvin) Rhodes, was born in Clarksburg, Calif., on December 30, 1877. He received his preparatory education in the public and High Schools of Woodland, Calif., and his engineering education at the University of California, from which he was graduated with the degree of Bachelor of Science in Mining in 1902.

After extensive experience in California, Arizona, and Alaska, on problems involving surveying, stream gauging, drainage, mining, canal lining, water

[1] Memoir prepared by F. M. Faude, Assoc. M. Am. Soc. C. E.

supply, and other work of like character, Mr. Rhodes' education, training, and experience resulted in his appointment as Engineer in Charge of the design, manufacture, and installation of 14 miles of large diameter transmission pipe line for the Monterey County Water-Works and in the location and construction of 23 miles of scenic highways on the Monterey Peninsula.

He was closely identified with the work of rebuilding San Francisco, Calif., after the great fire of 1906, and devoted more than three years to the inspection of materials for, and the installation of, sewers, public buildings, the high-pressure fire system, reservoirs, pavements, and other structures. Later, he was placed in charge of the construction and operation of the water supply and gas systems for the Panama-Pacific Exposition.

From 1918 to 1923, Mr. Rhodes was with the Hydraulic Division of the Railroad Commission of the State of California, serving with distinction as Chief Hydraulic Engineer for the last two years of this period.

In 1923, he joined the staff of the Loveland Engineers, Incorporated, of San Francisco, where his ability and wide experience were at once fully recognized and appreciated. In 1925, he became Vice-President of the organization, and at the time of his death was a Vice-President of Western Continental Utilities, Incorporated, and of The Southwest Telephone Company.

Mr. Rhodes was a member of the Commonwealth Club of California, the American Waterworks Association, and the Engineer's Club of San Francisco. He enjoyed an enviable reputation for loyalty to his friends and associates and for his ability and the painstaking care with which he approached and carried through the many and varied classes of work with which he was entrusted. He had a host of friends, and his untimely passing is mourned by all his acquaintances and associates.

He was married on January 15, 1905, to Lucy Boettiger, and is survived by his widow, a daughter, Anita Louise Rhodes, a son, Thomas E. Rhodes, and two brothers, Glenn Rhodes, of San Francisco, and Lester Rhodes, of Seattle, Wash.

Mr. Rhodes was elected a Junior of the American Society of Civil Engineers on March 5, 1907; an Associate Member on March 1, 1910; and a Member on January 17, 1927.

## FRANKLIN RIFFLE, M. Am. Soc. C. E.[1]

DIED OCTOBER 29, 1929

Franklin Riffle was born on April 19, 1858, in Somerset County, Pennsylvania, the son of William and Mary (Spiecher) Riffle. The family moved West, stopping for a time at Akron, Ohio, but settling eventually on a farm near Spring Hill, Kans., where Mr. Riffle's early life was spent. At fifteen years of age he taught the district school while fitting himself for admission to the University of Kansas, from which he was graduated in 1880. Such was his

[1] Memoir prepared by the following Committee: Frank T. Oakley, E. T. Thurston, and Victor H. Poss, Members, Am. Soc. C. E., and Thomas W. Brooks, Esq., San Francisco, Calif.

scholastic record that some years later when chapters of the Sigma Xi and Phi Beta Kappa Fraternities were established at the University of Kansas, on the recommendation of his former instructors he was made a member of both these honor societies.

Immediately after graduation Mr. Riffle found employment with the pioneering railroad development in the Northwest. Beginning in July, 1880, he occupied the position of Draftsman in the office of the Chief Engineer of the Oregon Railway and Navigation Company, and in 1881 and 1882 was an Assistant on the construction of the Columbia River Division.

On January 1, 1882, he was married to Veola Bardwell, of Lawrence, Kans.

In 1882 and 1883, he was an Assistant Engineer on the construction of the Clarks Fork Division of the Northern Pacific Railroad and, in 1884, he was employed on the construction of the Palouse Branch and also the Cascade Division of the same line. In 1885, he returned to the employ of the Oregon Railway and Navigation Company, in charge of the construction of the Pataha Branch.

In 1886 and 1887, Mr. Riffle was a Resident Engineer in charge of the construction of three branch lines of the Burlington and Missouri River Railroad in Nebraska. Again, he returned to the Oregon Railway and Navigation Company as Locating Engineer. From 1888 to 1891, inclusive, he was, successively, Superintendent of Construction and Chief Engineer of the Oregon and Washington Territory Railway, with headquarters in Walla Walla, Wash.

From 1892 to 1895, inclusive, he was associated with his brother, the late Albert S. Riffle, M. Am. Soc. C. E., in a general contracting business under the name of the Oregon Bridge Company, with headquarters in Portland, Ore. This Company was engaged chiefly in the construction of highway bridges throughout the States of Oregon and Washington, but its most noteworthy undertaking was the furnishing and laying of a 28-in. submerged cast-iron pipe across the Willamette River at Portland. The unusual nature of this project was illustrated by the fact that of sixteen leading pipe founders in the United States invited to bid, only three submitted proposals. A permanent record of the experience on this undertaking was prepared by Mr. Riffle.[2]

In 1897 he went to Victoria, B. C., Canada, and in the following year developed and managed the White Water Deep Mines. From 1899 to 1901 he was Manager of the Pipe and Mining Machinery Departments of the Wolf and Swicker Iron Works, at Portland.

In 1901 he went to San Francisco, Calif., where he accepted the management of the Pipe Department of the Dunham, Carrigan, and Hayden Company, later taking over also the Iron and Steel Department, which position he retained for twenty-two years. His identification with the commercial end of the iron and steel industry came at a time when steel was coming into general use, particularly in the soft weldable grades. Through research and practical experiment Mr. Riffle became a recognized authority on the characteristics and uses of iron and steel, and was the author of several pamphlets and monographs which were favorably received and which enjoyed a wide

[2] *Transactions*, Am. Soc. C. E., Vol. XXXIII (1895), p. 257.

circulation. He was held in the highest esteem by his employers and associates and his resignation in August, 1923, was the cause of general regret.

Aside from his business activities, Mr. Riffle was greatly interested in the research and educational work of the Commonwealth Club of California. Also he was one of the organizers, the first Secretary, and, in 1910, the President of the San Francisco Section of the Society. He was a member of the Engineers' Club of San Francisco.

A few days after the destructive earthquake and fire in 1906, the San Francisco Section appointed a General Committee, as well as sub-committees, to study the earthquake effects on various classes of structures, the reports of which were published by the Society.[3] Franklin Riffle was a member of the General Committee and also of the Committee on the Effect of the Earthquake on Water-Works Structures. The lively interest he took in this study is evidenced by his discussion of the report on "Damage to Buildings".[4]

Mr. Riffle definitely retired from business in the summer of 1924 and in August of that year departed on a tour of Europe. After a year of travel in the British Isles and on the Continent, he took up his residence in St. Cyr, France, whence he made numerous tours through France, Spain, Italy, and other continental countries, often going afoot, as walking had always been with him a favorite means of recreation. A distance of from 16 to 20 miles over hill and dale was an easy day's tramp for him.

In June, 1929, an ailment of long duration became acute, and he entered the American Hospital at Paris, France, for treatment. He left the hospital on September 27 in good spirits and supposedly on the road to recovery, although continuing precautionary daily treatments. However, suffering a relapse after ten days, he returned to the hospital where he grew rapidly worse and passed away three weeks later, on October 29, 1929.

Both professionally and ethically Franklin Riffle represented the highest standards of the Engineering Profession. All those associated with him respected his high ideals. Young men who were so fortunate as to spend the early years of their professional training under his guidance were enthusiastic admirers of his character and his thorough and systematic business methods, and were always loud in praise of his kindness as manifested toward them. They looked up to him with pride as a leading member of the profession.

He was a man of simple habits and practiced moderation in all things. A logical thinker with an unusually well-balanced mentality and even temper, he was always cheerful and optimistic; irritability and needless worry were foreign to his nature. In spirit and appearance he was young for his years, keeping himself informed on the important events of the day, which he discussed in the faultless English of which he was a master. These and his other fine qualities made him a delightful and lovable companion. Contact with him was ever satisfying and beneficial. Few men have had the universal esteem and respect of their fellows that Franklin Riffle enjoyed.

As a personality, once seen he was not soon forgotten. His tall, well-knit figure, high-held chin, kindly, deep-set eyes beneath dark shaggy brows looking

[3] *Transactions*, Am. Soc. C. E., Vol. LIX (December, 1907), p. 208.
[4] *Loc. cit.*, p. 266.

straight ahead whether moving briskly with easy stride and preoccupied mien along the street or mingling socially with his fellows, made him always an impressive person. Although of a cordial and friendly disposition, he was on excellent terms with himself and frequently elected to walk alone. He loved the great outdoors and during his residence in California, he maintained a cabin high in the foothills overlooking the Napa Valley where he and Mrs. Riffle, occasionally with friends, were wont to spend their week-ends and short vacations.

Mentally, as physically, he seemed to hold aloof from the petty, inconsequential things about him and to dwell serenely and thoughtfully in an amosphere all his own, to which he welcomed his friends with all the kindliness, consideration, and cordiality of the cultured gentleman.

Mr. Riffle was elected a Member of the American Society of Civil Engineers on November 7, 1898.

## EDWARD AUSTIN RIX, M. Am. Soc. C. E.[1]

DIED JANUARY 8, 1930

Edward Austin Rix, the second son of Judge Alfred Rix and Chastina (Walbridge) Rix, was born on January 29, 1855, in a house which then stood at 640 Market Street, opposite the Palace Hotel, in San Francisco, Calif. His parents were of long established New England ancestry, his father having come around Cape Horn to San Francisco, in 1849, his mother arriving not long afterward. Mrs. Rix died when the boy was only a year old and his upbringing was under the care of near relatives.

Mr. Rix was educated in the public schools of San Francisco, and in September, 1873, entered the University of California, which he attended for four consecutive years. His studies were in the College of Mechanics, and he was a member of the first class to be graduated from that Department. The graduation exercises were held in the open air under the famous oaks in Faculty Glade, June 6, 1877. He received the degree of Bachelor of Philosophy; he also was given a commission as Captain in the Cadet Corps.

Throughout his college life he was a member of the Zeta Psi and Sigma Chi Fraternities, was remarkably active in all college affairs, universally regarded as a "good sport", and highly popular with all his fellows. He belonged to the Durant Rhetorical Society, and was a fluent and clear speaker. He was also Editor of the *Berkeleyan*, one of the college publications.

Practically from the moment of his graduation from college Mr. Rix was enthusiastically interested in the design and manufacture of compressed-air machinery. In the fifty-two years of his connection with this work he rose to be one of the acknowledged leaders in the industry. If success may be correctly defined as the realization of one's ideals, he was indisputably a successful man.

[1] Memoir prepared by Harold F. Gray, M. Am. Soc. C. E.

His labor was unremitting in his chosen field, and he had a deep interest in every scientific subject in any way allied with it.

His achievements make a long list. He was one of the first to recognize the use to which compressed air could be put in machinery, and devoted his engineering knowledge to its development. He held many patents on his inventions, and kept these patents from becoming obsolete by adding valuable improvements prior to the time of expiration. Among these are: The compressed air automatic hammer; the first direct-connected tangential water wheel on an air compressor; the air compressors for the dynamite gun plant at Fort Riley, Kansas (1896); the first variable-volume air compressor; and the first supercharger air compressor.

Mr. Rix was awarded the Gold Medal of the Pacific Coast Gas Association for his treatises on gas transmission and compression. He built the first liquid air machine on the Pacific Coast, and read the first paper in California on liquid air, at Stanford University, in 1895. He published the first handbooks on compressed air engineering, and on the use of air-hammer drills in mining. He was President of the Rix Companies, Incorporated, of San Francisco and Los Angeles, Calif., manufacturers of an extensive line of compressed-air machinery.

Mr. Rix had a high artistic sense, and some of the ingenious devices made with his own gifted hands are memorials to his fine taste and indefatigable industry. His fertile mind worked along individual lines, betokening an exceptional intelligence.

He had his own philosophy of life, and it was genial, kindly, and sympathetic. To his friends he was devotedly loyal, and by them he was deeply loved in return. His capacity for friendship was limitless, and was swayed by no motives apart from the worthiness of that friendship.

Mr. Rix was one of the founders of the famous Olympic Club of San Francisco; he was also a member of the Claremont Country Club, of Oakland, Calif. He was a member of the American Society of Mechanical Engineers, the American Association for the Advancement of Science, and many other scientific organizations.

Mr. Rix was married twice. His first wife was Kate Elizabeth Kittredge, of San Francisco, to whom he was married on May 2, 1878. They had four children, Genevieve (Mrs. Burrows), Chastina (Mrs. Sterling), Austin Julian, and Harold (deceased). His second wife, to whom he was married on September 24, 1913, was Gail Wheeler Shipman, of Emerson, Iowa. They had one child, Elizabeth.

He was in failing health for some years before his death, from serious heart trouble which impeded his activities, but did not daunt his interest in his life occupation. He was seized with a cerebral hemorrhage early one morning in January, 1930, and died on January 8, a few minutes after his wife, summoned from a visit to her parents in Iowa, reached his bedside. The funeral was held on Saturday, January 11, and his remains were placed in the mausoleum of Mountain View Cemetery, in Piedmont, Calif.

Mr. Rix was elected a Member of the American Society of Civil Engineers on April 7, 1897.

## THOMAS RODD, M. Am. Soc. C. E.[1]

DIED AUGUST 3, 1929

Thomas Rodd was born in London, England on June 13, 1849, the son of Horatio and Anne (Theobald) Rodd. His father was a bookseller, distinguished for his intimate knowledge of books and portraits; and his grandfather, Thomas Rodd (1763-1822), was an eminent member of that profession, as well as an author and scholar of note. His family emigrated from England in 1856, settling in Philadelphia, Pa.

In October, 1862, at the age of thirteen, Thomas Rodd entered the United States Navy, and served continuously until the close of the Civil War. He rose to Ship's Writer, Acting Mate, and Captain's Clerk; his last service was on board the United States Steamer *Galena*, under Capt. Francis Wells, who recommended his appointment to the United States Naval Academy. He became a Cadet Midshipman at Annapolis in 1865, and passed all the examinations there, except the final one, which occurred shortly after his resignation. In the course of his studies, he had resolved upon an engineering career, and, finding that graduation would involve the delay of an extended cruise, he resigned in February, 1869, without waiting for the final examination and graduation. Soon afterward he was employed by Jesse Lightfoot, Engineer and Surveyor of Germantown, Pa., as a Rodman. In the same year, he obtained a position with the City of Philadelphia, under Strickland Kneass, Chief Engineer and Surveyor, in which he remained until 1872.

Mr. Rodd entered the service of the Pennsylvania Railroad Company on May 20, 1872, as a Rodman and, subsequently acted in the following capacities: From March 1, 1873, to July 1, 1877, Assistant Engineer on construction work; from July 1, 1877, until July 1, 1889, Principal Assistant Engineer; from July 1, 1889, until January 1, 1901, Chief Engineer of the Pennsylvania Company; and from January 1, 1901, until July 1, 1918, Chief Engineer of the Pennsylvania Lines West of Pittsburgh, Pa. From July 1, 1918, until the time of his retirement, June 30, 1919, during the period of Government control, Mr. Rodd was Corporate Engineer of the Pennsylvania Lines West of Pittsburgh. From 1905 to January, 1927, he was also Consulting Engineer of the Pittsburgh, Fort Wayne, and Chicago Railway Company. From November 24, 1913, until May 1, 1919, he served as Chief Engineer of the Chicago Union Station Company, which erected the new and magnificent terminal at Chicago, Ill., under his supervision. He was largely responsible for the design and plans adopted for this station. From May 1, 1919, until December 31, 1925, he was Consulting Engineer for the Chicago Union Station Company. In 1887, as Engineer and Architect, he designed and supervised the construction of the Union Station for the Indianapolis Union Railway Company, at Indianapolis, Ind.

Mr. Rodd was prominently connected with the rebuilding of the Pennsylvania Railroad after the historic flood of Johnstown, Pa., in 1889. In addition to his work with the Pennsylvania Railroad Company, he had a private practice

[1] Memoir prepared by Robert Trimble, Esq., Pittsburgh, Pa.

as Engineer and Architect and designed and constructed many large structures, among which were the following: The Westinghouse Electric and Manufacturing Company's Plant and the Westinghouse Machine Company's Works, at East Pittsburgh, Pa.; the Union Switch and Signal Company's Works at Swissvale, Pa.; and the plant of the British Westinghouse Electric and Manufacturing Company, at Trafford Park, Manchester, England.

In 1884 and 1885, Mr. Rodd made a comprehensive investigation and report on the ore and coal-handling facilities of the Pennsylvania Railroad Company at the various ports on Lake Erie. At this time, the machinery in use was extremely crude with high labor usage; and, as a result of his recommendations, modern machinery, such as car dumpers and Brown hoists, was installed, which resulted in quickening and cheapening the handling of coal and ore. He also had an active part in the adoption of hopper-bottom cars for use with these materials, which resulted in decreased cost and increased speed in the handling of them.

From the time that Mr. Rodd became Principal Asssistant Engineer, he took an active interest in the designing and building of bridges and was a leader in foreseeing the future development of heavier loads; as a consequence, the bridges built under his administration on the Pennsylvania Lines West of Pittsburgh were decidedly in advance, in carrying capacity, of those of other lines. In this work he was assisted by such engineers as the late William Scherzer, M. Am. Soc. C. E., the inventor of the Scherzer lift bridge, and August Ziesing, M. Am. Soc. C. E., who, later, became President of the American Bridge Company.

At the time Mr. Rodd became connected with the Pennsylvania Company, the maintenance of the railroad was in charge of road-masters, men who received their training as trackmen. He was active in the replacement of these trackmen by men of engineering training, a practice which is general to-day on the System. He also interested himself in unified standards for railroad maintenance and construction.

Mr. Rodd was a Charter Member of the Engineers' Society of Western Pennsylvania, which was organized in 1880. He was a member of the first Board of Directors, and Vice-President in 1881, and, again, in 1882. He also served on several of its committees and took an active interest in the welfare of this Society. He was a Charter Member of the American Railway Engineering Association, organized in 1899, and served as a member of the Committee that drafted its Constitution and By-Laws. He was a Director in the Association from 1899 to 1903.

He took an active interest in the work of the Society. He was a member of the Committee on Proper Relations to Each Other, of the Sections of Railway Wheels and Rails, as well as a member of the Committee on Rail Sections; and, after the adoption of the Am. Soc. C. E. Standard Sections for Rails, he succeeded in having them adopted as standard on the Pennsylvania Lines West of Pittsburgh.

On October 23, 1879, Mr. Rodd was married at Pittsburgh, to Mary Watson Herron. Mrs. Rodd died in 1917. He is survived by two sons, William H. and Thomas Rodd, Jr., and a daughter, Mrs. Mary Herron Kelsey.

He died at his home in Pittsburgh, on Saturday, August 3, 1929, of heart trouble after a short illness.

Mr. Rodd was elected a Member of the American Society of Civil Engineers on June 5, 1878.

## HANS HENRIK RODE, M. Am. Soc. C. E.[1]

DIED JULY 18, 1930

Hans Henrik Rode was born in the small mining town of Roeros, Norway, on January 29, 1885, where his father was a lawyer, and, later, a judge. He received his technical education in Germany and was graduated in 1908 as a Civil Engineer from the Polytechnical College of Hannover. His first position was with the firm of Louis Eilers, in Hannover, as a Designer in its Bridge Department, acting at the same time as Assistant in Statics and Steel Structures at the Polytechnical College.

In 1909, Mr. Rode followed the call of the New World and was for three years Assistant to Gustav Lindenthal, Hon. M. Am. Soc. C. E., Consulting Engineer, New York, N. Y. He was engaged as a Supervisor of Design with the McClintic-Marshall Company, Pittsburgh, Pa., on the design of the New York Connecting Railroad, including the Hell Gate Bridge, and on the design and field inspection of the Kentucky River High Bridge. He also took active part in developing the plans of Mr. Lindenthal's unique, competitive design for the Quebec Bridge, a braced, three-hinged suspension bridge with a center span of 1 758 ft.

In 1913, Mr. Rode was again back in Germany as Chief Engineer for the Steel Bridge Department of Steffens and Noelle, Berlin-Tempelhof. He retained this position until the fall of 1914, when he was called by the Norwegian Government to be Professor of Technical Mechanics at the Polytechnical College in Trondhjem (Nidaros), and was allotted two years to "round out" his theoretical studies. He spent that period in Germany on a Government scholarship and received his Doctor's Degree in 1916 from the Polytechnical College in Hannover on a thesis entitled, "Beitrag zur Theorie der Knickerscheinungen". In the fall of this same year he was finally appointed to his Professorship, which he held until his death on July 18, 1930.

From 1924 to 1926, Professor Rode was in the United States and again working with his former chief, Mr. Lindenthal, this time as Resident Engineer in charge of the Burnside, Ross Island, and Sellwood Bridges, which were built for Multnomah County, in Portland, Ore. Of these, the Burnside Bridge has a large bascule span; the Ross Island Bridge is characterized by its graceful appearance and its ingenious cantilever scheme; and the Sellwood Bridge has the distinction of having continuous girders over four openings.

In addition to the thesis for his doctorate degree, Professor Rode had written a textbook on Mechanics and different articles for Norwegian technical magazines. As a professor, he was very popular with the students, not only

[1] Memoir prepared by Gustav Lindenthal, Hon. M. Am. Soc. C. E.

on account of his interesting lectures, but also because of the vivid interest which he took in everything concerning the students. Another reason why Professor Rode appealed so greatly to his students was because of his happy blending of a keen theoretical insight and practical executive ability. Mr. Lindenthal regarded Professor Rode highly for his unusual theoretical and executive ability.

It was therefore a valuable life, with an excellent professional record and a still more promising future, that was abruptly cut off by Professor Rode's sudden death on July 18, 1930. He and his wife were on their way home to Norway after an automobile trip to Italy; when motoring through the Tyrol their car got out of control on a slippery road and toppled into a river, where it overturned, with the tragic result that both were drowned. Thus, by a blind accident, in the prime of his manhood, an unusually able engineer and a fine man was lost to the profession.

Professor Rode was elected a Member of the American Society of Civil Engineers on August 31, 1925. He was also a Member of the Norwegian Society of Engineers, Oslo, Norway.

## JOHN HENRY ROSTOCK, M. Am. Soc. C. E.[1]

DIED MARCH 18, 1929

John Henry Rostock, the son of John and Mary Rostock, was born on August 20, 1858, at Milwaukee, Wis.

On August 16, 1878, six days before Mr. Rostock was twenty years of age, he enlisted in the United States Army and was assigned to Troop K, Eighth U. S. Cavalry, stationed at Fort Clark, Texas. In December, 1880, he was transferred to Department Headquarters at San Antonio, Tex., where he served as Clerk to the Department Engineer, Captain (now Colonel) W. R. Livermore, U. S. Corps of Engineers. Mr. Rostock was promoted to be Topographical Assistant in June, 1881, serving in the office at Headquarters and in the field, until May 17, 1886.

In 1880, while on a surveying expedition into that part of Texas lying west of the Pecos River, toward the Rio Grande on the west, and into Southern New Mexico on the north, under the command of Captain Livermore, he was sent to select sites for new military posts. While he was surveying in the territory, hostile Indians appeared, and Captain Livermore, joining his troops with those under the command of General Griersom, prepared to drive them out. Mr. Rostock was ordered to take a position in front of the troops as a scout at a distance of 100 yd. He immediately took the lead, the troops following in a single file through a very narrow, winding, and rockbound pass which led southward from Rattlesnake Spring. The Indians were encountered in the Diablo Mountains, but finally escaped into Mexico. For his valor and courage, Mr. Rostock was awarded the Indian Campaign Badge.

[1] Memoir prepared from information on file at the Headquarters of the Society.

Several of his engagements with the Engineer Department, U. S. Army, during a subsequent period were as follows: 1886 and 1887, Chief Clerk, on the improvement of the Missouri River from its mouth to Sioux City, Iowa; 1887 to 1895, Assistant Engineer, river and harbor improvements, Newport, R. I., District; 1896, employed in the office of Commissioner of Highways of Rhode Island; and 1896 to 1898, Inspector of Material used in the construction of lighthouses of the iron tubular type at Spring Point, Portland Harbor, Me., and Butler's Flats, New Bedford Harbor, Mass.

From 1898 to 1906, Mr. Rostock was in charge of the construction of fortifications at Fort Warren, Fort Strong, and Fort Andrew, in Boston Harbor. His engineering work during this period included the emplacements for a number of guns of large and small caliber and designs for a drainage system for the perpetual removal of water from pockets of quicksand; he successfully built part of a mortar battery on this underdrained quicksand as a foundation. Later, he was in charge of cement tests to determine the comparative value of various sands and granite crusher dust in cement mortars. He prepared specifications for the purchase of practically all materials and supplies at an expenditure of $500 000.

In 1906, he became Principal Assistant Engineer, New York District No. 1, Col. W. M. Black, Corps of Engineers, U. S. Army (now Brigadier-General, U. S. Army (*Retired*)), M. Am. Soc. C. E., in charge. At his death, Mr. Rostock was Senior Engineer of the New York First District and his last services were rendered in that District and also on the Board of United States Civil Service Examiners.

In all, Mr. Rostock served in the War Department for fifty-one years. Untiring and energetic, he labored incessantly in the performance of distinctly important work affecting the improvement of harbors of the Eastern Coast from Portland, Me., and Newport, R. I., to New York, N. Y., toward the development of which he contributed materially and prominently.

He was a member of the Society of American Military Engineers and the International Navigation Congress. He was a member of Ashler Chapter, A. F. and A. M., of Rockport, Mass.

In 1898, during the conflict with Spain, and in the recent World War, when Mr. Rostock volunteered for active service, his superior officer, as well as the authorities in Washington, advised him that his services in the home district were too important and too greatly needed for him to be spared in any other capacity. However, he was one of the founders of the Home Guard in Mamaroneck, N. Y., where he resided during the war, and served in that way.

He was married in Boston, Mass., on August 11, 1894, to Mary Virginia Hill, a daughter of Caspar Hill, Sculptor, of Newport. He passed away on March 18, 1929, at Mamaroneck. He is survived by his widow, and one daughter, Mrs. Lawrence Waterbury. At his burial he was accorded military honors. In addition to the twenty-five officers of the U. S. Engineers Corps who attended, a firing squad of men who had known and loved him acted as escort to the Greenwood Union Cemetery where he was laid to rest, a salute being fired and taps sounded as his flag-draped coffin was prepared for final burial.

The following tribute was paid him by the Board of United States Civil Service Examiners at the time of his death:

"April 12, 1929.

"The Local Board of U. S. Civil Service Examiners, Engineer Department at Large, New York City, records, with sorrow, the death, in his 71st year, of its fellow member

JOHN H. ROSTOCK

which occurred at Mamaroneck, N. Y., on March 18, 1929.

"For over half a century he rendered distinguished service in the War Department of the United States Government, as a soldier in the 8th Cavalry and in the civilian service as an Engineer, his last service having been rendered in the First New York Engineer District. For this, as an accomplished Engineer and a member of the American Society of Civil Engineers, he was eminently fitted. Untiring and energetic he labored incessantly in the performance of distinctively important work affecting the improvement of the harbors of Newport and New York to the development of which he contributed materially and prominently.

"During the many years up to his demise as a member of the Local Civil Service Board his experience in this capacity proved of constant value to his associates on that Board.

"His character was above reproach and in his dealing with his fellow men he was upright and just.

"We deplore the loss of this conscientious Christian gentleman and exemplary Husband and Father.

"To his surviving devoted family, to whom he leaves a proud heritage, we tender our heartfelt sympathy in their great bereavement."

Mr. Rostock was elected a Member of the American Society of Civil Engineers on May 3, 1910.

---

## HARRY HARWOOD ROUSSEAU, M. Am. Soc. C. E.[1]

DIED JULY 24, 1930

Harry Harwood Rousseau, the son of Jeanette (Parker) and William White Rousseau, was born in Troy, N. Y., on April 19, 1870. Valedictorian of the Class of 1887 of the Troy High School, he entered the Rensselaer Polytechnic Institute in the same year. He worked during vacations (as Inspector, Troy Public Improvement Commission, in 1889 and 1890), and was graduated with the degree of Civil Engineer in 1891. Joining the Rensselaer Society of Engineers early in his student days he found time, among other activities, to be one of the staff of *The Polytechnic*, the monthly publication of the Institute, and was Editor-in-Chief during the school year, 1890-1891.

Mr. Rousseau's first work after graduation was with Charles F. Stowell, M. Am. Soc. C. E., Structural Engineer, Albany, N. Y., in 1891 and 1892; in 1893, he served as Assistant Engineer with the Brooklyn Elevated Railroad Company; and from 1894 to 1897, inclusive, with the Pittsburgh Bridge Company, as Assistant Superintendent, in the Structural Department (1894); in

[1] Memoir prepared by F. T. Chambers, Rear-Admiral, C. E. C., U. S. N., M. Am. Soc. C. E.

the Design and Estimating Department (1895-1896); and as Principal Assistant Engineer (1897).

The following year he took a competitive examination for entry into the Civil Engineer Corps of the Navy, which, at that time, required a degree from a recognized technical institution and five years of active practice, two of which must have been in responsible charge. As he was first in merit, Mr. Rousseau was appointed, with the rank of Lieutenant, Junior Grade, on October 12, 1898. Of his first eight years in the Navy, he spent about four at Navy Yards, engaged upon the maintenance and construction of various public works of the Naval Establishment and the remainder at the Bureau of Yards and Docks, the headquarters for Naval public works activities. He was stationed at the Mare Island Navy Yard, in California, for several years and was there on November 26, 1906, when his former chief, the late Rear-Admiral Mordecai T. Endicott, C. E. C., U. S. N., Past-President, Am. Soc. C. E., reached the retiring age, and Lieutenant Rousseau was appointed by President Roosevelt, at the age of 36 years, as Chief of the Bureau of Yards and Docks, with the rank of Rear-Admiral for a term of four years from January 6, 1907.

He was not, however, to serve any considerable part of this term. Several Panama Canal Commissions had been appointed, all composed mainly if not entirely of elderly men. President Roosevelt determined to have younger engineers and to establish them at Panama. It was also decided that the canal construction should go forward under the War Department and its Corps of Engineers. The late Maj.-Gen. George W. Goethals, U. S. A. (*Retired*), M. Am. Soc. C. E. (then Lieutenant-Colonel, Corps of Engineers, U. S. A.), was selected to head the Commission and Rear-Admiral Rousseau, having served less than three months with the highest regular rank then in the Navy, reverted to the rank of Lieutenant and became a Panama Canal Commissioner with Colonel Goethals. He did of course receive the higher compensation allowed by Congress for Canal Commissioners. In addition to the duties of Commissioner, each member was assigned as head of a department under Colonel Goethals as Chief Engineer. Commissioner Rousseau became head of the Departments of Building Construction, Motive Power and Machinery, and Municipal Engineering, with more than 10 000 employees under him. Upon the general re-organization in 1908, he was placed in charge of the Second Division of the Chief Engineer's Office, with the title of Assistant to the Chief Engineer, and this position he held until the Isthmian Canal Commission was terminated by Congress, April 1, 1914. Colonel Goethals then became the first Governor of the Panama Canal and Commissioner Rousseau became Engineer of Terminal Construction.

He seems to have acquired an early habit of taking on additional duties. In 1911, in addition to his other work, he was given charge of the design and construction of the canal terminals, including the dry docks, ship repair shops, piers, coaling plants, fuel oil plants, breakwaters, floating cranes, etc. Those members of the Society who have inspected the canal activities will realize the great extent of this assignment. It was to complete these ancillary works of the canal establishment that Lieutenant-Commander

Rousseau remained on the Isthmus after the Commission, as such, was no more. The only exception Colonel Goethals ever made to his announced principle, as a matter of organization, that "no one was indispensable to the canal work", was when, in reply to Secretary of the Navy Meyer's cable asking him to release Lieutenant Commander Rousseau from the canal work so that he could re-appoint him Chief of the Bureau of Yards and Docks, he cabled that he regretted that he could not do so as "Rousseau was indispensable to the canal work." As a result, he remained at Panama until the terminals were successfully completed within the estimated cost and the estimated time. The cost was more than $20 000 000.

By an Act approved March 4, 1915, Congress extended its thanks to Lieutenant Commander Rousseau as a member of the Isthmian Canal Commission for having "rendered distinguished service in constructing the Panama Canal", and authorized the President to advance him to the grade of Rear Admiral. For fifteen years, to the day of his death, he served on the active list in this rank. The terms of the Congressional Act would also have permitted him to retire as others of the Canal Organization in like case did and to reap in civil life the financial rewards which, without doubt, could have been his. Some have asked why he did not do this and others have known without asking that it was a characteristic of the man. He felt that his Government had treated him well; that he owed it his active assistance so long as his efforts were found of particular value. That his efforts were highly appreciated is conclusively proved by the record of his subsequent career.

Returning from Panama, Admiral Rousseau was appointed a member of the Commission on Navy Yards and Naval Stations which existed over a considerable period of years and which surveyed the three coasts of the Continental United States for navy yards, naval bases, submarine bases, and aviation bases. Particularly on the Pacific Coast, and most notably at San Francisco Bay, an exhaustive study was made for a main West Coast base. This and other reports were published as Congressional documents. Meanwhile, the World War engaged the attention of the Nation, and ships for the transport of both men and material were required in large numbers over and above the existing supply. The United States Shipping Board organized the Emergency Fleet Corporation to design and build the needed ships. Before such ships could be built in requisite numbers, however, additional shipyards must be designed and built. Admiral Rousseau became Assistant General Manager and Head of the Shipyards Plant Division of the Emergency Fleet Corporation.

Besides designing and building new shipyards and additions to existing commercial yards, the Shipyards Plant Division allocated and designed many marine railways and dry docks to care for the ship-building program, and all this work was under Admiral Rousseau's supervision. In addition to his duties with the Emergency Fleet Corporation, Admiral Rousseau served as Associate Director of the United States Housing Corporation, in charge of Naval housing matters; Project Manager in charge of the expenditure of Naval funds for improvements to plants of shipyards having contracts for Naval vessels; and as a member of the Government Munitions Board. For

his efforts he was awarded the Navy Cross "for exceptionally meritorious service in a duty of great responsibility." Admiral Rousseau was also a member of the Port Facilities Commission of the United States Shipping Board, serving part of the time as its Vice-Chairman.

After the war, he continued his Navy Yard Commission duties, to which were added many others. He was constantly serving on Boards for various purposes, such as President of numerous Naval Examining Boards for the appointment and promotion of officers in the Corps of Civil Engineers, U. S. Navy; Alternate Navy Member of the Interdepartmental Board on Contracts and Adjustments, under the Bureau of the Budget, from 1922; Senior Member of the Board appointed by the Secretary of the Navy to consider claims of land owners arising from the commandeering of land for the Naval Operating Base at Hampton Roads, Va.; and Senior Member of numerous Boards to report on the settlement of Navy war contracts with the Bureau of Yards and Docks. Since 1923, Admiral Rousseau had served as Chairman of the Metals Committee, Federal Specification Board, under the United States Bureau of Standards. For three years he was Government Receiver in the oil litigation over Naval Petroleum Reserve No. 1, known as the Elk Hills suit, receiving the commendation of the Court for his assistance in this difficult matter. His work in connection with the Naval oil reserves was extended and, for three years prior to his death, he was Director of the Naval Petroleum and Oil Shale Reserves. Meanwhile, in addition to his other duties, he was made Chief Co-Ordinator of the Bureau of the Budget to administer, under the Director of the Budget, all Federal co-ordinating agencies, a position of great responsibility, requiring close detailed application. While recognizing to the full Admiral Rousseau's tremendous abilities and capacity for work, his intimates nevertheless believe his close attention to Budget matters was contributory to his final collapse.

Admiral Rousseau, since Panama Canal Commission days, had been a Director of the Government-owned Panama Railroad Company which operates the railroad in the Canal Zone, and the Panama Railroad Steamship Company. He died at sea on the S. S. *Cristobal*, on his way to the Canal Zone to make an inspection.

Admiral Rousseau had delivered addresses and presented papers before various technical societies, covering miscellaneous engineering subjects, port development, oil shales, and the Panama Canal. In 1923, he delivered the principal graduating address at Rensselaer Polytechnic Institute.

A first-rate engineer, an able executive, Admiral Rousseau's general demeanor was one of unusual reserve. His was, however, a kindly nature. He was ever ready to help. He carried the respect, the high regard of those who knew him in his work. Socially, he was quite responsive. With a keen sense of humor, among his friends he was both an enjoyer and a lender of gayety to the party.

He was a member of the Rensselaer Society of Engineers and of the Engineers Society of Western Pennsylvania, the American Association of Port Authorities, and the Permanent International Association of Navigation Congresses. He was also a member of the Army and Navy, the Metropolitan,

and the Chevy Chase Clubs, of Washington, D. C., and of the New York Yacht Club. A staunch Churchman all his life, he was, at the time of his death, a Vestryman of St. Thomas Protestant Episcopal Church, Washington, from which the funeral was held. He was buried in Arlington National Cemetery with full military honors.

Admiral Rousseau found his bride at Panama. He was married to Gladys Fargo Squires, the daughter of the American Minister to Panama, in 1908. She, with three sons, Henry H., William P., and Bard S., survives him. He also leaves behind him a brother, W. W. Rousseau, Assoc. M. Am. Soc. C. E., of the Rensselaer Polytechnic Institute, at Troy.

Admiral Rousseau was elected a Junior of the American Society of Civil Engineers on June 6, 1893; an Associate Member on April 4, 1900; and a Member on January 18, 1916.

---

## RICHARD LORD RUSSELL, M. Am. Soc. C. E.[1]

---

DIED MARCH 16, 1930

---

Richard Lord Russell was born in Brooklyn, N. Y., on February 27, 1874. Both his father, William Warren Russell, and his mother, Margaret Butler (Hartt) Russell, were descended from early Colonial New England stock. He received his technical training at the Polytechnic Institute of Brooklyn, earning the degree of Bachelor of Science in 1893 and that of Civil Engineer in 1897. He took a post-graduate course from September, 1893, to February, 1894.

From February to June, 1894, Mr. Russell served as Instructor in Civil Engineering at his Alma Mater. From June, 1894, until September, 1896, as Leveler for the Department of Water Supply, Brooklyn, he had charge of a transit party locating a new steel pipe line, and surveyed locations for new driven-well stations at Freeport, Merrick, and Massapequa, N. Y. In September, 1896, he returned to the Polytechnic Institute as Assistant Professor of Civil Engineering, which position he held until September, 1897.

From February to December, 1898, as Resident Engineer of the Nassau Electric Railroad, Mr. Russell superintended the erection of an addition to the Third Avenue Power Station. From January, 1899, to July, 1902, he was with the Brooklyn Heights Railroad Company, beginning as Assistant Engineer. In April, 1899, he was promoted to Assistant to the Chief Engineer and in January, 1900, became Assistant Engineer on Maintenance of Way.

In July, 1902, as Resident Engineer for the Flatbush Avenue Terminal and the Carlton and Sixth Avenue Freight Yards on the Atlantic Avenue Improvement, for the Long Island Railroad Company, he made topographical surveys and designed the track layout, masonry, drainage system, and other items for a 16-track underground terminal station. He also made the designs for three blocks of freight yards and had active charge of the construction of all these projects.

[1] Memoir prepared by Rex B. Mesny, Esq., Phoenix, Ariz.

From February to August, 1905, Mr. Russell served as Principal Assistant Engineer on the Brighton Beach Improvement, in charge of the construction of Section 1 and the surveys and plans for Sections 2 and 3. During this time he built the depressed section of the Brighton Beach Railroad under traffic.

In August, 1905, he became Chief Engineer for Charles Cranford, General Contractors, and, in 1908, he added to this the duties of the same office for the Borough Development Company of Brooklyn. He held both these positions until 1913, when he became Vice-President of the Sanborn-Russell Construction Company. Mr. Russell was a co-patentee of the Sanborn-Russell High Temperature Incinerator. The following year he became a partner in the firm of Harrison and Russell.

The next two years, from 1915 to 1917, Mr. Russell spent in the capacity of Chief Engineer of the Eastern Contracting Company of Brooklyn; and the following two, from 1917 to 1919, as Consulting Engineer of the Uvalde Asphalt Company of America.

From 1919 to 1922, he was with The Foundation Company. During this time he had charge of the construction of a 936-ft. mine shaft for the Miami Copper Company, at Miami, Ariz. Subsequently, he was Works Manager on the construction of extensions to the Standard Oil Refinery at El Segundo, Calif., and, later, District Manager for the Company in the Los Angeles territory. In 1923, he went with the Austin Company as Sales Engineer.

Mr. Russell was greatly interested in construction engineering, and devoted considerable time to the work of the Construction Division of the Society. During the last year of his life he did a great amount of research work on sound-proof construction for the talking films. He had an open, genial nature, and was highly respected and loved by all the construction men who came in contact with him. Being an inveterate reader, he collected an extensive library, and was a conversationalist of rare charm. He was the author of "Contractors' Cost Keeping" and "Sinking and Concreting 936 Foot Mine Shaft."

The radio was one of his hobbies, and another was the study of Nature, in which interest he was joined by his wife. He was deeply devoted to his family, and enjoyed participating with them in many sports, the chief of which was yachting. In fact, his boat, *Patricia*, won many cups in the skimmer class on the Western Coast.

Mr. Russell was married in Brooklyn, on October 10, 1900, to Ruth Eloise Maddren, who, with a son, Richard, and a daughter, Dorothy, survives him.

He was a member of the Corporation of his Alma Mater, the Polytechnic Institute of Brooklyn, from 1907 to 1918, having served as Secretary of the Corporation from 1913 to 1918. He was also a member of the Protestant Episcopal Church; the Republican Party; the Engineers (Brooklyn), University, Jonathan, and City (Los Angeles) Clubs; the American Society of Engineering Contractors; the American Association of Engineers; and the National Geographic Society. He was the first Commodore of the Alamitos Bay Yacht Club.

Mr. Russell was elected a Junior of the American Society of Civil Engineers on February 5, 1895, an Associate Member on April 3, 1901, and a Member on September 4, 1906.

## GEORGE FREDERICK SAMUEL, M. Am. Soc. C. E.[1]

DIED NOVEMBER 5, 1930

George Frederick Samuel was born in New York, N. Y., on May 8, 1859. He was graduated from the University of Michigan with the degree of Bachelor of Science in Civil Engineering in 1885.

In this same year, Mr. Samuel accepted a position as Assistant Engineer for the Town of Lake View, Ill., which he held until 1887, when he was appointed Assistant Engineer for the City of Topeka, Kans., in charge of sewer construction.

In 1888, he entered the service of the City of Chicago, Ill., as Assistant Engineer in the Department of the Bureau of Streets, in charge of street-paving and improvements. From 1895 to 1897, he served as Consulting Engineer on street improvements and sub-divisions. In 1898, he was transferred to the Bureau of Engineering and for the ensuing twelve years he was employed as Assistant Engineer in local charge of the construction of many of the large tunnel and pumping station projects of Chicago.

In 1910, Mr. Samuel temporarily filled the office of City Engineer of Chicago, after which he was appointed Assistant City Engineer. In May, 1911, he became Engineer of Track Elevation, but, in 1914, he returned to the Bureau of Engineering as Assistant Engineer of Water-Works Construction. From 1916 until 1919, he served as Engineer of Water-Works Design and, in January, 1919, was appointed Assistant Engineer in local charge of construction on the Western Avenue and Chicago Avenue Tunnels. He held this position until he retired from the service on July 1, 1930. He then went to Brooklyn, N. Y., where he made his home until his death on November 5, 1930.

Mr. Samuel was a member of the Chicago Athletic Club and of the Municipal Employees Society of Chicago. From an obituary published by the latter is quoted the following tribute to his memory:

"He gave his best to the service of the City of Chicago. Long hours and hard work had no terrors for him, and, up to the day that he left the office for the last time, he maintained close contact with every activity under his supervision."

* * * * * *

"His death ended the career of one of the Bureau's most capable engineers, and there is lost to the City the experience, knowledge, and ability which Mr. Samuel possessed."

Mr. Samuel was elected a Member of the American Society of Civil Engineers on September 6, 1910.

[1] Memoir prepared from information on file at the Headquarters of the Society and from data supplied by James J. Versluis, Esq., Chicago, Ill.

# IVAN OSCAR SHAFFER, M. Am. Soc. C. E.[1]

DIED JANUARY 25, 1928

Ivan Oscar Shaffer was born in Waterford, Ireland, on July 24, 1887, the son of Isaac and Fanny Wolpert Shaffer. When Mr. Shaffer was seven years old, his family emigrated to America, where he received his early education in the public elementary and high schools. He received the degree of Civil Engineer from the Polytechnic Institute of Brooklyn in 1915.

While Mr. Shaffer was attending school, he was employed in various capacities. From 1906 to 1918 he received his training in various fields of engineering, including drafting, designing, and construction supervision on the Hudson River Tunnels, Pennsylvania coke mines, West Virginia Coke and Coal Company, and on the construction of locks and dams with the War Department; during this period he also was employed in the sewage and water supply branch of engineering with the firm of Hering and Fuller, as well as with George W. Fuller, M. Am. Soc. C. E.; during the latter period up to 1918, Mr. Shaffer was Engineer of Design with the American Can Company, and with Weiskopf and Borroughs in connection with buildings in New York, N. Y.

From 1918 to 1922, he was Chief Engineer of the Fleischmann Construction Company, during which period many of the New York theatres, large motion picture studios, film laboratories, and miscellaneous structures were built under his supervision.

In 1922, he entered the firm of Parker and Shaffer, Engineers and Industrial Architects, in New York City, and during this partnership, the firm was retained to plan the Lloyds Film Storage Building, the Miller Shoe Factory, the Ronzoni Macaroni Factory, the Stanley Patterson Building, the Master Printers Building, and many other structures in New York. In 1926 this firm was dissolved, and Mr. Shaffer practiced as an Industrial Engineer and Architect in the construction of industrial buildings until his death.

Mr. Shaffer was an engineer of varied experience, and a recognized expert in industrial building design. Prior to his death, he was being considered for some of the outstanding building work in New York City. He had established an enviable reputation as an Engineer and Designer, and had the confidence of his clients for his unimpeachable honesty, ability, and dependability.

It is unfortunate that his accidental death cut short a career which had already started in the limelight of success, and would no doubt have been climaxed by a unique and enviable position in his field. Mr. Shaffer is survived by his widow, Bess Shaffer, and a daughter, Muriel Shaffer.

Mr. Shaffer was elected an Associate Member of the American Society of Civil Engineers on October 9, 1917, and a Member on April 16, 1923.

[1] Memoir prepared by William Ginsberg, M. Am. Soc. C. E.

## STANLEY RUSH SHARTS, M. Am. Soc. C. E.[1]

DIED DECEMBER 5, 1930

Stanley Rush Sharts was born at Dayton, Ohio, on June 18, 1874, the son of Joseph William and Belle (Ealy) Sharts. His father was a lawyer, an associate of the famous Valandingham. Both families were descended from old pioneer stock of that section of Ohio, his maternal grandfather, Dr. Ealy, having been a well-known physician of Dayton's early days.

Mr. Sharts attended the public schools in Dayton and studied civil engineering at the Ohio State University from 1893 to 1897. On the completion of his course at the University, he served, until June, 1898, as Deputy Surveyor of Williamson County, Illinois, where his work consisted mostly of mine locations. At the outbreak of the war with Spain he joined the Second Engineers Regiment of Volunteers and was in Cuba with the United States Army from June, 1898, until May, 1899, engaged in military surveying and mapping. He assisted in laying out the first sanitary sewers in the vicinity of Havana, at Mariano, Cuba.

After his honorable discharge from the Army he returned to Dayton, but very shortly went with the Baltimore and Ohio Southwestern Railroad Company as Instrumentman, in which capacity he remained until January, 1900. In May, 1900, he became connected with the City Engineer's Office in his home city where he was actively engaged until March, 1901. At that time he was appointed Assistant Engineer on ditch and waterway construction in the County Engineer's Office of Montgomery County, Dayton. In September of the same year Mr. Sharts was made Chief Assistant Engineer in charge of the design and construction of bridges and roads. The cost of the steel highway bridges built under his supervision, ranged from $3 000 to $170 000 each. He also designed reinforced concrete slab, girder, and small arch bridges valued at $200 to $8 000 each. From September, 1917, to September, 1919, he was County Engineer in charge of annual improvements the cost of which approximated $600 000. For a short period after leaving the County Engineer's Office, he did general engineering work in and around Lima, Ohio.

In March, 1920, Mr. Sharts left Dayton for Minneapolis, Minn., having received an appointment as Senior Highway Engineer with the Bureau of Public Roads, U. S. Department of Agriculture. For about six months he was assigned to various projects in the States comprising District No. 4, namely, Minnesota, Wisconsin, North Dakota, and South Dakota, but in October, 1920, he was sent to Bismarck, N. Dak., to establish an office of the Bureau. During his nearly eleven years of service there, he saw the highways of North Dakota emerge from a network of trails and a few good roads to many hundreds of miles of a modern Federal highway system.

The large steel bridge spanning the Missouri River between Bismarck and Mandan, N. Dak., was completed at a cost of more than $1 250 000, under his supervision. He also completed the large steel spans at Williston and Sanish, both over the Missouri River, as well as the Roosevelt Memorial

[1] Memoir prepared from information on file at the Headquarters of the Society.

Bridge over the Little Missouri at Chaloners, in the Grand Canyon of this river, in the heart of the Bad Lands. All these bridge sites had been ferry crossings before the construction of these modern highway structures under Federal Aid.

In these progressive years when he was in charge of the work of the Bureau of Roads in North Dakota, Mr. Sharts, peculiarly fitted as he was by education, wide experience, personality, and a judicial mind trained to survey all angles before deciding, accomplished far more for the good of the Bureau and the State than many men in the same position would have been able to do in a similar length of time. This work, well known to the public generally in the State and District, will always stand as a monument to the ten years and more of earnest and too strenuous endeavor which he gave to North Dakota.

Mr. Sharts was a member of the Ohio Engineering Society, the Spanish War Veterans, and the American Legion, having held a Captain's Commission in the Reserves. By pressure of official groups in Montgomery County, he was persuaded, with great regret, to resign this Commission, in order to continue his engineering work there. He was also a Thirty-second Degree Mason and Shriner, and had been a Knight of Pythias for many years, as well as a member of the Order of Eagles. He was affiliated with the Delta Tau Delta Fraternity at Ohio State University.

Mr. Sharts was of a quiet disposition, choosing to let his work speak for itself. He was, however, an excellent conversationalist when he felt so inclined. He was a great lover of such sports as hunting and fishing and was a periodical visitor and an indefatigable follower of his favorite pastimes in various parts of Ohio, as well as in North Dakota, South Dakota, and Minnesota. A man who readily made friends and kept them always, he was whole-souled, charitable, and generous to a fault. To his many friends and business associates his loss is irreparable, yet the memory of him and his great work will be an inspiration to those who follow.

He was married in December, 1904, to Bessie Ethel Bone, of Dayton, who survives him.

Mr. Sharts was elected an Associate Member of the American Society of Civil Engineers on December 6, 1915, and a Member on November 26, 1918.

## BRONSON HASBROUCK SMITH, M. Am. Soc. C. E.[1]

DIED JUNE 6, 1930

Bronson Hasbrouck Smith, the son of P. Minturn and Ella E. (Phillips) Smith, was born on May 9, 1880, in Brooklyn, N. Y. He attended the public schools in Plainfield, N. J., the Brooklyn Collegiate and Polytechnic Institute, the Cascadilla Preparatory School, at Ithaca, N. Y., and was graduated from Cornell University in the Class of 1901. He was a member of the Zeta Psi Fraternity, and rowed on the Cornell crew.

[1] Memoir prepared by Henry R. Kent, Esq., Rutherford, N. J.

After his graduation Mr. Smith secured the position of Assistant to the General Manager of the Perth Amboy Shipbuilding Company, with which Company he remained until it went out of business. He then became associated with the Holland Submarine Torpedo Boat Company, co-operating in the construction, outfitting, testing, and operation of submarines.

From 1904 to 1913 he was identified with Westinghouse, Church, Kerr and Company, starting as Draftsman and advancing to Engineer in Charge. During this period he was associated with many important undertakings, including the Pennsylvania Railroad Terminal in New York, N. Y., and the electrification of the Long Island Railroad.

The next two years were devoted to the railway properties of the United Gas and Electric Engineering Corporation and its allied interests. As Senior Operating Officer of the Jamestown, Chautauqua, and Lake Erie Railroad Company on one of its railroad and steamboat properties at Jamestown, N. Y., he built up the property, improved its operating efficiency, and increased the earnings, so that it was finally sold to competing interests. He then went to the International Railway Company at Buffalo, N. Y., and under Mr. E. G. Connette laid down a new high-speed interurban line between Buffalo and Niagara Falls, N. Y. Later, under Mr. B. F. Wood, then Vice-President, he supervised the design, the placing of contracts, and the construction of steel motor cars for the Memphis, Tenn., and New Orleans, La., properties of the United Gas and Electric Engineering Corporation. He also planned and installed power-house extensions and was concerned with the management of the Richmond Light, Heat, and Power Company, Richmond, Ind.

In March, 1915, Mr. Smith was retained as Senior Engineer in Charge by Henry R. Kent and Company and had responsible charge of the design, purchase, and installation of industrial power plants and manufacturing buildings. He handled three contracts with the Spicer Manufacturing Company, South Plainfield, N. J., including a complete 2 000-kw. power plant, a dam and water supply, and transmission lines. He sponsored three contracts with the American Brass Company, including a 4 000-kv-a. plant at Waterbury, Conn., with transmission line and high-tension sub-station; a power house extension with fire and service water supply at Ansonia, Conn., also a large warehouse at the latter place; a contract with the American Cotton Oil Company for a complete power plant of 2 500-kw. capacity, together with the motorization of its plant at Memphis, Tenn.; besides these were numerous other undertakings, one of peculiar interest being a plant for the recovery of arsenic by the Cottrell Precipitation System.

Mr. Smith left Henry R. Kent and Company in November, 1920, to take a position as Chief Mechanical Engineer with the American Cotton Oil Company, New York, as a result of the Company's satisfaction with the Memphis Plant built by the Kent Company under his supervision. He spent three years modernizing the plants, improving operating conditions, supervising power-plant operation, making extensions and additions to power plants, providing engineering reports, and standardizing purchases of power and mechanical equipment, structures, and supplies.

From August, 1923, to August, 1927, he was Managing Engineer for Meyer and Holler, Engineers and Architects, Los Angeles, Calif. With this Company his duties were largely executive, including engineering, estimating, purchasing, construction, and cost accounting; also work in connection with the negotiation of new contracts and the handling of clients. Outstanding among the many important buildings carried through to successful completion were the Petroleum Securities Building and Grauman's Chinese Theatre in Los Angeles. In the fall of 1927, Mr. Smith severed his connection with Meyer and Holler on account of the recession in building activity in Southern California and devoted his time to consulting work.

His health became impaired in the latter part of 1929, and in November of that year he experienced an attack of Malta fever, followed by a relapse early in 1930. He was never able to regain his strength and passed away on June 6, 1930, in Los Angeles.

Mr. Smith was an engineer of wide experience, an untiring and very productive worker. He possessed to an unusual degree the combination of technical ability and financial sense. He was an enthusiastic yachtsman and was a member of the California Yacht Club and the New York Harbor Yacht Club. He was also a member of the Cornell Club of Los Angeles and the American Society of Mechanical Engineers.

He was married to Florence Merwin, of Brooklyn, on June 19, 1905. Mrs. Smith, with one son, Bronson, and three daughters, Gladys, Evelyn, and Barbara, survives him.

Mr. Smith was elected a Member of the American Society of Civil Engineers on November 26, 1923.

---

## LINTON WADDELL STUBBS, M. Am. Soc. C. E.[1]

---

DIED JANUARY 18, 1930

---

Linton Waddell Stubbs, the son of Frank P. and Margaret (Linton) Stubbs, was born on October 5, 1855, at Thomasville, Ga. His early education was obtained in the local schools at Monroe, La., and at the Brothers' College, at Bay St. Louis, Miss. Later, he entered Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated in 1877.

On the completion of this course, Mr. Stubbs entered the service of the United States Government in its survey of the Missouri River. Later, in 1888, he became Resident Engineer of the Meridian-Shreveport Division of the then Queen and Crescent Railroad System, and continued in that position until 1901. During Mr. Stubbs' service with this System, the road-bed between Delta Point, and Monroe, La., was raised to a grade above the high-water mark in the territory at that time.

In 1902, Mr. Stubbs entered the service of the Southern Pacific Railroad Company. His employment with this Company embraced construction of

[1] Memoir prepared from information on file at the Headquarters of the Society.

works of great significance, chief among which was the important bridge across the Atchafalaya River at Morgan City, La.

In 1909, Mr. Stubbs resigned from the service of the Southern Pacific Railroad Company to become Engineer in charge of the construction of the Galveston (Tex.) Causeway, a large and important task which was completed in 1912. At this time he retired from the active practice of his profession. In later years, he devoted his time to the supervision of his landed and other interests which developed and grew steadily under his wise and capable direction.

Mr. Stubbs was an Engineer of marked ability and his service was ever characterized by fidelity and devotion to his trust. He was deeply interested in civic affairs and was the author of many forceful and interesting articles relating to the public interest.

He was a Mason, and a member of the Presbyterian Church. Mr. Stubbs leaves a widow, Mrs. Helen (Chase) Stubbs, of Shreveport, La., and two daughters, Mrs. Horace M. Witherspoon and Mrs. J. O. Crawford, both of Los Angeles, Calif.

Mr. Stubbs was elected a Member of the American Society of Civil Engineers on October 3, 1888.

## HARRY TAYLOR, M. Am. Soc. C. E.[1]

DIED JANUARY 27, 1930

Harry Taylor, the son of John Franklin and Lydia Taylor, was born at Tilton, N. H., on June 26, 1862. His ancestors were of English stock who came to the United States about 1650 and were among the early settlers of Central New Hampshire. They helped found the Town of Sandbornton Bridge, later called Tilton, and several of them served in the Revolutionary War. Prior to becoming a Cadet at the United States Military Academy, West Point, N. Y., Harry Taylor resided in Tilton and attended the Tilton Academy. He entered the U. S. Military Academy on July 1, 1880, was graduated on June 15, 1884, and was appointed Second Lieutenant in the Corps of Engineers, U. S. Army.

Lieutenant Taylor's first assignment was at Willets Point (now Fort Totten), N. Y., where he served with the Battalion of Engineers and at the Engineer School of Application from 1884 to 1887. In 1887, he was assigned to duty at Wilmington, N. C., where he served as Assistant to the late Brigadier General (then Captain) William H. Bixby, Corps of Engineers, U. S. A., M. Am. Soc. C. E., the District Engineer in charge of river and harbor improvements in North Carolina and South Carolina. He was promoted to First Lieutenant on December 1, 1887. In 1888, he was transferred to duty at the U. S. Military Academy, where he remained about one year, being assigned in 1889 to duty under the orders of Lt.-Col. G. L. Gillespie, Corps of Engineers, U. S. A., then at New York, N. Y., and was placed in local

[1] Memoir prepared by Herbert Deakyne, M. Am. Soc. C. E.

charge of the construction of new fortifications at Sandy Hook, N. J. In 1891, Lieutenant Taylor was transferred to the Pacific Coast where he was placed in local charge of the construction of the lock at The Cascades, Oregon, on the Columbia River. He supervised the erection of the lock-gates, the largest that had been erected to that time, and designed the operating machinery for them as well as many of the masonry details.

He was promoted to Captain, Corps of Engineers, January 6, 1896, and in the same year was placed in charge of the construction of fortifications on Puget Sound and also of the improvement of waterways in the newly-created Seattle Engineer District, remaining on this duty until 1900. He was then assigned to duty at Boston, Mass., in charge of the construction of fortifications and the works of river and harbor improvement in the Boston Engineer District. He remained there until 1903. Captain Taylor was placed in command of Company L, 3d Battalion of Engineers, in 1903, and took his company to the Philippine Islands in October of that year. He served in the Philippines until October, 1905, and while there was on duty, successively, as Engineer Officer, Department of Luzon; Commander of the 3d Battalion of Engineers; and District Engineer in charge of fortification construction, which was initiated in 1904. He was promoted to the grade of Major, Corps of Engineers, in 1904.

Returning to the United States, Major Taylor, after a few months' duty in the Office of the Chief of Engineers, was assigned, in 1906, to duty at New London, Conn., in charge of river and harbor work in that vicinity and of fortification work at the eastern entrance of Long Island Sound. He was also charged with the purchase and issue of 60-in. searchlights and gasoline-actuated generating sets required for fortifications in the United States and its possessions. The purchasing agency established by him at New London was later moved to Washington, D. C., and during the World War was the procurement agency which purchased a large part of the equipment and materials required by the Engineer Service. It still exists as part of the Supply Section of the Office of the Chief of Engineers.

Major Taylor was promoted to the grade of Lieutenant-Colonel, Corps of Engineers, June 24, 1909. He remained on duty at New London until 1911, when he was transferred to the Office of the Chief of Engineers, Washington, D. C., and was placed in charge of the River and Harbor Section of that office, where he remained until 1916. He reached the grade of Colonel, Corps of Engineers, February 28, 1915. In 1916 he was transferred to duty in New York City, in charge of the work of river and harbor improvement in the First New York District, and as Department Engineer of the Eastern Department, U. S. Army. At the time of Colonel Taylor's assignment to duty in New York, the prospect of the entry of the United States into the World War was growing, and, as a result, in addition to his regular duties, he was engaged in the examination of applicants for commissions in the Reserve Corps and in the selection of sites for camps and for the training of troops.

On May 26, 1917, Colonel Taylor was selected as Chief Engineer, American Expeditionary Forces; he sailed for France on May 28, 1917. He was

appointed Brigadier-General, National Army, August 5, 1917, and remained in France until September 12, 1918, initiating the large engineering works required for the support of the American Army in France.

On his return to the United States he was assigned to duty in the Office of the Chief of Engineers, Washington, D. C. He was honorably discharged as Brigadier General, June 1, 1919, and on July 1, 1920, was appointed Brigadier General and Assistant Chief of Engineers. General Taylor on his assignment to duty in the Office of the Chief of Engineers in 1918 was again placed in charge of the River and Harbor Section and continued in this work until his appointment as Chief of Engineers, on June 19, 1924, with the rank of Major General. He served as Chief of Engineers until June 26, 1926, when he was placed on the retired list of the Army, having reached the statutory age of sixty-four years.

General Taylor was awarded the Distinguished Service Medal for his services in the American Expeditionary Forces with the following citation:

"For exceptionally meritorious and distinguished services. Arriving in France June 11, 1917, as chief engineer, American Expeditionary Forces, he organized and administered the Engineer Department, which included the construction of wharves, depots, railways, barracks, and shelters throughout the theater of operations. He continued these duties with most marked and conspicuous ability, building a complete and efficiently functioning institution."

He was also made a Commander of the Legion of Honor by the French Government for his services during the war.

During his forty-two years' service as an officer of the Corps of Engineers, General Taylor served on many official boards, both in connection with the preparation of plans for the defense of the coasts and in the interest of the improvement and utilization of the rivers and harbors of the United States for navigation and other purposes. He was a member of an Advisory Board of Officers of the Corps of Engineers appointed in 1910 by direction of the President to assist the Secretary of the Interior in connection with granting permission to the City and County of San Francisco to use the Hetch Hetchy Valley in California for a new water supply system.

His experience in fortification construction began with the construction of new works of harbor defense in the early Nineties when Congress, realizing the defenseless condition of the coasts, again began to make appropriations for new fortification construction after a lapse of about twenty years. He was an outstanding fortification engineer, and when a Captain, devised with Capt. R. R. Raymond, Corps of Engineers (now Colonel, U. S. Army, (*Retired*)), an ingenious hoist for transferring the heavy ammunition from the magazine level of the batteries to the firing platform above. This hoist was used to a large extent in batteries constructed prior to the World War. During his long service in the Office of the Chief of Engineers as an Assistant to the Chief, Assistant Chief, and Chief of Engineers, General Taylor's duties were primarily in connection with the improvement and maintenance of rivers and harbors for the purpose of navigation. He acquired an extended acquaintance with the numerous projects adopted or under consideration by Congress, and

his intimate knowledge of works of river and harbor improvement, combined with his sound judgment of their value to water-borne commerce, was of great assistance to the committees of Congress in the preparation of appropriation bills for these works. While serving in the Office of the Chief of Engineers he had supervision over many important engineering works for the Federal Government. One of these was the Wilson Dam on the Tennessee River at Muscle Shoals, Ala., in which he was particularly interested and which was completed while he was Chief of Engineers.

General Taylor was an engineer of great ability, with an active, logical mind, and his decisions were made quickly and with excellent judgment. Following his retirement from the Army in 1926, he engaged in consulting practice and was actively occupied with this work at the time of his death.

His youth in his native State had been spent largely in the open, and he had a fondness for hunting and fishing which remained with him all his life. This liking for outdoor life was no doubt largely responsible for his excellent physique, and for his physical appearance which gave little evidence of advancing years. His untimely death from pneumonia, after a brief illness, in Washington, D. C., where he had made his home after retirement, was a shock to his many friends. He was buried in the Arlington National Cemetery where he rests after a life that devoted to his country's service the talents which brought him honor and distinction.

General Taylor was married at Portsmouth, N. H., on October 30, 1901, to Adele Austin Yates, the daughter of Capt. Arthur Reid Yates, U. S. N., of Schenectady, N. Y., and Mrs. Yates, who was Susan Thompson Dwight, of Portsmouth. He is survived by Mrs. Taylor and their two children, Arthur Yates Taylor and Margaret Taylor, now Mrs. Alfred Craven Bruce.

He was a member of the Society of American Military Engineers, and served as its President in 1925. He was also a member of the Army and Navy and Chevy Chase Clubs of Washington.

General Taylor was elected a Member of the American Society of Civil Engineers on October 7, 1896.

## LOUIS LINCOLN TRIBUS, M. Am. Soc. C. E.[1]

DIED NOVEMBER 9, 1930

Louis Lincoln Tribus was born on May 26, 1865, in Northampton, Mass. He was the son of Louis Tribus, of French descent, and Harriet Jeanette (Kingsley) Tribus, of Westhampton, Mass. His father, at one time a Professor in Amherst College, was an Instructor in a prominent preparatory school, the Willinston Seminary, in Easthampton, Mass. His mother was a descendant from an old Massachusetts family.

After obtaining his early education in private schools on Staten Island, New York, Mr. Tribus entered the Engineering Course of New York Uni-

[1] Memoir prepared by Edward Wegmann, M. Am. Soc. C. E.

versity and was graduated in 1885 with the degree of Bachelor of Science and Civil Engineer. In 1888, he received from this University the honorary degree of Master of Science.

After graduating, Mr. Tribus spent two years as Assistant Engineer in the employ of Samuel R. Bullock and Company, of New York (franchise constructors and owners of water-works). The following year he was made Resident Engineer. While in this employ he supervised the construction of water-works for Pensacola, Fla., and Mobile, Ala., and reported on a proposed water-works for Gainesville, Fla., and Tuscaloosa, Ala.

In 1887, he became Assistant Engineer with the late Charles B. Brush, M. Am. Soc. C. E., and was given special charge of water-works design and construction; he was also engaged in many other engineering matters. Mr. Brush had an extensive practice and during the six years Mr. Tribus stayed in his employ he was engaged in making valuations and reports and on the design and construction of water-works and sewers for various places in the States of Ohio, Virginia, Pennsylvania, New Jersey, New York, Kansas, and Missouri. He also made studies for classification yards, traffic handling, and terminal station for the New York and New Jersey Bridge Commission.

From 1887 to 1890, Mr. Tribus was engaged at New York University as Instructor and Acting Professor of Civil Engineering. From 1894 to the end of 1901, he was in private practice as Consulting Engineer in New York, N. Y., reporting on various projects, and designing and superintending the construction of public utilities and water power plants, mainly in the Eastern States, although his practice extended as far as California, Kansas, Nebraska, Ohio, Michigan, and British Columbia.

In 1902, Mr. Tribus went into partnership with Mr. Charles G. Massa, under the firm name of Tribus and Massa, continuing the business of Consulting Engineering which had been so well established by Mr. Tribus.

In this year, he was appointed by the Hon. George Cromwell, who had been elected Borough President of Richmond, as Consulting Engineer and Commissioner of Public Works for this Borough. While in this position, which he held for twelve years, he was at times Acting President of the Borough and Deputy Member of the Board of Estimate and Apportionment, and Alderman. He was a member and Secretary of the New York State Bay Pollution Commission from 1903 to 1906; member of the Board of Consulting Engineers of New York City, and of the Sewer Plan Commission, from 1910 to 1913; and Project Engineer for the United States Housing Corporation, at New London and Groton, Conn., in 1918 and 1919. He was also a member of the following technical societies: The American Society of Municipal Improvements; the Municipal Engineers of the City of New York; the American Water Works Association; and the New England Water Works Association. Mr. Tribus was a good writer and speaker, and had contributed papers to the several societies to which he belonged; he also took part in the discussions of various papers, especially those pertaining to water-works, sewerage, and harbor pollution.

He spent most of his life on Staten Island and took a deep interest in all public and civic matters which affected its welfare. While Commissioner of

Public Works of the Borough of Richmond he was responsible for many engineering improvements that were made, such as the perfection of the highway system on the Island and of trunk and storm relief sewers, as well as the very comprehensive topographical map of the Borough.

He was Past-President of the Staten Island Chamber of Commerce; a Trustee of the Samuel R. Smith Infirmary (now Staten Island Hospital); President of the Tompkinsville Savings and Loan Association; a member of the Staten Island Academy of Arts and Sciences; and Ruling Elder of the First Presbyterian Church of Stapleton. He was a member of the Alumni Association of the New York University and belonged to Psi Upsilon, Phi Beta Kappa, and Iota Alpha (honorary engineering) Fraternities.

Mr. Tribus was an engineer of much ability and of large and varied experience. In the high positions he held for many years, he always acted with dignity, but in dealing with his subordinates he was genial, just, and very kind.

He is survived by his widow, *née* Letitia Hall McCampbell, to whom he was married on October 3, 1899, and by his son, Lucien Hall Tribus.

Mr. Tribus was elected a Junior of the American Society of Civil Engineers on April 4, 1888; an Associate Member on June 1, 1892; and a Member on April 1, 1896.

## EDMUND KIMBALL TURNER, M. Am. Soc. C. E.[1]

DIED MAY 6, 1915

Edmund Kimball Turner was born in Marblehead, Mass., on May 11, 1848. His father, Joseph P. Turner, was for many years Cashier of the National Grand Bank of that town, and his mother who died when he was a child, was Mary K. Kimball, of Marblehead.

In September, 1867, Mr. Turner entered the Massachusetts Institute of Technology, then in its infancy, from which he was graduated in Civil Engineering in 1870. He was an enthusiastic student and was one of the Captains of the Institute Battalion, military drill being required at that time, as it is now.

Following his graduation, he was engaged as Assistant Engineer for the City of Charlestown in 1871, and, in 1872, became Assistant Engineer and then Engineer of Construction on the Nashua, Acton, and Boston Railroad, a short line which has since been consolidated with the Boston and Maine System. On the completion of this work he was appointed Chief Engineer of the Fitchburg Railroad, which position he held for seventeen years. In addition, he served during part of this time, as Assistant Superintendent of the Vermont and Massachusetts Division of this railroad.

In 1890, Mr. Turner resigned his position as Chief Engineer with the Fitchburg Railroad Company and entered into private practice as a Consulting Civil Engineer, with an office in Marblehead. He continued in this work

[1] Memoir prepared from information on file at the Headquarters of the Society and from the memoir prepared by the late George F. Swain, Past-President and Hon. M. Am. Soc. C. E., *Journal*, Boston Soc. of Civ. Engrs., November, 1916, p. 477.

until the time of his death. In 1895, he was appointed Consulting Engineer for the Massachusetts Board of Railroad Commissioners on various problems connected with the construction of the Boston Elevated Railway, the appraisal of railroad and street railway properties, and other matters of a like nature, continuing to act as such for practically the remainder of his life. He was active on many important commissions appointed by the Courts, as provided by statute, for the abolition of grade crossings throughout Massachusetts, and was engaged by the Fitchburg Railroad Company in a consulting capacity, making annual inspections of the property. He also advised its officers with reference to maintenance and needed improvements.

Mr. Turner was a member of the Institute of Consulting Engineers and of the Boston Society of Civil Engineers which he joined in 1874.

He was a man of wide experience, of well-balanced judgment, and of unlimited information on transportation matters. His knowledge of European as well as American practice may be accounted for by his annual trips abroad for study, observation, and recreation during a period of nearly twenty-five years.

Mr. Turner was of a reserved nature, undemonstrative, and slightly diffident. He was a strict disciplinarian, with himself, as well as with others, and an individual of decided and definite ideas. He was well read in a wide variety of subjects and a great lover of art and music and of all that was beautiful in Nature.

He was held in high esteem by members of the Legal Profession with whom he frequently had occasion to work. Many of his personal qualities made him an excellent witness and during his professional career he often appeared before Courts or other legal tribunals. Regarding his less known services, those in other than the engineering field, one of his lawyer friends writes as follows:

"Entirely apart from Mr. Turner's services in the strict lines of his profession, he was much sought after by his friends and others for advice on legal and business matters and on affairs of property interests. His selection as executor of the William C. Todd estate, involving a very considerable sum of money given for educational purposes and as to which there were several legal controversies, is an illustration of how he was regarded by one of the early business men of New England. Those who had occasion to consult him always obtained a sympathetic hearing and definite advice that was always honest and sound, though perhaps not always in accordance with their desires."

Mr. Turner was elected a Member of the American Society of Civil Engineers on November 4, 1891. He also served as a Director of the Society from 1899 to 1901.

## CHARLES AUGUSTUS VAN KEUREN, M. Am. Soc. C. E.[1]

DIED APRIL 21, 1930

Charles Augustus Van Keuren was born in New York, N. Y., on August 23, 1852. In his early years he moved to Jersey City, N. J., where he attended

[1] Memoir prepared from information supplied by N. D. Wortendyke, Assoc. M. Am. Soc. C. E., and on file at the Headquarters of the Society.

the public schools and received his primary education. He then attended Hasbrouck's Institute, in Jersey City, and afterward took a Special Course in Civil Engineering.

In 1873 and during part of 1874, Mr. Van Keuren was employed in the office of John P. Culver, Civil Engineer and Surveyor, of Jersey City, as an Assistant in general surveying and map work. In 1874 and 1875, he served as Rodman in the offices of the New Jersey and New York Railroad Company, and from 1875 to 1880, he was with the Pennsylvania Railroad Company in its Transportation Department. On March 30, 1880, he was appointed Clerk to the Chief Engineer, in the Engineering Bureau of the Board of Public Works of Jersey City; he resigned from this office on June 6, 1881.

From 1881 to 1884, Mr. Van Keuren served as Transitman and Assistant Engineer with the West Shore Railroad Company (Buffalo Division) and assisted in the preliminary survey and location of the line from Buffalo to the Genesee River (about 65 miles). He made the final location, and was in charge of a 9-mile section from Akron, Ohio, west; later, he was placed in charge of an additional 9-mile section. On the completion of the railroad, he was appointed Engineer of Maintenance of Way, with headquarters at Buffalo, N. Y. Subsequently, he was employed as Assistant Engineer with the Erie Railroad Company at Jersey City.

In 1884, Mr. Van Keuren was appointed Assistant Engineer with the Municipality of Jersey City, which position he retained until January, 1898, when he was made Chief Engineer of the same municipality, serving as such until his death. His duties consisted of the superintendence of all classes of municipal work and various improvements.

Mr. Van Keuren was a member of the Masonic Order, a Knights Templar, and a member of the Shrine, the Jersey City Lodge of the Benevolent and Protective Order of Elks, the Holland Society, of New York, the National Water Works Association, and the New Jersey State Board of Professional Engineers and Land Surveyors. He was also Vice-President and Trustee of the New York Bay Cemetery in Jersey City. He is survived by his widow and a son.

Mr. Van Keuren was elected a Member of the American Society of Civil Engineers on May 3, 1905.

---

## ROBERT LAWRENCE VAN SANT, M. Am. Soc. C. E.[1]

---

DIED APRIL 4, 1930

---

Robert Lawrence Van Sant was born in Jefferson County, Virginia, on February 11, 1853.

Mr. Van Sant's engineering service was begun in 1870 as Rodman in the Engineer Corps on the Hannibal and Central Missouri Railroad. In 1871, he was engaged as Assistant Engineer on surveys and construction for the Sny Island Levee in Illinois. From 1873 to 1875, he was employed on railroad surveys and also conducted a general practice in Missouri, Kansas, and

[1] Memoir prepared from information on file at the Headquarters of the Society.

Colorado. The following year he acted as Assistant Engineer on the Union Depot Extension of the St. Louis, Kansas City, and Northern Railway from St. Louis to Ferguson, Mo.

In 1876, Mr. Van Sant again entered private practice in Missouri, Kansas, and Illinois, and at the expiration of a two-year period he was appointed Chief Engineer for the Memphis, Kansas, and Colorado Railroad Company, on location and construction. In 1879, he was employed as Assistant Engineer for the St. Louis and San Francisco Railroad Company. In this capacity he was in charge of location and construction in Kansas, Missouri, and Arkansas, as well as of a survey through Indian Territory, between Fort Smith and Paris, Ark. In 1884, he made surveys in Missouri and Illinois and was engaged on a contract for repairing the Memphis and Little Rock Railroad between Forrest City and Memphis, Tenn., which had been severely washed away in the floods of 1882, 1883, and 1884.

During this period he was located in Memphis where he was also engaged in general engineering and contract work. His several engagements during successive years were as follows: Construction of about 30 miles of the St. Louis, Troy, and Easton Railway, a coal road in Illinois; 1886, contracting and bridge building on an extension of the St. Louis, Peoria, and Northern Railroad, in Illinois, in partnership with Mr. R. P. Lutes; the rebuilding of the Howe truss span for the Atchison, Topeka, and Santa Fé Railroad Company, in Kansas; 1887, Chief Engineer, the St. Louis, Arkansas, and Texas Railroad (Cotton Belt), changing the gauge from 3 ft. to 4 ft. 8½ in.; 1892 to 1904, Contractor engaged on river-protection work in the Middle West for the Wabash and Santa Fé Railroad Companies; and 1904 to 1909, engaged in private practice as a Contractor, with an office in St. Louis. This period marks Mr. Van Sant's actual retirement from active business.

He was a bachelor, and after his retirement lived a quiet and secluded life in St. Louis, until his death on April 4, 1930.

Mr. Van Sant was elected a Member of the American Society of Civil Engineers on September 3, 1884.

## HARRY LEE VAN ZILE, M. Am. Soc. C. E.[1]

DIED JANUARY 6, 1931

Harry Lee Van Zile was born at Troy, N. Y., on September 20, 1864, the second son of Oscar Edward and Sarah (Perry) Van Zile. As a boy, he exhibited marked ability in mathematics and entered the Rensselaer Polytechnic Institute at a comparatively early age. The combination of insight and industry that had enabled him to stand well in his elementary schools made his career at the Institute notably successful and obtained for him, after he had received the degree of Civil Engineer, the position of Assistant to the Director of the Institute and Instructor in Surveying and Map-Drawing.

In 1885, his father, Oscar E. Van Zile, had founded a Company, with a plant at Albany, N. Y., to manufacture water-tube boilers and small iron and

[1] Memoir prepared from information on file at the Headquarters of the Society.

steel bridges. This concern eventually became the Franklin Boiler Works Company. On the death of his father, Harry Lee Van Zile took up his residence in New York, N. Y., and established the Van Zile Ventilating Corporation, the output of which consisted of an air-deflecting apparatus which he had invented and patented.

Mr. Van Zile, in 1914, had reached middle age without suspecting that there was to come to him a clarion call for participation in the first world-wide war in which mankind had as yet indulged. When the United States entered the conflict in 1917, it became immediately apparent that the Government was in great need of constructing engineers technically equipped to overcome the stupendous obstacles confronting them, and physically fitted to endure the hardships that service of this nature engendered. That President Wilson was fully justified, at this crisis, in conferring upon Mr. Van Zile the rank of Major of Engineers subsequent events proved. The more spectacular features of a great war are bound to overshadow the achievements of those whose devotion and technical skill make it possible for an army to function at the front as a fighting force. However, future historians, it may safely be predicted, will be inclined to give high praise to the Engineering Department of the American Expeditionary Force for what it accomplished, against almost insuperable difficulties, in rendering 2 000 000 comparatively untrained American combatants eventually effective as decisive factors in the final battles of the first World War.

In this memoir only a general outline can be given of the activities in which Major Van Zile, with headquarters at Tours, France, was engaged during those crucial months in 1917 and 1918, when Yankee ingenuity performed the miracle of transferring an army of fighting men across 3 000 miles of water, beneath which lurked enemy submarines, with the loss of only a few combatants. "The Historical Report of the Chief Engineer", published by the United States Government in 1919, makes repeated references to Major Van Zile's distinguished services as a constructing engineer at Tours. His task is described as "technical supervision of the construction of oil-storage facilities and of various plants." Refrigeration plants and electrical and mechanical installations came under his supervision. Regarding one feature of the gigantic operations devolving upon Major Van Zile at that crucial juncture, the official report states:

"In the formation of the division of construction and forestry, which succeeded to the work of the chief engineer, line of communications, all engineering, both design, supervision and construction in connection with electric power, was allotted to an electrical-mechanical section which had been consolidated with other sections into the plant construction division under Major Van Zile."

These quotations from the Chief Engineer's official report, a publication that will be of inestimable value to future historians, give merely a hint as to the varied, exacting, and supremely important activities in which Major Van Zile was engaged during the two years of his war service in France. That his energy, ability, enthusiasm, and technical skill were of very real service to the cause of the Allies was a fact recognized officially by both the Govern-

ment of the United States and that of France. In 1919, the latter country conferred upon him the "Palmes d'Officier de l'Instruction Publique et des Beaux Arts."

Major Van Zile was a member of the Engineers Club of New York. Although he was a bachelor, he was not especially devoted to club life. He had the faculty of making and keeping friends, but was not what is somewhat loosely called "a good mixer." He was absorbed in the technical problems that confronted him both as an inventor and manufacturer, but was inclined, in his hours of leisure, to broaden his mind by omnivorous general reading, displaying always a special fondness for books dealing with historical and biographical subjects. He was also greatly interested in the recent scientific generalizations by which Einstein, Jeans, Eddinger, Millikan, and others have awakened the interest of the public at large in problems and mysteries that have come within the purview of contemporary commentators on recent scientific progress.

Such in its simple outlines is the story of a life that was justified by unselfish and worthy achievement. In this connection it would be unfair to the memory of Harry Lee Van Zile not to stress the kindly, sympathetic, and self-sacrificing qualities that endeared him to all who had the privilege of knowing him intimately. Following his death on January 8, 1931, one who knew him well paid to him a tribute in verse, the last stanza of which may well be quoted here in connection with the foregoing:

"His soul was as the souls of humans are
Whose minds obey the promptings of the heart.
He passed anon to seek a beckoning star—
Who loves his kind pursues God's greatest art!"

Mr. Van Zile was elected a Junior of the American Society of Civil Engineers on January 6, 1886, and a Member on October 8, 1918.

## EDWARD FRANKLIN VINCENT, M. Am. Soc. C. E.[1]

DIED DECEMBER 29, 1923

Edward Franklin Vincent, the son of Charles Floyd and Hannah (Reynor) Vincent, was born at the farm home near Maquoketa, Jackson County, Iowa, on July 11, 1863. In 1869, his parents moved to Mason City, Iowa, where his father, a Civil Engineer, held the office of County Surveyor for Cerro Gordo County from 1870 to 1888. Having acquired an early education in the public schools and having been graduated from the Mason City High School in 1880, Mr. Vincent entered the Iowa State University, from which he received the degree of Civil Engineer in 1884.

After teaching two years in the Mason City schools, he began his professional career in the spring of 1886 when he was employed by the Union Pacific Railroad Company in Wyoming. In the fall of 1887 Mr. Vincent accepted a position as Engineer for the contractor engaged in constructing

[1] Memoir prepared by a Committee of the Colorado Section, consisting of R. C. Gowdy, Arthur O. Ridgway, and the late Herbert L. Aulls, Members, Am. Soc. C. E.

the State Capitol Building at Denver, Colo., and continued in that capacity until 1889, when he again began a short period of service with the Union Pacific Railroad Company on surveys in Utah, Wyoming, California, and Nevada. At the close of this period he was placed in charge of a field party for the United States Geological Survey on the head-waters of the Arkansas River, near Leadville, Colo.

During the decade from 1889 to 1900, Mr. Vincent served the City of Denver in the capacity of Engineer on public improvement work, and for six years of this period he was Principal Assistant Engineer for the Board of Public Works. From 1900 to 1904, he occupied the position of Resident Engineer for the Fort Worth and Denver City Railway Company, and during this time he made his home in Fort Worth, Tex. In 1904, he was Assistant Chief Engineer for the Wyoming State Railway Company which was subsequently absorbed by the Chicago and Northwestern Railway Company. Later in 1904 he was Assistant Engineer on location for the Missouri Pacific Railway, and afterward had charge of the drafting forces of that Company in St. Louis, Mo. He returned to Colorado in 1906 as Assistant Chief Engineer of the Colorado and Southern Railway Company with headquarters in Denver, where he also made his home. In 1915, he succeeded the late Herbert W. Cowan, M. Am. Soc. C. E., as Chief Engineer of this Company, in which position he remained until March 1, 1919, when he was assigned to special engineering duties with the title of Special Engineer.

Eminently well fitted by years of experience with its pertinent characteristics, as Chief Engineer and Special Engineer of the Colorado and Southern Railroad Company, Mr. Vincent gave unstintingly of his best efforts to its welfare. After years of hard work in the discharge of his exacting duties and with few if any vacations, he was persuaded during the holidays at the close of 1923 to avail himself of a few weeks' rest and recreation in Florida. It was while on his journey there that illness overtook him, his death occurring December 29, 1923, at Jacksonville, Fla. His remains were returned to and interred at his home town, Mason City.

Mr. Vincent's outstanding characteristics were conscientious devotion to his chosen profession, and his thorough and painstaking care, even to the minutest detail, in all his engineering accomplishments. As a Mason he was a member of Oriental Lodge No. 87, A. F. and A. M. He received the Royal Master Degree, Denver Council No. 1, R. S. M., February 28, 1916, was greeted as a Select Master on the same date, and was chosen as a Super-Excellent Master, May 22, 1916. He was one of the earliest members of the Colorado Society of Engineers, and was also a member of the Colorado Engineering Council during the period 1916-1921, representing thereon the Colorado Section of the Society, of which Section he served as President for one term.

He was married June 1, 1892, at Mason City to Myrtie Ann Gregory, who, with a son, Gregory A., survives him.

Mr. Vincent was elected a Member of the American Society of Civil Engineers on August 31, 1909.

## ALBERT LOWRY WEBSTER, M. Am. Soc. C. E.[1]

DIED MARCH 24, 1930

Albert Lowry Webster was born in Orange, N. J., on August 3, 1859. His father was Benjamin Crampton Webster, President of the Lehigh Zinc Company, in Bethlehem, Pa., and also of John Jewett and Sons until this firm was merged with the National Lead Company of New York, N. Y. He had acted as Private Secretary to Governor Morgan of New York State during a part of the Civil War. His mother was Eliza Campbell (Wilbur) Webster, the daughter of Marcus and Catharine (Campbell) Wilbur, of Orange.

During his early youth Mr. Webster attended the Moravian School in Bethlehem. He received his preparatory education at Holbrook's Military Academy (the Briarcliffe School), at Ossining, N. Y., from which he entered the Sheffield Scientific School of Yale University. He was graduated from Yale in 1879, with the degree of Bachelor of Philosophy, receiving honorable mention for excellence in physics and the unusual merit of his thesis. In 1892, he received the degree of Civil Engineer. Mr. Webster subsequently enrolled as a graduate student at Yale, at the same time acting as Assistant Instructor in Surveying and Drawing. He was a member of Alpha Chi and Berzelius Fraternities.

From 1881 to 1884, he was connected with the United States Geological Survey as an Assistant Topographer in Utah, New Mexico, and Nevada; from 1884 to 1885 he was a Fellow by courtesy at the Johns Hopkins University, at Baltimore, Md., and from 1885 to 1886, he was engaged chiefly in the office of W. H. Lindley, Consulting Engineer, and Stadtbaurat, at Frankfurt-am-Main, Germany, acting as an Associate in the design of the sewage disposal plant and water-works of that city. During this time, Mr. Webster also designed the famous water tower in Warsaw, Poland.

In 1887 he returned to New York, where he opened an office for the private practice of his profession, engaging in consulting civil and sanitary engineering work which he continued until his retirement in 1926. During this period he also served in the following capacities: From 1888 to 1889, Expert Sanitary Engineer for the Department of Public Works of the City of New York; 1897, on the Board of Organizers of the Tenement House Department; 1901, expert for the Tenement House Commission, and, subsequently, Consulting Engineer for the Property Owners' Committee in the matter of the slide in the Park Avenue Subway Tunnel, for the construction of the water main and sewers in the extension of Riverside Drive, and for many New York buildings, including the Grand Central Terminal; the New York County Courthouse; the Postal Telegraph Building; the Bellevue Hospital group; the Public Library; the Woolworth, Municipal, and Equitable Buildings; Barnard College; the Brooklyn Young Men's Christian Association; Mount Sinai Hospital; and the New York Infirmary for Women and Children. Later, he served as Consulting Expert in connection with various projects

[1] Memoir prepared with the assistance of Prof. Duane Reed Stuart, Princeton, N. J., and from data on file at the Headquarters of the Society.

elsewhere in the country, such as the construction of the sewerage plant at Hampton Institute, Hampton, Va., the Esmeralda Water Company, at Goldfield, Nev., the Carnegie Building, and the Carnegie Institute, at Pittsburgh, Pa.

Incidentally, from 1893 to 1894, Mr. Webster was a Special Student in Architecture at Columbia University, and, from 1900 to 1901, Lecturer in Sanitary Science at the Cornell Medical School in New York. About this time, he also directed the design and construction of the sea-wall for the Westchester County Land Association, as well as systems of water supply, sewage disposal, sewerage, drainage, under-drainage, and plumbing for institutions, private properties, and similar structures.

Mr. Webster was a member of the American Public Health Association, the American Association for the Advancement of Science, the Philosophical Society of Washington, the Franklin Institute, the Century Association, and the Yale Club of New York. During the World War, he served as Chairman of the Committee on Drinking Water for the Sanitary Committee of the Council of National Defense. From 1917 to 1920, and from 1922 until 1924, he was a member of the Executive Committee of the Yale Engineering Association. He was also a member of a Sub-Committee on Plumbing of the Building Code Committee for the United States, which was appointed in 1921 by President Hoover, then Secretary of Commerce.

He was the author of various reports and monographs for the United States Geological Survey, as well as "Principles of Modern Plumbing Practice" (1901), and "Caleb and the Friendly Animals", a collection of children's stories, with illustrations by himself, published in 1928. He also contributed articles on technical sanitary subjects to various scientific periodicals.

Mr. Webster's death occurred on March 24, 1930, from angina pectoris, and he was buried in Rosedale Cemetery, at Orange, N. J.

On June 1, 1897, he was married in New York City to Mary Say, a daughter of Cyrus Jay Lawrence and Emily Amelia (Hoe) Lawrence. Mrs. Webster, together with two children, Benjamin Lawrence and Aileen Webster, survives him.

Mr. Webster was elected a Junior of the American Society of Civil Engineers on September 6, 1882; an Associate Member on June 3, 1891; and a Member on April 6, 1909.

## JAMES EDWARD WHITFIELD, M. Am. Soc. C. E.[1]

DIED NOVEMBER 4, 1930

James Edward Whitfield was born in Albany, N. Y., on September 27, 1859, the son of Robert P. Whitfield, a well-known geologist and paleontologist, who was for many years Curator of the Department of Geology of the American Museum of Natural History, in New York, N. Y. Mr. Whitfield's education was received at the Rensselaer Polytechnic Institute, Troy, N. Y.

[1] Memoir prepared by Frederick Wynkoop, Esq., Philadelphia, Pa.

From 1880 to 1888 he was connected with the United States Geological Survey, under A. A. Blair, at Newport, R. I., and with Rafael Pompelli in the Northern Transcontinental Survey for the Northern Pacific Railroad, after which he went to Washington, D. C., deserting the field of engineering for that of chemistry. He analyzed many of the new minerals found in the West and numerous analyses by him were published in the Survey reports and copied by James Dwight Dana in his "System of Mineralogy". Mr. Whitfield was considered an authority on the analysis of meteorites, and made many of the analyses for Dr. George P. Merrill, of the Smithsonian Institution, Washington, in his great work on meteorites. While in Washington Mr. Whitfield became Professor of Chemistry in the National College of Pharmacy from which institution he was granted the degree of Doctor of Philosophy.

In 1888 he became a partner in the firm of Booth, Garrett and Blair, Analytical and Consulting Chemists, Philadelphia, Pa., of which firm he was Senior Partner at the time of his death. While with this firm he gained considerable reputation in metallurgical analysis and the investigation of mining and cement properties throughout the United States.

On December 25, 1885, Mr. Whitfield was married to Florence P. Morton, who died in 1928. They had no children. He left the income from his estate to a favorite sister-in-law, upon whose death the principal goes to the American Philosophical Society, Philadelphia, in which he took great interest. He was also a member of the American Chemical Society, the Franklin Institute, and the American Association for the Advancement of Science.

He had not been well since the death of Mrs. Whitfield; his death, however, was a great shock to all his friends and associates. He was a great fisherman, spending a number of weeks every winter in tarpon fishing in Florida. His unfailing good nature and geniality to all with whom he came in contact will cause him to be missed greatly by those who were privileged to know him.

Mr. Whitfield was elected a Member of the American Society of Civil Engineers on March 2, 1904.

## FRANK CLINTON WIGHT, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 18, 1927

Engineer and journalist of rare ability, Frank C. Wight, Editor-in-Chief of *Engineering News-Record*, died on September 18, 1927, at the age of 45 years, when he had only just entered upon a career of wide and influential service to the profession. His qualities of mind and spirit, his prodigious capacity for work, as well as his character as a man, all promised that he should become one of the notable figures of the Civil Engineering Profession in his generation.

[1] Memoir prepared by F. E. Schmitt and Willard T. Chevalier, Members, Am. Soc. C. E.

The story of his career is soon told, for nearly the whole period of his manhood was devoted to the paper he served and revered. Nor can that story portray his individuality and powers. These live in the memories of his friends as his true memorial.

Born in Washington, D. C., on February 26, 1882, Frank Clinton Wight received his technical education at Cornell University (1904), and then entered the Bridge Department of the District of Columbia, under Walter J. Douglas, M. Am. Soc. C. E. A large bridge program was then in execution, and work on both steel and concrete structures, notably the Piney Branch, Anacostia, and Connecticut Avenue Bridges, gave Mr. Wight a firm grounding in the practical side of engineering methods. Even at that time his work revealed clearly that he would rise to prominence in whatever field of engineering he might enter.

After less than three years came an opportunity to join the Editorial Staff of *Engineering News*, then under the able direction of the late Charles Whiting Baker. In the new activity Mr. Wight's work won instant approbation from his superiors and colleagues, not only because of the technical and journalistic abilities that it revealed, but even more because of his skill in planning and administration. It was this latter quality that led to his being appointed Managing Editor in 1913, when the growth of the paper compelled Mr. Baker to relinquish part of his duties. Mr. Wight met the increased responsibilities even more capably than had been expected, and because of his great working capacity he managed, not merely to direct the business of the paper with high efficiency, but also to continue his technical work undiminished.

In 1917 the consolidation of *Engineering News* with *The Engineering Record* to form *Engineering News-Record* brought E. J. Mehren, M. Am. Soc. C. E., to the editorship of the new paper. Four years later, however, the new Editor enlisted Mr. Wight's administrative skill by placing him in operating charge as Managing Editor. In 1923, when Mr. Mehren was advanced to an executive position, Mr. Wight was the unanimous choice of officers and staff to succeed him as Editor-in-Chief. In this position of leadership he raised the paper to increased strength and influence. His broad technical knowledge and keen insight, his journalistic intuition, and his distinctive personality, were equally effective in the daily tasks of the editorial sanctum, staff and company councils, and outside contacts.

Less than four years were granted him to serve as leader of his paper. Yet in that short time he contributed fundamentally to enhance its strength and to lay a solid foundation for its future progress. In addition, he was active outside the paper, in both technical and journalistic fields. He served on numerous committees of the American Society of Civil Engineers, the American Concrete Institute—the *Proceedings* of which he edited for some years—the New York Editorial Conference, and the National Conference of Business Paper Editors. The two last-named organizations he served as President. He was a member also of Secretary Hoover's Committee on Highway Traffic Safety, and Chairman of the National Fire Protection Association's Committee on Fire Protection of Construction Operations.

Rugged and active, Mr. Wight was none the less of so intense a nervous organization that overwork finally took its toll and in 1927 a threatened nervous collapse compelled him to take several months' rest. With characteristic impatience to be about and doing, he insisted on returning to the Editor's chair before his vitality had been fully re-established. Soon after his return a throat infection took hold of him and within less than a week he had succumbed.

Those who had been longest associated with him voiced appreciation of their friend and leader in a record of personal impressions published within a few days after his death in the paper he had just left. A few brief quotations from this tribute[2] will tell most eloquently of his rank among his fellows:

"An active brain, a penetrating vision and fearless courage are the characteristics of the great editor, and with them must come that undefinable journalistic intuition that goes beyond. Wight possessed all these. In lore and in keenness, in breadth of sympathies and in understanding, he was one of the elect few. In vision he was at once the dreamer of possibilities and the prophet of coming realities. In courage he was supreme.

"Journalism has lost as much as has our paper itself. It is an art that flourishes on the ideals contributed by strong leaders. Wight brought to it unfaltering ideals and a forceful personality; through them he was an inspiration to others. And even farther abroad he was an influence for progress. The larger journalism of public information and opinion was gaining strength from him. That influence was destined to become much stronger, and to help bring back to honor in these hurrying days some of the old-time editorial virtues.

"An engineer of brilliant talents, a champion of all that was constructive, an enemy of debasing tendencies, he was sorely needed by the profession. His influence had to be exercised mainly through the pen. But perhaps never was such influence more valuable than at present, when engineering as a profession is crossing paths with industrial growth and evolution. Wight discerned clearly the new complications then arising, and foresaw the many changes in engineering life which it must bring. He appreciated as well how human conditions and ways are changing as life comes to depend ever more intimately on the engineer's planning. He shared in every movement and effort on which the future of the profession must be erected."

The spirit and substance of the foregoing lines best portray Mr. Wight's great service to civil engineering. He was a virile leader in the work of recreating the Engineering Profession to serve most effectively the new mechanism of industrial and business co-operation. Although by temperament an individualist, he perceived the need for efficiently planned joint effort so clearly that all his endeavors were enlisted in its behalf. Struck down prematurely, his striving to this end had only begun; yet by virtue of his ability to inspire others with his ideals and convictions, his influence will persist for years to come as a potent factor in behalf of sound professional progress.

Mr. Wight was married in 1911 to Julia T. Welles, of New York, N. Y., who, with four children, surives him.

Mr. Wight was elected a Member of the American Society of Civil Engineers on April 3, 1922.

[2] *Engineering News-Record*, September 22, 1927.

## FRANK MARTIN WILLIAMS, M. Am. Soc. C. E.[1]

DIED FEBRUARY 20, 1930

Frank Martin Williams was born on April 11, 1873, in Durhamville, N. Y., the son of William and Ellen L. (Sterling) Williams. He was of Welsh and Mohawk Dutch descent. On his mother's side he was of the fifth generation removed from Henrich Starin, the first Judge of Herkimer County, New York, and an officer in the American Army at the Battle of Oriskany in the Revolutionary War.

Mr. Williams' schooling began in the district school at Durhamville. Afterward, he attended the Oneida, N. Y., High School, from which he was graduated in 1890. In the fall of 1891, he entered Colgate University where he became a member of the Phi Gamma Delta Fraternity. He was graduated from Colgate in 1895 with honors and with membership in Phi Beta Kappa.

After graduation, Mr. Williams accepted employment with the City of Oneida as an Engineer on Highway and Sewer Construction, and spent his spare time in the study of law in the office of the late J. T. Durham in that city. Believing that a full course in law would be of assistance to him in the Engineering Profession, he entered the College of Law at Syracuse University and was graduated with the degree of Bachelor of Laws in 1897, and admitted to the Bar.

In December, 1897, he entered the service of the New York State Engineer and Surveyor as Rodman and remained until April, 1898. In November, 1898, Mr. Williams became Resident Engineer for the Stanwix Engineering Company, of Rome, N. Y., in charge of the construction of water-works and electric light plant at Charlotte, N. Y.

In April, 1900, he again entered the engineering service of the State of New York, advancing, successively, from the grade of Rodman, through that of Leveler and Assistant Engineer to Resident Engineer in charge of maintenance and construction of highways in various counties of the State.

In November, 1908, Mr. Williams was elected State Engineer and Surveyor of New York State, serving a two-year term from January, 1909, to December, 1910, inclusive. During this term as State Engineer and Surveyor, certain canals of the State were in process of improvement, the project being commonly known as "The Barge Canal Improvement." Under his supervision and direction, plans and estimates were prepared and contracts were let for more than $30 000 000 worth of work; and $14 000 000 worth of construction was completed. During 1910 and 1911, Mr. Williams was also Chairman of the Barge Canal Terminal Commission and, in that capacity, in the summer of 1910, inspected the harbors of Europe.

In June, 1911, he became Chief Engineer of the Coleman-du Pont Road, Inc., in charge of surveys, plans, and estimates for the proposed du Pont Boulevard in the State of Delaware. In 1912, Mr. Williams was appointed Chief Engineer of the Portage County Improvement Association, with head-

[1] Memoir prepared by Roy G. Finch, M. Am. Soc. C. E.

quarters at Ravenna, Ohio. This work involved the supervision of an extensive mileage of highway improvement in Eastern Ohio.

In November, 1914, Mr. Williams was again elected to the office of State Engineer and Surveyor in New York and, with three subsequent re-elections, served from January 1, 1915, to December 31, 1922, inclusive. During these eight years, many of the most difficult problems connected with the Barge Canal construction were solved, including the settlement of the railroad-crossing question, and the location, design, and construction of terminals. The entire Barge Canal System was opened for service on May 15, 1918.

From January, 1923, to the date of his death, Mr. Williams was associated with Roy G. Finch and Edward H. Sargent, Members, Am. Soc. C. E., as Consulting Engineer, with offices in Albany, N. Y.

He was a Consultant for the New York State Bridge and Tunnel Commission and the New Jersey Interstate Bridge and Tunnel Commission on the construction of the Holland Vehicular Tunnel under the Hudson River, connecting New York, N. Y. with Jersey City, N. J. He was also Consultant for the Hudson River Regulating District on the construction of the Sacandaga Reservoir; for the Water Service Commission of the City of Oswego, N. Y., on the construction of a hydro-electric development at Dam No. 6, Oswego River; and for various public utility corporations.

Mr. Williams was a member of the American Institute of Consulting Engineers, New York State Society of Professional Engineers, and an Honorary Member of the Albany Society of Engineers.

Colgate University, his Alma Mater, honored him in 1915 with the degree of Doctor of Science, and he was a Trustee of that institution for more than twelve years prior to his death; and, in addition, for three years, he served as President of Colgate University Alumni Association. In 1919, Syracuse University conferred upon him the degree of Master of Civil Engineering. His latest honor came only a short time before his death, when President Hoover appointed him a member of the Interoceanic Canal Board.

In politics, Mr. Williams was a staunch Republican, and his life was marked by clean achievement in that field. His personality and his conduct in office inspired confidence.

He was a member of the First Presbyterian Church, Albany, of the Masonic Order, in Goshen, N. Y., and of the Benevolent and Protective Order of Elks, in Oneida.

In 1907, he was married to Lucy Mary Sterling, of Watkins Glen, N. Y. They had two sons, Frank Martin Williams, Jr., who died in infancy, and David Sterling Williams.

The life of Frank M. Williams comprised a variety of interests, but whatever he attempted he did thoroughly. He was probably best known as the New York State Engineer and Surveyor who was elected to that office five times and during whose administration the greater part of the Barge Canal Improvement was planned, constructed, and completed.

His life has been well outlined and epitomized by one whose acquaintance and friendship covered college days and extended to the time of his death,

Dr. A. W. Risley, Professor of History in the New York State College for Teachers, Albany, who is quoted,[2] as follows:

"As we think of Frank Williams, devoted son of Colgate, we are sure that three qualities jut out boldly. These are common sense, silent fighting purpose, and reliability. Of these, the last was most evident in his entire career. Diligence, more than brilliance. Reliability, not display."

Mr. Williams was elected a Member of the American Society of Civil Engineers on May 28, 1912. He served as Director of the Society from District No. 3 for the term, 1926-1928, and was also a representative from the Society on American Engineering Council.

## WILLIAM FISH WILLIAMS, M. Am. Soc. C. E.[1]

DIED OCTOBER 1, 1929

William Fish Williams, the son of Captain Thomas W. and Eliza Azelia (Griswold) Williams, was born on the whaling ship, *Florida*, in the South Pacific Ocean, somewhere between Tasmania and New Zealand, on January 12, 1859, in a howling gale of wind. The first seven years of his life were passed aboard the various vessels of which his father was Master, accompanied by his mother and a younger sister, who was also born at sea.

He received his early education in the schools of Oakland and San Francisco, Calif. He was graduated from Columbia University, New York, N. Y., in 1881 with the degree of Civil Engineer, and, in 1882, with that of Mining Engineer.

During 1883 Mr. Williams was engaged in examining mines in Colorado, Utah, and California, and the years from 1884 to 1888 were spent in private practice as a Civil Engineer in Connecticut. From 1890 to 1893 he served as Chief Engineer of Cumberland Lands, Limited, in Stewart County, Tennessee, a property of 46 000 acres of farming, timber, and mineral lands. His work during this period included a survey of the entire property, laying out of town sites, and the location of 15 miles of railroad, as well as designs for the mechanical work of the plant.

From 1893 to 1912, he filled the office of City Engineer of New Bedford, Mass., during which time he represented the City as Engineer in supervising the elimination of railroad grade crossings in that municipality. Mr. Williams likewise served as Chief Engineer of the Fairhaven Bridge constructed under his direction at a cost of $1 250 000. The intercepting sewer system was also under his direction for two years after he went to the State House.

In 1912, he was appointed Chief Engineer of the Massachusetts Board of Harbor and Land Commissioners, and, later, as Engineer of Waterways and Public Lands. During this period, Mr. Williams represented the State of Massachusetts in connection with the construction of the Cape Cod Canal.

[2] *Colgate Alumni News*, April, 1930.

[1] Memoir prepared by Charles R. Gow and James W. Rollins, Jr., Members, Am. Soc. C. E.

He also conducted a survey and reported upon the water and power resources of the State.

In 1920, when the Massachusetts Commission of Public Works was created, Mr. Williams was appointed its Bridge Engineer and remained in that capacity until December 6, 1922. At this time he was selected by Governor Cox as Chairman of the Commission, in which capacity he directed all State highway construction, including the operations of the Registry of Motor Vehicles, and, in addition, supervised the administration of all State-owned harbor facilities and such construction as was connected therewith. In this position he assumed responsible charge of an annual expenditure approximating $15 000 000. His administration of this important office was marked by an utter absence of any public criticism and a pronounced improvement in efficiency of operation. He retired from this office on December 25, 1928, having attained the legal age limit of 70 years.

After his retirement from public office Mr. Williams was engaged by the Commonwealth to advise and represent the State in connection with a legislative measure for the abolition of railroad grade crossings. He was similarly employed in a consulting capacity to advise the Commission to Investigate Pollution of Boston Harbor, as well as a commission appointed to report upon the filling in of a portion of Fort Point Channel and South Bay in Boston.

As a public official Mr. Williams was an ideal representative. He was not only an eminent engineer; he possessed to an unusual degree the attribute of sound common sense and, in addition, displayed rare executive ability, which combination resulted in a high standard of efficiency in the conduct of his office. He won the respect and complete confidence of the many State, County, and Municipal officials with whom he had to deal. He was at his best when appearing before the several legislative committees having jurisdiction over matters affecting his Department. So impressed were they with his judgment that he once said, "No bill affecting my Department which I opposed, ever passed the Legislature during my term of office."

Mr. Williams was a man of unusually attractive personality and friendly persuasiveness. Always a thorough gentleman under every circumstance, he was able to meet and overcome trying situations by virtue of his calmness, poise, patience, and understanding of human nature. His logic was as invariably sound and clear as his arguments were convincing. He was uniformly popular alike with superiors, associates, and subordinates. His judgment was exceptionally keen and extended into a wide variety of fields other than that of his chosen profession.

He was a delightful companion, taking always a loving, living interest in his fellow men and maintaining a broad outlook upon life. His early years had been filled with adventure, and his reminiscences of those experiences recited in his customary modest and lucid style invariably captivated his listeners. Mr. Williams numbered among his intimates men from every walk of life, including many of the leading citizens of his State. He was a most welcome guest at the firesides of his host of friends who loved and sought his companionship.

He was a distinguished member of the Engineering Profession for almost fifty years without a single blemish on his record. His keen powers of analysis permitted him to render wise decisions respecting problems with which often he had enjoyed little previous experience. He possessed the rare faculty of developing the facts clearly and of drawing sound conclusions from them. His opinion was widely sought by his fellow engineers because of this unusual gift.

Mr. Williams maintained constantly a rigid standard of professional ethics. He invariably held himself aloof from controversy and endeavored to harmonize conflicting opinions. He steadfastly refused to deviate from the paths of duty as he saw them, even to favor a personal friend. He stood loyally by his superiors whenever put to the test, and no official was ever embarrassed even in the slightest degree by any action or statement of his. He was an inspiration to all who were fortunate enough to be associated with him in his work, and his example might well be emulated by the younger generation of present-day engineers.

He died suddenly on October 1, 1929. His passing leaves a void in the hearts of many who knew him and who had learned to love him for his personal qualities. The estimate of his oldest friend is,

"A noble soul has lived, stamped its mark on the world, and gone, but its record will live, and the love and admiration we have for him will last beyond life's closing day. For more than sixty years I have been his friend and confidant. During that long period we have never had an unpleasant word. I have never known him to have an ignoble thought or do a wrong act. He was loyal, faithful, and true to himself, his friends, and his duty."

Mr. Williams was married to Anna L. Cornor on April 7, 1883. He is survived by two sons, Thomas W. Williams, Assoc. M. Am. Soc. C. E., of New Bedford, and Harold Williams, of Pelham, N. Y., and two daughters, Mrs. F. W. Oesting, Jr., of New Bedford, and Mrs. James M. Buchanan, of Maplewood, N. J. A sister, Mrs. Edgar R. Lewis, of Prosser, Wash., also survives him.

Mr. Williams was elected a Member of the American Society of Civil Engineers on April 4, 1906.

## CARLTON CARPENTER WITT, M. Am. Soc. C. E.[1]

DIED DECEMBER 17, 1930

Carlton Carpenter Witt was born in Indianapolis, Ind., on December 15, 1870, the son of Bennett F. and Lucy (Carpenter) Witt. His father and mother continued to reside in Indianapolis until their death some years ago. Mr. Witt's childhood and youth were spent in that city. He entered Purdue University, Lafayette, Ind., and was graduated therefrom in 1892 with the degree of Bachelor of Science in Mechanical Engineering. Prior to his graduation from Purdue, he had become interested in mechanical engineering work

[1] Memoir prepared by C. H. Spencer, Superv. Engr., Bureau of Valuation, Interstate Commerce Commission, Washington, D. C.

and, in 1895, he entered the service of the Lassig Bridge and Iron Works of Chicago, Ill., serving, successively, as Designer, Draftsman, and Chief Draftsman.

In 1898, Mr. Witt entered the employ of the Chicago and Northwestern Railway Company as Chief Draftsman and, later, as Assistant Engineer on Construction, Bridge Department, and continued in that service until November, 1907.

In 1907, he was appointed Chief Engineer of the Railroad Commission of South Dakota and directed the preparation of a complete valuation of railroads and other utilities in that State. In 1911, he was appointed Chief Engineer of the Public Utilities Commission of Kansas, and performed similar duties with that Commission. The work done by Mr. Witt in connection with the two State Commissions involved the complete appraisal of more than 16 000 miles of railroad, in addition to a large number of electric light, telephone, and gas properties.

Immediately after the enactment by Congress in 1913 of the Transportation Act, requiring a Federal valuation of railroads throughout the United States, Mr. Witt was appointed District Engineer of the Western District for the Bureau of Valuation, Interstate Commerce Commission. He became the immediate Assistant of the Member of the Engineering Board for that District, in charge of field and office work for this stupendous undertaking. In 1919, on the retirement of the latter, Mr. Witt was promoted to the position of Member of the Engineering Board and continued as such until November, 1921.

In 1921, on the completion of the field work, covering approximately 50 000 miles of railroad in the Western District, the five districts of the United States were consolidated, with headquarters in Washington, D. C. Mr. Witt, with a considerable number of his force, was transferred to that city where he assumed the position of Assistant Supervising Engineer of the Bureau of Valuation, charged with the completion of the valuations of all railroads in the United States.

Coming into his new surroundings, he quickly won the regard and esteem of all his fellow employees who soon recognized in him a man thoroughly versed in the problems facing a valuation engineer. His gentlemanly qualities and the spirit of fairness accorded those who came in contact with him, won him a host of friends. Railroad officials quickly recognized his integrity and fair dealing, as well as his sure knowledge and acquaintance with all problems with which he had to deal.

In 1924, on the death of Howard M. Jones, M. Am. Soc. C. E., then Supervising Engineer, Mr. Witt was promoted to that position in entire charge of the engineering work connected with the valuation of 250 000 miles of railroad, the primary valuations of which had been brought to a practical completion just prior to his death.

By Mr. Witt's death, the Interstate Commerce Commission lost one of its ablest and most valued officials, and the Profession an engineer of unexcelled ability, known and esteemed throughout the railroad world.

Mr. Witt was a member of the American Railway Bridge and Building Association, a Director of the Washington Society of Engineers, and a member of the Cosmos Club, in the City of Washington.

He was married on February 10, 1921, to Helen R. Creasey, of Kansas City, Mo., who, with two children by a former wife, survives him.

Mr. Witt was elected a Member of the American Society of Civil Engineers on April 6, 1909.

## MORGAN EDWARD YEATMAN, M. Am. Soc. C. E.[1]

DIED NOVEMBER 17, 1929

Morgan Edward Yeatman was born at East Sheen, Surrey, England, on August 8, 1851, the son of Morgan and Mary C. L. (Penrhyn) Yeatman. He was educated at Marlborough, graduated with honors in Mathematics and Classics at Trinity College, Cambridge, became Wrangler in 1874, and Master of Arts in 1877.

Mr. Yeatman was articled in 1874 to George Fosbery Lyster, Chief Engineer to the Mersey Docks and Harbour Board, and was engaged on extensive new dock and harbor works for that Board, including the preparation of the first plans for the Liverpool Overhead Railway from 1877 to 1881.

He then came to the United States and served until 1884 as Assistant Engineer on the construction of the Pittsburgh, McKeesport, and Youghiogheny Railroad, under the late Jonathan Wainwright, M. Am. Soc. C. E., Chief Engineer. Mr. Yeatman was engaged on the design and construction of many of the bridges on that road.

From 1884 to 1885, he was Principal Assistant Engineer (Maintenance) on the Pittsburgh and Lake Erie Railroad (Lessees of the Pittsburgh, McKeesport, and Youghiogheny Railroad). In 1886, with Mr. Wainwright, he entered into private practice as Consulting and Constructing Engineer, with headquarters in Pittsburgh, Pa. In this capacity he was engaged until 1888 on various bridges and railroads, his experience including bridge detailing for the Keystone Bridge Works and the Iron City Bridge Works (C. J. Schultz and Company).

From 1889 to 1896, Mr. Yeatman was Principal Assistant Engineer, Maintenance of Way, on the Norfolk and Western Railroad, with headquarters at Roanoke, Va., in charge of bridge work on 1 500 miles of line. This work included the renewal of a large number of the older bridges. He compiled the first Standard Bridge Specification for this railroad.

From 1898 to 1908 he was on the staff of S. Pearson and Son, on the design of new bridges for the Tehuantepec National Railroad, in Mexico, and the Arica-La Paz Railway in Chile. He also designed the structural steelwork for the Mexican Ports of Coatzacoalcos and Salina Cruz, including wharves, quay walls, breakwaters, and other harbor works, drainage works, and water supply.

[1] Memoir prepared by S. Alfred Frech, Cons. Civ. Engr., London, S. W. 1, England.

In 1908, Mr. Yeatman began the private practice of engineering in England which practice he continued in Westminster until 1915. He was a Member of the Institution of Civil Engineers. During the World War he gave his services to the Mechanical Warfare Department, and was engaged chiefly in the design of "tanks", until the Armistice was signed in 1918.

In 1888, at Pittsburgh, he was married to Blanche D. Fullerton, and is survived by his widow and three children—two sons, Morgan John, who is Lieutenant-Commander in the Royal Navy, and Edward Stanley; and one daughter, Ellinor (Mrs. C. E. May).

He was a man of many hobbies; he was fond of sailing and was an exceptionally fine musician. By his death, which occurred at his residence at Hill House, Buckingham, on November 17, 1929, after a short illness, at the advanced age of 78 years, the Engineering Profession loses a man of keen intellect, a great mathematician, and bridge expert.

Mr. Yeatman was elected a Member of the American Society of Civil Engineers on May 14, 1892.

## SAMUEL McCAIN YOUNG, M. Am. Soc. C. E.[1]

DIED OCTOBER 28, 1930

Samuel McCain Young, the son of Dr. John W. Young and Mary Louise (McCain) Young, was born in Carroll County, Mississippi, on December 14, 1873. He was graduated from Washington and Lee University in 1898 with the degree of Civil Engineer.

After his graduation Mr. Young's professional career for a time took him into many fields of effort. He was on United States Deep Waterways Surveys in New York State, on flood protection work on the Mississippi River, and on preliminary and location surveys for railroads, serving at different times the Choctaw, Oklahoma, and Gulf, the Chicago, Rock Island, and Pacific, and the New Orleans Great Northern Railway Companies. He constructed water-works and electric light plants, and electric railways. He opened and operated a rock quarry, and had activities in still other branches, including general practice as a Consulting Engineer, and military services as Captain of Engineers during the World War.

His outstanding professional work, however, was in the line of port development. Mr. Young was Chief Engineer of the Board of Commissioners of the Port of New Orleans, La., for two years prior to the war and again occupied that position from 1921 until his death. He displayed infinite ingenuity and ability in coping with the many problems with which he was confronted in this great work, and his part in the development of the Port of New Orleans was such that it entitles him to a place of special honor in the annals of that Port.

Mr. Young always showed a lively interest in civic affairs, and his services were available at any time to aid in community development. He expended

[1] Memoir prepared by J. F. Coleman, Past-President, Am. Soc. C. E., and W. T. Hogg, M. Am. Soc. C. E.

a great deal of time in the study of the traffic and transportation problems of the City of New Orleans, formulating plans for a Union Station layout, and trying to harmonize public opinion thereon. He was an active member of the New Orleans Planning and Zoning Commission, and performed many other duties of value to the city.

Mr. Young was elected an Alumni Member of the Washington and Lee Chapter of Phi Beta Kappa in June, 1930. He was a member of the Delta Tau Delta Fraternity, a Mason, and a Knight Templar. He was also a member and a Past-President of the Louisiana Engineering Society and was always active in its affairs. He was a Past-President of the Louisiana Section of the Society, in which he was much interested.

Mr. Young was a man among men, straightforward, honorable, and true. He was a skillful and accomplished engineer, and a highly efficient executive. All who came in contact with him were impressed with his sincerity and his love for his fellow man, and, in consequence, few men have possessed more friends than he. He was a good son and brother, a good husband, a good friend, a good citizen.

He was married in 1923 to Katherine Harrison, and is survived by his widow, by three sisters, one brother, and by his father who was a distinguished member of Forrest's Cavalry during the Civil War.

Mr. Young was elected an Associate Member of the American Society of Civil Engineers on June 7, 1905, and a Member on September 6, 1910.

## RAYMOND ARDEN EDWARDS, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 13, 1930

Raymond Arden Edwards was born in San Francisco, Calif., on July 30, 1886. His father, Harry B. Edwards, was of English descent, the son of one of the Governors of the Penal Colony of Australia. His mother, Alice (Doud) Edwards, was of Scotch ancestry, the daughter of Aaron Doud, a well-known pioneer of San Francisco, Calif.

Mr. Edwards obtained his early schooling in Los Gatos, Calif. He had not quite finished High School when his father died and at the age of seventeen he was forced to leave school and go to work. He began his business career as a hardware store clerk, but he gave it up after six months and took a position as office boy with the Pacific Mail Steamship Company. His early ambition was to become a civil engineer, and he devoted all his spare time to poring over engineering books. Mr. A. B. Southard, a well-known San Francisco engineer, encouraged and helped Mr. Edwards in his studies. He gave him his start in engineering by employing him as Chainman on the San José and San Francisco Electric Railroad in 1905 and from this position he rapidly advanced to that of Leveler and Transitman.

From July, 1906, to August, 1907, under the direction of Mr. Southard, he was in charge of field work and the construction of a mining flume in the

[1] Memoir prepared by R. W. Olmsted, Assoc. M. Am. Soc. C. E.

Yuba River Canyon, a concrete building, sea walls, a pier, and water supply works at Clear Lake, Calif.

While gaining practical experience in construction, Mr. Edwards, with a determination that was characteristic of everything he undertook, pursued his engineering studies by attending night school. He developed a natural ability to organize and superintend construction projects and from August, 1907, to July, 1912, he had charge of several important works of engineering in Northern California. During this period his list of accomplishments includes sub-division and street improvement work, the construction of a seven-story steel frame and concrete building, highway and dam construction, irrigation works, and a large concrete railroad roundhouse.

The field of irrigation engineering attracted him and in July, 1912, he became Superintendent for the Beard Construction Company on the building of the Goodwin Dam on the Stanislaus River, California. This dam diverts approximately 1 400 cu. ft. per sec. into the canal systems of the South San Joaquin and Oakdale Irrigation Districts, supplying water to about 150 000 acres of valley lands.

In April, 1913, Mr. Edwards was made Chief Engineer of the Modesto Irrigation District, in charge of hydrographic investigations and construction and also of the operation of the extensive canal system delivering water from the Tuolumne River to 83 000 acres of irrigable land. He planned and carried out many important betterments for the irrigation system during his two years as Chief Engineer.

In March, 1915, he joined the United States Reclamation Service as Engineer in charge of field investigations for the preliminary report on the Lower Pitt River Irrigation Project, in California.

In January, 1916, Mr. Edwards became Supervising Engineer for the Foster and Kleiser Company, Outdoor Advertisers, with headquarters in San Francisco. He pioneered in a field that has since attracted a large number of civil engineers. He was responsible for many of the improvements that were made in the outdoor advertising industry, and instrumental in the standardization of this medium throughout the United States.

In July, 1919, he was appointed to be Southern California Manager of the Foster and Kleiser Company, and, under his able direction, the business in this section grew to large proportions and reached a high state of perfection. His executive ability and advanced ideas brought him further recognition and, in July, 1923, he was called to the Main Office in San Francisco to create and manage a Statistical and Research Department; and in July, 1928, he became San Francisco Branch Manager, a position he held at the time of his death.

Mr. Edwards was a very public spirited citizen. He never hesitated to give his time and energy to civic affairs. He was a member of the Planning Commission in San Francisco, a Rotarian, and Secretary of the Club in Los Angeles. He was a Thirty-second Degree Mason, a member of the Young Men's Christian Association Board, and active in Advertising Club work.

His delightful personality and keen sense of humor won for him a host of friends both within and without the profession. He had a keen understand-

ing of human nature. Men who worked under him loved him. He was extremely energetic, almost tireless, and always ready to lend a helping hand to others.

For recreation, Mr. Edwards turned to hunting and fishing. He had a keen liking for the outdoor life and never missed an opportunity to spend a week-end or vacation in the mountains. He had purchased a large tract of mountainous land in Napa County, California, and had built a hunting lodge where he could take his family and friends for outdoor recreation.

Death came to Mr. Edwards very suddenly while at his mountain lodge. A long tramp through the hills on an extremely hot day was too much even for his tremendous strength and healthy constitution, and he died of heat prostration. His passing, in the prime of life, was a great loss and shock to his family and to his many friends.

He was married on April 28, 1912, to Adelaide May Roberts, of San José, Calif., who, with two children, Jane and Harry Wilson, survives him.

Mr. Edwards was elected a Junior of the American Society of Civil Engineers on June 24, 1914, and an Associate Member on November 28, 1916.

## WILLIAM JAMES FULTON, Assoc. M. Am. Soc. C. E.[1]

### Died August 21, 1930

William James Fulton was born on July 13, 1889, at Waddington, N. Y., the son of John and Isabel Fulton. He attended Cornell University at Ithaca, N. Y., from which he was graduated as a Civil Engineer in 1912.

Mr. Fulton's first position after his graduation was with the American Bridge Company, at the Brooklyn, N. Y., Plant, as a Draftsman and Designer on building work. After a year he went to Syracuse, N. Y., where he was employed by the Archbold-Brady Company as Draftsman and Designer on transmission towers. In 1916, he joined the engineering forces of the Sement-Solvay Company, also of Syracuse, as a Designer of buildings, bins, and general structural work.

On June 27, 1917, shortly after the entry of the United States into the World War, Mr. Fulton enlisted in the Army at Fort Slocum, New York. He was soon appointed Corporal in Battery E of the 16th Regiment of Field Artillery at Camp Robinson, Wisconsin, and, in September, was transferred as Sergeant to Fort Oglethorpe, Georgia. He received his commission as Second Lieutenant on December 6, 1917, and was appointed to Company B, 327th Brigade, Tank Corps. On March 9, 1918, he went overseas, where he served with credit and distinction for eleven months. He received his discharge as First Lieutenant on May 19, 1919, at Camp Meade, Maryland.

In October, 1919, Mr. Fulton went with the Montana State Highway Department, at Helena, as Squad Boss in charge of highway design. In a short time he was promoted to the position of Assistant Engineer, with the additional duties of making preliminary inspections, determining grades, alignment, structure type, and location on all highway projects.

[1] Memoir prepared by Fred L. Klein, Esq., San Francisco, Calif.

In October, 1921, he was appointed Designing Engineer with the New Mexico Highway Commission, at Santa Fé. At that time the State was expanding its highway program and Mr. Fulton's executive ability was soon recognized by his superiors. He was given the task of re-organizing and building up the personnel of the drafting-room and had charge of the preparation of all road plans, route maps, and estimates. The State had no bridge engineer, nearly all the bridges being of the standard trestle type. Progress in highway design showed that heavier and more permanent structures were needed, and, in the summer of 1921, Mr. Fulton was promoted to serve as State Bridge Engineer. He was given the task of creating a Bridge Department, and with his characteristic energy he worked night and day, making long trips about the State to inspect bridge sites and to determine the type best suited for the location. He soon built up a smooth-running organization which testified to his ability.

He left Santa Fé in July, 1924, and engaged in private practice, specializing in highways, bridges, and grade separations.

In June, 1926, Mr. Fulton was appointed Bridge and Office Engineer for Caddo Parish, at Shreveport, La., having charge of all highway and bridge projects.

His untimely end, at the hands of a disgruntled draftsman, whom it had been necessary to discharge a month previously, cut short a career which promised great success in the engineering field. He had a high sense of responsibility and devotion to duty. He was energetic, resourceful, and had a marked degree of initiative, and all work which was entrusted to him was carried out with painstaking care. He was devoted to his family and left a place in their hearts which will never be filled.

On October 4, 1921, Mr. Fulton was married to Ann Kanthack, of Bluffton, Minn. He is survived by his widow; a son, Billy; his father, John Fulton; and two sisters, Edith, of Waddington, and Mrs. R. E. Taylor, of Fortuna, N. Dak.

Mr. Fulton was elected an Associate Member of the American Society of Civil Engineers on April 7, 1924.

---

## ARTHUR BATES GOODWIN, Assoc. M. Am. Soc. C. E.[1]

---

DIED SEPTEMBER 21, 1930

---

Arthur Bates Goodwin was born in New York, N. Y., on August 10, 1884, the son of Robert and Ella (Bates) Goodwin. He received his education at the Dobbs Ferry, N. Y., Preparatory School, and at Columbia University, New York City.

In 1905, Mr. Goodwin entered the employ of the Board of Water Supply of the City of New York in connection with the construction of the City's waterworks.

[1] Memoir prepared by Harry W. Levy, Prin. Asst. Engr., Office of Commr. of Public Works, Borough of Manhattan, New York, N. Y.

From 1907 to the date of his death he was with the Department of Public Works, Borough of Manhattan, New York City, where he advanced along engineering lines through industriousness and capability to the position of responsibility which he occupied at the time of his death. For many years, Mr. Goodwin had responsible charge of the repair gangs in the maintenance of the streets of the Borough of Manhattan.

In 1929, he was assigned as Engineer in the field to supervise and control the work of paving, repaving, and regulating streets, he also was in charge of the construction of new sewers, and the reconstruction and alteration of old ones.

When the United States entered the World War, Mr. Goodwin was among the first to volunteer his services. His war record is as follows: He accepted an appointment as First Lieutenant, Engineer Officers Reserve Corps, in July, 1917, and was assigned to active service at the Engineer Training Camp, American University, Washington, D. C., where he was placed on duty with the 305th Engineers. He was then transferred to Washington Barracks, Washington, D. C., where he organized the 464th Engineers' Pontoon Train, and was promoted to the rank of Captain. He left the United States with his organization in July, 1918, and arrived in France on August 4, 1918. He was ordered to Jaulgonne (Aisne) for the purpose of salvaging all German pontoon equipage found in the valley of the Marne River in that area. Subsequently, he served in the St. Mihiel and Meuse-Argonne offensives, returning to the United States in April, 1919; he was honorably discharged on June 17, 1919. He accepted a commission as Captain, Engineer Officers' Reserve Corps, on November 20, 1919, and later was promoted to the rank of Major, which he held at the time of his death.

The passing of Major Goodwin is a distinct loss to the Office of the Borough President of Manhattan. He was a capable and efficient worker, and possessed courage and vision to "see a thing through". One of his last acts was the supervision of the repaving of Fifth Avenue from 42d to 23d Streets (one of the most prominent and heavily traveled thoroughfares in the Borough of Manhattan). He received special commendation for the manner in which this work was conducted, not only from his superiors in office, but from civic associations and the general public as well.

Taken ill with appendicitis, an operation revealed the fact that the appendix had been ruptured, with the result that Major Goodwin died from peritonitis on September 21, 1930. He was buried with full military honors in Sleepy Hollow Cemetery, at Tarrytown, N. Y. He is survived by his widow, Louise Du Pre Goodwin, his mother, Mrs. Ella B. Goodwin, and his sister, Mrs. Robert Curry.

At the time of his death, Major Goodwin was Past Commander of the President of the Borough of Manhattan Post No. 84, American Legion, which he organized in 1926, and in which he had served as Commander for the first three years of its existence. He was also a member of Westchester Lodge, F. and A. M., and the Supreme Council of the Scottish Rite.

Major Goodwin was elected an Associate Member of the American Society of Civil Engineers on July 6, 1920.

## CHARLES ELLETT HART, Assoc. M. Am. Soc. C. E.[1]

DIED JANUARY 3, 1929

Charles Ellett Hart was born in Bay City, Mich., on June 16, 1888, the son of Charles Matthew and Lottie Elizabeth (Kline) Hart. After completing his elementary training in the Bay City public schools, he attended the University of Michigan, and was graduated from the Engineering Department in 1911. During the summer of 1910 he acted as Draftsman for the American Bridge Company at Ambridge, Pa.

In July, 1911, Mr. Hart entered the employ of the Truscon Steel Company in Detroit, Mich. and his entire professional career was with this Company from that time until his death in January, 1929. Starting in the Drafting-room he advanced through the stages of detailing, checking, estimating, and designing, to the head of the Engineering Department. Later, he was transferred to the Sales Department.

Mr. Hart's career lacked the striking or spectacular accomplishments so often met with by the engineer in outside activities. His was rather one of steady, quiet progress. Personally, he was not the aggressive type—rather modest and retiring, but sincere and dependable and very well liked by those with whom he came in contact.

Mr. Hart was elected an Associate Member of the American Society of Civil Engineers on June 1, 1920.

## ROBERT GRIER HEMPHILL, Assoc. M. Am. Soc. C. E.[2]

DIED JUNE 19, 1930

Robert Grier Hemphill, the second son of the late Gen. Robert R. Hemphill and Eugenia (Taylor) Hemphill, was born on February 6, 1885, at the family residence in Abbeville, S. C.

He attended the graded school at Abbeville and then entered Charleston College from which he was graduated with high honors in 1903 at the age of eighteen. After teaching school for a session at Monroe, Ga., he entered Clemson College with the object of taking a course in Civil Engineering. Failing health, however, forced him to abandon the course before the first year was completed. A period of two years was spent chiefly at Saranac Lake, New York, in efforts to regain his health, and, at its close, he was advised by his physicians to find employment if possible in one of the Rocky Mountain States.

There happened to be at that time a subordinate position open in Colorado under Elwood Mead, M. Am. Soc. C. E., who was then in charge of the "Irrigation Investigations" of the United States Department of Agriculture, and in June, 1906, Mr. Hemphill received the appointment.

[1] Memoir prepared from information on file at the Headquarters of the Society.
[2] Memoir prepared by Samuel Fortier, M. Am. Soc. C. E.

It was at the base of the Rockies that he laid the foundation of that extensive knowledge, which he later acquired, of the intricate relationship of plants to water. The trees of the orchard and the plants of the field became to him members of his household. To some, he gave large quantities of water, to others, small or medium amounts. If one cultural method seemed to be faulty, he tried another, always watching with critical eye and measured results the effect on the plants.

As the years passed, the scope of his work broadened, and larger problems engrossed his attention. Clustering around the old Union Colony which Horace Greeley founded in 1870, amid cacti and jack-rabbits, were to be found the most productive lands of Colorado, the crop returns from which yielded $25 000 000, or more, annually. The wealth derived from these soil products depended almost entirely on one mountain stream—the Cache la Poudre. Mr. Hemphill and his associates undertook to determine how this valuable water supply was diverted or stored, distributed, and used, with a view to the further definition and protection of water rights to individuals and communities, and the betterment of irrigation practice. In Mr. Hemphill's report covering this work, entitled "Irrigation in Northern Colorado", which is a classic of its kind, he traces the water from the time it leaves its rocky canyon through many canals, laterals, and farmers' ditches, until it is transpired by the foliage of plants. Carrying capacities, seepage losses, storage, exchange of water, water rights, distribution, and use, are all considered. No statement is made that is not supported by fact and all is presented in simple, clear, and expressive English.

If Mr. Hemphill had done nothing more than prepare this report he would have been entitled to the plaudits of the rural population of the Rocky Mountain region, but the solution of still larger water problems was demanded. This time it was the South Platte River, of which the Cache la Poudre was but a tributary. What is the return flow of this river, and how can it be made to serve best the interests of farming communities? These were the problems to be solved. Here, again, thousands of water measurements had to be made, the results compiled, and a report prepared by Mr. Hemphill's superior, Ralph L. Parshall, Assoc. M. Am. Soc. C. E.

With the completion of this and other irrigation investigations in Colorado, Mr. Hemphill's duties and responsibilities were enlarged by receiving an appointment on July 1, 1920, as Resident Irrigation Engineer for Western Texas. In this new field, with its different climatic and plant conditions, he was obliged to study once more the water requirement of plants, and, with this knowledge as a nucleus, to extend the activities of his Bureau to streams, pumping plants, irrigation systems, irrigation requirements, and the welfare of farming communities in general.

From 1925 his major work had consisted in a study of river silt in Texas streams and its relation to the life of reservoirs.

From 1907 to 1925, it was the privilege of the writer to help plan Mr. Hemphill's work, direct its operation, and supervise the results. In this long association the writer early learned to place implicit confidence in his honesty, ability, and painstaking efforts. If working eight hours a day did not suffice, ten or twelve hours would be devoted to the task, and when it was completed

reliance could be placed on the facts submitted. These qualities of industry, perseverance, and accuracy, combined with a cheerful disposition and reticence to allude to his physical disability, endeared him to all his co-workers.

Mr. Hemphill was married to Jessie Culver, at Canyon City, Colo., on August 3, 1910, but after six years of happy married life, Mrs. Hemphill succumbed to an attack of influenza. They had no children.

Mr. Hemphill was elected an Associate Member of the American Society of Civil Engineers on October 15, 1923. He was also a member of the American Society of Agricultural Engineers.

## EDWARD BAXTER HILL, Assoc. M. Am. Soc. C. E.[1]

DIED APRIL 26, 1930

Edward Baxter Hill was born in Syracuse, N. Y., on August 9, 1890. He was the son of Bella S. and the late William Ryan Hill, M. Am. Soc. C. E., who was serving as a Director of the Society at the time of his death on June 16, 1918.

Edward Baxter Hill received his early education in the public schools of Syracuse and Brooklyn, N. Y. After the family moved to Albany, N. Y., in 1907, he attended the Albany Academy and, later, the Troy Academy. After his graduation from the Troy Academy in 1913, he attended Rensselaer Polytechnic Institute for two years.

He was first employed by the United States Geological Survey as a Rodman in the summer of 1912, and he was re-employed in the same capacity, when not attending school, until 1917. On May 8, 1917, he was appointed a Field Aide, and on June 1, 1919, Junior Topographer. He resigned from the Geological Survey in December of the same year, but was reinstated in the following June. He served in various grades until December 8, 1927, when as Assistant Engineer he was transferred to the United States War Department.

During his employment by the War Department, Mr. Hill had his headquarters at the United States Engineer Office, Rock Island, Ill., where he was engaged in the compilation of maps of the Mississippi River from St. Paul, Minn., to St. Louis, Mo.

His work for the War Department having been completed, Mr. Hill was transferred back to the U. S. Geological Survey on October 26, 1928. After his return to the Survey, he was engaged in map compilation, geodetic computations, and topographic surveys. He was engaged on a topographic survey in Kentucky when he was stricken with the illness that resulted in his death.

Mr. Hill was careful, conscientious, and able in his work as an engineer, to which he devoted himself with persistence and industry. By his fairness, kindness, and generosity, he won the friendship and affection of his associates and of those with whom he came in contact. He was a splendid example of American manhood and his fondness for and devotion to his home and family were notable traits of his character.

[1] Memoir compiled by J. G. Staack, M. Am. Soc. C. E.

In December, 1917, Mr. Hill was married to Leila Hart, of Georgetown, Del., who, with a son, Edward, survives him.

Mr. Hill was elected an Associate Member of the American Society of Civil Engineers on July 6, 1925. He was also a member of the Washington Society of Engineers.

## EDWIN ALLSTON HILL, Assoc. M. Am. Soc. C. E.[1]

DIED OCTOBER 28, 1929

Edwin Allston Hill was born in New York, N. Y., on January 18, 1850, the son of Benjamin Scranton and Elizabeth (Stokes) Jones Hill, who was a lineal descendant of Deputy Governor Jones of the New Haven Colony. He also had two *Mayflower* lines—John Alden and John Howland.

Mr. Hill received the degree of Bachelor of Arts from Yale University in 1875, and the following year was enrolled as a student in the Columbia Law School. His further honorary degrees were, Master of Science and Doctor of Philosophy from George Washington University in 1901 and 1903, respectively, and Master of Arts from Yale in 1902. Mr. Hill was admitted to the New York Bar on May 25, 1878, and to the Connecticut Bar on October 28, 1879, on examination.

In 1877, he was employed with the legal firm of Anderson and Man, in New York, and in the fall of that year went to New Haven, Conn., on legal work for this firm in connection with the real estate of the Boston and Air Line Railway, formerly a Division of the New York, New Haven, and Hartford Railroad. He continued with the Boston and Air Line Railway Company, as Assistant Attorney, Right-of-Way and Claim Agent, and Assistant Superintendent until January, 1883, at which time he became engaged in surveys in Southern Connecticut for the Hartford and Harlem Railroad Company.

From 1885 to 1888 he served as Right-of-Way Agent and Chief Engineer for the Indianapolis, Decatur, and Springfield Railway Company, with headquarters at Indianapolis, Ind.

In the summer of 1888, Mr. Hill became Real Estate Agent and Tax and Insurance Agent for the Cleveland, Cincinnati, Chicago, and St. Louis Railroad Company, and, later, Assistant Engineer, establishing his home at Fernbank, Ohio. From 1893 to 1894 he served as Railway Expert to the banking house of Hatch and Foote, in New York, which firm he represented in Illinois as Assistant Receiver of the Jacksonville-Southeastern Railways System during 1893 and 1894.

In 1894, Mr. Hill returned to New Haven where he remained until December, 1895. He then went to Washington, D. C., as Private Secretary to the Commissioner of Patents, John S. Seymour, and the two following Commissioners, Benjamin Butterworth and Charles H. Duell. On December 3, 1898, he was assigned to duty in the Classification Division, promoted to Third

[1] Memoir compiled from information on file at the Headquarters of the Society.

Assistant Examiner on August 28, 1900, Second Examiner, October 2, 1903, and First Examiner on June 28, 1907. He was admitted to the Bar of the Supreme Court of the District of Columbia on February 14, 1903, and to the Court of Appeals of the District of Columbia on February 24, 1903. He was duly admitted and qualified as an Attorney and Counsellor of the Supreme Court of the United States on May 15, 1911. He was also registered to practice as an Attorney before the United States Patent Office on September 9, 1926. While he was in the Classification Division he designed the system of Indexing Chemical Literature and Patents adopted by the United States Patent Office and, later, by the American Chemical Society.[2]

Concurrently with Mr. Hill's legal work in Washington, he was actively engaged on the faculty of George Washington University. He was Instructor and Assistant Professor of Chemistry for evening classes from 1901 to 1926, at which time he became Professor of Chemistry in both night and day schools until 1929. He was elected Professor Emeritus by the Faculty the morning before he died, but his election was too late to be confirmed by the Board.

Professor Hill was always interested in chemical and microscopical matters, even when engaged in engineering work. He also spent much time in genealogical research, and a list of his published literary papers embraces, not only civil engineering, but genealogy, history, chemistry, and other sciences as well. He was also exceedingly interested in music.

He was a member of the following clubs and organizations: The Western Society of Engineers; the Engineering Societies of Connecticut and Illinois, and the Cincinnati, Ohio, and Washington, D. C., Societies of Engineers; a member of the Board of the Washington Chapter of the American Chemical Society; the American Association for the Advancement of Science; the Postal and Washington Microscopical Societies; the State Societies of Ohio, New York, Connecticut, and Vermont; the Alumni Societies of Yale, Columbia, and George Washington Universities; a member of the Board of the District of Columbia Choral Society; the Patent Office Society; the National Genealogical Society; the Connecticut and District of Columbia Societies of Mayflower Descendants, having served as Historian for the former from 1897 until his death, his last act having been to sign his Thirty-second Report, and Secretary and Charter Member of the latter; Vice-President, Registrar, and member of the Board of the District of Columbia Society of Sons of the American Revolution; a member of the Board of the District of Columbia Society of Colonial Wars; the Order of Washington; the Wyoming Club, Jacksonville, Ill.; the Sangamo Club, Springfield, Ill.; the Home Club, District of Columbia; Delta Kappa Fraternity, at Yale, and Alpha Xi Sigma, at George Washington University; also, a member of the Inaugural Committees at the inaugurations of Presidents McKinley, Roosevelt, Taft, Wilson, and Harding; member of the Standing Committee on Street Decorations, and of various Reception Committees for most of the unveilings of statues, in Washington for the last twenty years.

[2] See Papers 30, 32, 33, and 34; H. R. Doc. No. 1110, 63d Cong., 3d Session, pp. 599 to 618; also, Condon and Patterson's Guide to the Literature of Chemistry, pp. 191–192.

Professor Hill was married on June 18, 1884, at New Haven, to Ida M., the daughter of Alonzo F. Wood, who survives him.

As a tribute to Professor Hill's memory, the following is quoted from the *Parish Bulletin* of All Souls Protestant Episcopal Church, in Washington, of which he was a member:

"A scholar of distinction, unostentatious and simple in his ways, he sang in our choir from its early days with a faithfulness and joy that were an inspiration to minister, choir, and people. The mellowness of his years and the youthfulness of his heart were two of the signs of the reality of his Christian experience. Withdrawn from our immediate vision, we know that the tie that binds us to him and him to us is not broken."

Professor Hill was elected an Associate Member of the American Society of Civil Engineers on May 3, 1893.

## CORNELIUS JOSEPH O'CONNOR, Assoc. M. Am. Soc. C. E.[1]

DIED JANUARY 29, 1929

Cornelius Joseph O'Connor, the youngest of three sons of Cornelius and Alice (Gerarty) O'Connor, was born in New York, N. Y., on January 26, 1876. His early education was obtained in the public schools of his native city, where he also prepared for entrance to the College of the City of New York in which he was enrolled as a student from 1892 to 1896. Subsequently, in 1897, he attended extension courses at Columbia University.

In 1896, following the completion of his studies at the College of the City of New York, Mr. O'Connor entered the engineering service of New York City, and remained in the public service almost without interruption to the time of his death. Starting as Sounder, and then as Axeman, in the Bureau of Street Improvements, he was soon transferred to the Department of Sewers in the Borough of The Bronx. He held, successively, the positions of Rodman, Leveler, Transitman, and Assistant Engineer during the twelve years spent in this Department. His work, during this period, covered both preliminary surveys and supervision of construction of sewerage works in a rapidly growing section of the city.

In July, 1910, Mr. O'Connor was appointed Assistant Engineer with the New York Board of Water Supply. This Board was then engaged on the development of the Catskill Water Supply System, consisting of the construction of reservoirs, aqueducts, and arteries of distribution. Mr. O'Connor was assigned to the City Aqueduct Department which was charged with the construction of the City Tunnel, a deep distribution tunnel, 15 to 11 ft. in diameter, extending under three of the Boroughs of the City. He continued on this work for six years, first as Assistant Section Engineer and, later, as Section Engineer on the northerly portion of the work.

On the completion of the City Tunnel, Mr. O'Connor was transferred to the Reservoir Department of the Board of Water Supply under the supervision of which the development of Schoharie Creek, intended to augment the

[1] Memoir prepared by Roger W. Armstrong and James A. Guttridge, Members, Am. Soc. C. E.

supply from the completed Esopus Creek development, was being started. For somewhat more than a year, he was engaged on riparian surveys on Schoharie Creek. Then, with the commencement of work on the Shandaken Tunnel, an 18-mile aqueduct for the transportation of the waters of Schoharie Creek through the divide to the Esopus water-shed, he was assigned as Senior Section Engineer on its construction, first with the Prattsville Division and, later, with the Allaben Division.

In December, 1921, before the completion of the Shandaken Tunnel, Mr. O'Connor was appointed Division Engineer and assigned to the Southern Division of the Aqueduct Department. This Department had charge of the completion of the steel pipe siphons of the Catskill Aqueduct, of which only one-third of the final installation had been included in the original construction. In this position he supervised the construction of seven siphons consisting of double lines of steel pipes varying from 7 ft. 10 in. to 11 ft. 3 in. in diameter, with concrete envelopes and mortar linings and having an aggregate length of 13 700 ft.

This work was completed in 1926, and Mr. O'Connor then left the Board of Water Supply to accept a position with the Board of Transportation as Adjuster of Claims on subway construction. He remained with this Board for two years reporting directly to the Deputy Chief Engineer.

In 1928, the Board of Water Supply started work on City Tunnel No. 2, a deep distribution tunnel similar to, but larger than, the first. When this project was started, Mr. O'Connor returned to the Board of Water Supply as Division Engineer in charge of the Queens Division. The work of this Division included about 4½ miles of deep pressure tunnel, 17 ft. in diameter, with four distribution shafts and their appurtenant structures. This position he held at the time of his death on January 29, 1929.

Mr. O'Connor was of a genial and sociable disposition and had acquired a large circle of acquaintances and friends. His good nature and pleasing personality, combined with his devotion to duty and fairness in all his dealings, made his business relations extremely pleasant and won for him the confidence and respect of all with whom he had intercourse.

On April 20, 1927, he was married to Ella L. Driscoll, a resident of New York City, and thereafter made his home in Bronxville, N. Y.

Mr. O'Connor was elected a Junior of the American Society of Civil Engineers on March 1, 1904, and an Associate Member on June 5, 1907.

## WALDO JUSTIN BICKLE PORTER, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 6, 1930

Waldo Justin Bickle Porter was born at Crawford, Nebr., on May 9, 1895. His mother, Edith M. Porter, died when he was about four years old, after which time he lived with his grandparents, Mr. and Mrs. James Porter, in Moose Jaw, Saskatchewan, Canada. After graduating from the High School

[1] Memoir prepared from information on file at the Headquarters of the Society.

there, he attended Iowa State College, at Ames, Iowa, from which he was graduated as a Civil Engineer in 1916.

As soon as the United States entered the World War, Mr. Porter went in training at Fort Riley, Kansas, for a commission in the artillery, sailing for France as a Second Lieutenant in Battery C, Eightieth Field Artillery, of the Seventh Division, with which he served until the end of the war.

On his return to the United States, he entered the Department of Public Works of the State of Nebraska; he was employed in this office for about eight years. He was District Engineer with headquarters at Ainsworth, Nebr., when he resigned that position to accept another with the American Paving Corporation of Omaha as Construction Superintendent and Engineer. He had been in charge of that Company's construction work in Iowa, Kansas, Illinois, Oklahoma, Missouri, and Nebraska.

Mr. Porter was living at Plattsmouth, Nebr., at the time of his fatal illness. Three weeks elapsed before he was taken to the hospital in Lincoln, Nebr., where he died from a ruptured appendix on February 6, 1930; he was buried in Wyuka Cemetery on Sunday, February 9.

He has left a place in the hearts of his relatives, friends, and business associates that never can be filled. He was by nature somewhat quiet, reserved, and conservative in manner, but extremely courteous and considerate in his treatment of others. Naturally of a retiring disposition, his ability and personality were known only to those with whom he was associated, but by them he was held in the highest esteem. He was a member of the Masonic Order, and his religious affiliations were with the Baptist Church. He enjoyed his profession fully, and always took a keen delight in any unusual problems, no matter how difficult or tedious.

On May 8, 1926, Mr. Porter was married to Jean Karnes, of Lincoln. He is survived by his widow, his parents, Mr. and Mrs. J. E. Porter, and a brother, George, of Crawford, Nebr., and a sister, Mrs. Caroline Barnes, of March Field, Calif.

Mr. Porter was elected an Associate Member of the American Society of Civil Engineers on December 5, 1927.

## JOSEPH WARREN ROGERS, Assoc. M. Am. Soc. C. E.[1]

DIED NOVEMBER 21, 1930

Joseph Warren Rogers was born on August 29, 1861, at New Brighton, Staten Island, N. Y. His father, also Joseph Warren Rogers, was a member of the New York Stock Exchange, and his mother was Fanny (Edwards) Rogers, who was descended from Jonathan Edwards and from Governor Bradford of the Plymouth Colony. The Rogers family were early settlers in Connecticut, and later generations lived in Huntington, Long Island, and Hyde

[1] Memoir compiled from information supplied by William Hauck, Assoc. M. Am. Soc. C. E., and on file at the Headquarters of the Society.

Park, N. Y. His paternal great-grandfather served in the Revolution as one of the Connecticut Minute Men, and afterward became a famous sea captain.

When Mr. Rogers was an infant, his father bought a country place at Scarborough-on-Hudson, N. Y., and it was the family home for nearly forty years. The boy attended The Holbrook School and was anxious to enter West Point, but his parents disapproved and he prepared for college. He was graduated from the Sheffield Scientific School of Yale University in 1884, with the degree of Bachelor of Philosophy. His deep interest in the Army, however, continued throughout his life.

After his graduation Mr. Rogers was employed on construction by the West Shore Railroad Company, and in office work and inspection by the New York Central Railroad Company, until 1891. From 1891 to 1896 he was with the Cataract Construction Company, Niagara Falls, N. Y., as Assistant to the Resident Engineer in charge of tunnel and wheel-pit construction for a hydro-electric plant. In 1897, he was with the Metropolitan Street Railway Company, of New York, N. Y., as Instrumentman and Computer, and as such was engaged on the construction of an underground trolley system. For the first three months of 1898, he was with the East Jersey Water Company on the layout and construction of the head-race canal and pumping station, at Little Falls, N. J.

During the Spanish-American War Mr. Rogers served as Sergeant with the 12th New York Volunteer Infantry, which was part of the Army of Occupation in Cuba. When his regiment was mustered out of service in April, 1898, he returned to the East Jersey Water Company as Assistant Engineer on the construction of the Great Notch Reservoir. In 1900, he resigned his position with this Company and associated himself with the Pennsylvania Railroad Company in charge of the construction of a part of a new single-track branch line on the Middle Division of the System, including rock cut, masonry for 200-ft., plate girder bridges, timber trestle, culverts, etc. He was also in charge of general field work on an additional two-track road to the main line, from Mill Creek to Mt. Union, Pa. For about ten months he was likewise in charge of line and grade and inspection on the work of doubling the width of a ten-arch masonry bridge, 500 ft. long, on a curve on the main line.

In 1903 Mr. Rogers was employed by the Pittsburgh, Toledo, and Western Railroad Company as Inspector in charge of 1 000 ft. of double-track tunnel. In this position he was responsible for the line and grade, quantity and quality of timber, as well as the excavation and back-filling.

In May, 1904, he left railroad construction work to enter the service of the City of New York. For two years he was in the Borough of Richmond as Leveler and Transitman on the construction of streets and highways. In 1906, he was transferred to the Board of Water Supply, then engaged in developing the Catskill Water System, and was assigned to the Reservoir Department, living first at Brown's Station and, later, at Kingston and West Shokan, N. Y.

Beginning with field work, topographical surveys, and preliminary lines for the Olive Bridge Dam and Dikes, Mr. Rogers served as Instrumentman on the relocation of highways. In 1908, he was promoted to the position of Assistant Engineer, on line and grade of East Dike, and of ditches on swamp drainage.

From 1911 to December, 1914, Mr. Rogers was engaged on the inspection of construction work at Olive Bridge Dam, and in taking measurements by planimeter of the actual capacity of Ashokan Reservoir from detailed topographical sheets. On the completion of this dam in 1914, he was sent to Prattsville, N. Y., in the Schoharie Valley, where his work was the inspection and reporting on boring operations in the Schoharie Valley, in connection with the location of Gilboa Dam and the Shandaken Tunnel. He was also in charge of the construction of a model (half-size) of steps of the proposed Gilboa Dam. In 1920, he was in charge of the relocation of highways surrounding the Schoharie Reservoir. At this time, he moved to Grand Gorge, N. Y.

From 1921 to November, 1924, he was engaged on the construction of Gilboa Dam as Assistant Engineer, as well as on general hydrographic work and preliminary survey for the sewer, at Tannersville, N. Y.

From November, 1924, until his death, Mr. Rogers was Assistant Engineer with the Department of Water Supply, Gas and Electricity in the Borough of The Bronx, New York City. His work was in connection with the maintenance and improvement of the distribution system, including "strip maps" of location. Mr. Rogers died on November 21, 1930, of agranulocytic angina, having been absent from the office only five days.

He was a member of the National Security League, of the Society of American Military Engineers, and of the Protestant Episcopal Church.

He was married on November 29, 1911, to Helen Edwards, of Stockbridge, Mass., who survives him.

His recreation was in vigorous out-door activities. Hunting in the Maine woods was the object of his vacations for years, but his love of Nature took him to the near-by mountains and forests at all seasons. When he was first active in the Catskill Water Supply project, he initiated the young men of the Engineering Corps into the joys of mountain climbing and camping, and of trout fishing in remote mountain streams. Many of these men remember him affectionately as "The Scout".

In 1916, he attended the Citizens Training Camp, at Plattsburg, N. Y., and although he was in his fifty-seventh year when the United States entered the World War, he was greatly disappointed not to be called into service. He did everything in his power to assist the younger engineers in preparing for the Army, establishing a rifle range behind his house in Prattsville, where they practiced after working hours. He supported every phase of Red Cross work undertaken in the village, and his home was a center for its activities. He was given to hospitality and, as a small visitor once said, "He has a good idea of a host!"

The most unassuming of men, he would have been amazed at the love and grief expressed when he died, and at the number of engineers and other friends who came hundreds of miles to pay their last respects.

The following letter was addressed to Mrs. Rogers, by Mr. Rogers' associates in the Department of Water Supply of the City of New York:

"It seems fitting you should know the esteem and affection we in this office, held for Mr. Rogers. He was a gentleman (in the finest sense of the word), always industrious and painstaking with his work. He was known for his fairness and pleasantness towards all with whom he came in contact. We feel that we have lost a valuable asset to this office.

"We, who were associated with Mr. Rogers, wish to sign our names as evidence of our sincerity. We extend to you our sincere sympathy and hope that these few words will help you in your sorrow."

Mr. Rogers was elected an Associate Member of the American Society of Civil Engineers on October 1, 1912.

## NICHOLAS ALEXANDER SCRIPKO, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 21, 1930

Nicholas Alexander Scripko was born at Gorboff, Chernigovsky, Russia, on May 7, 1889. He was graduated from the Polytechnic Institute of Petrograd, Russia, in December, 1915, with the degree of Civil Engineer.

Previous to taking up a University course Mr. Scripko was employed by the Russian Government on the Trans-Siberian Railway at Kainsk, Tomsky, as Levelman and Draftsman. After beginning his engineering studies in the Polytechnic Institute, he was still employed by the Russian Government during the summer months in the Agricultural Department, first as Instrumentman and then as District Engineer in charge of five well-boring, surveying, and construction parties.

In 1915, not long after the commencement of the World War, he became an Ammunition Inspector for the Russian War Department at Petrograd, and a few months later was transferred in the same capacity to the Russian Embassy, at Washington, D. C. His duties were to inspect ammunition that was being made in Canada and the United States for the Russian Government.

After the Revolution in Russia, his services being no longer needed, he became Mechanical Draftsman with the Marlin Rockwell Corporation of Norwich, Conn., and then Masonry Inspector with the Erie Railroad Company, in New York, N. Y.

When the White Army in Eastern Siberia began to resume activities against the Soviet in 1919, Mr. Scripko went to Vladivostock, Siberia, in charge of the Department of Small Arms and Machine Guns in a movable artillery repair shop sent to the White Army by the Russian Embassy in Washington. In 1920, after these military operations had quieted down, Mr. Scripko became Chief Engineer of the Nikolajevsky Colliery Company, in Vladivostock.

In February, 1921, he returned to the United States, and having arrived in Oakland, Calif., took some post-graduate work at the Polytechnic College

[1] Memoir prepared by F. A. Kittredge, M. Am. Soc. C. E.

of Engineering in that city, specializing in structural and concrete design. On the completion of these studies, he entered the United States Reclamation Service, District 2047, Colusa, Calif., as Instrumentman, then Chief of Party, and, subsequently, Assistant Engineer on a $2 000 000 reclamation project.

He then in turn became Assistant City Engineer at Antioch, Calif.; Assistant Engineer with the Sugar Pine Lumber Company, at Fresno, Calif.; Resident Engineer for Hunt Mirk and Company, Incorporated, San Francisco, Calif., in charge of the construction of a power plant for a lumber mill; Inspector for the Western Willite Company, San Francisco, on asphalt pavement work; and, again, Assistant City Engineer at Antioch, in charge of field work on the construction of a reservoir.

In 1926, Mr. Scripko went to Martinez, Calif., as Senior Engineer Structural Draftsman with the Shell Oil Company. In 1927, he became Instrumentman with the California Highway Commission at Redding, Calif.; and, subsequently, Surveyor and Draftsman for the Board of Park Commissioners, San Francisco.

In 1928, he entered the National Park Service, at San Francisco, as Principal Engineering Draftsman, being promoted to Chief Draftsman in 1929, and to Assistant Engineer in January, 1930, which position he held at the time of his sudden death of heart failure in September, 1930.

His work latterly had been in the Sequoia National Park where, as also in the Headquarters Office and among his other numerous friends, his frank, open, and generous nature, and ever-constant cheerfulness in all circumstances made him endeared of all and a companion indeed hard to replace.

Mr. Scripko was a member of the High Sierra Club, the Russian Club, and Golden Gate Lodge of Masons, in San Francisco. In 1926, he was married, at Martinez, to Evelyn Hough, who survives him.

Mr. Scripko was elected an Associate Member of the American Society of Civil Engineers on October 14, 1929.

## WILLIAM LAURIE SEAMAN, Assoc. M. Am. Soc. C. E.[1]

DIED AUGUST 14, 1928

William Laurie Seaman was born at Glen Cove, Long Island, N. Y., on July 26, 1894, the son of William H. Seaman and Margaret (Laurie) Seaman. His ancestors on both sides of the family were among the earliest settlers in the Eastern States and on Long Island, extending back to Capt. John Seaman and Capt. John Underhill, the founders of these families, and on his mother's side to a Scottish great-grandfather. His father's paternal great-grandfather was Elias Hicks, the founder of the Hicksite Branch of the Religious Society of Friends, and William Laurie Seaman was thus born into a Quaker family.

As a boy, Mr. Seaman attended the Friends' Academy, at Locust Valley, Long Island, graduating from there in 1911. He entered Swarthmore College

[1] Memoir prepared by William H. Seaman, Esq., Glen Cove, N. Y.

at Swarthmore, Pa., in the autumn of that year, and was graduated in 1915, with the degree of Bachelor of Arts in Civil Engineering. He had been prominent in many activities during his college course; he belonged to the Phi Kappa Psi Fraternity, and to the Senior Honor Society, the Book and Key; had served as an Athletic Manager and President of the College Young Men's Christian Association; and was the President of his Class at graduation. A very conscientious, thoughtful, and kindly disposition made him greatly respected and beloved by both Faculty and friends, and his college career was a splendid foundation for later life.

Immediately upon leaving college, Mr. Seaman went to work with the Turner Construction Company in New York, N. Y. Between 1915 and 1917, he acted for that Company as Timekeeper, Material Clerk, and Piling Inspector, on construction work in and near New York City, and in South Carolina as Lumber Inspector and Traffic Manager, and, later, as Steel Foreman and Assistant Superintendent.

Mr. Seaman had enlisted in the Signal Reserve Corps of the Aviation Section of the United States Army, and was called in September, 1917, to the Massachusetts Institute of Technology in Boston, Mass., for preliminary training, and then to Texas for flying instruction, where he was commissioned as Second Lieutenant in November, 1917. From there he was sent to Dorr and Carlstrom Fields in Florida, where he acted as Flying Instructor and official Flight Tester, in the Engineering Department, until December, 1918, his commission as First Lieutenant being on its way to him when the Armistice was signed.

At the end of his war service, Mr. Seaman again entered the employ of the Turner Construction Company, as Assistant to the General Superintendent in Philadelphia, Pa. (1919-1921). During his summers, and in all other intervals of employment, he had worked as Transitman, Draftsman, and Chief of Party, etc., with his father, William H. Seaman, Civil Engineer, in Glen Cove. From September, 1921, to March, 1922, he acted as Division Commercial Survey Engineer for the Bell Telephone Company of Pennsylvania, directing and supervising a commercial survey of Philadelphia.

Mr. Seaman left this work to join a college friend in a tour around the world, making economic studies for journalistic and educational purposes. One of his articles, of interest to engineers, and illustrated with his own camera pictures, on the open coal mine in Fushun, South Manchuria, the thickest coal seam in the world, was printed in *Coal Age*, in April, 1923.

On his return to the United States, Mr. Seaman worked with his father until his departure for Australia, in June, 1924, where he was to be married. In the spring of 1925, he went to Sydney and entered into business with Mr. E. W. Bell, Loss Assessor, as head of the Engineering Department. Here, Mr. Seaman spent three very successful years. He was made a partner in Mr. Bell's firm, entering into the life in Sydney with great zest, joining the Automobile Club, the Aero Club, a Ski-ing Club, the American Club, of which he was almost immediately made Secretary and Treasurer, and the Australian Engineers' Club. In the United States, he previously had been a

member of the American Legion, American Flying Club, the Aero Club of America, and the Swarthmore Alumni Association and Men's Club.

Laurie Seaman was always fond of Nature and the out-of-doors and of games, as a recreation. When in Japan, with a party he climbed to the summit of Fujiyama, and during his second winter in Sydney, he joined a few members of his Ski-ing Club, and reached the summit of Mount Kosciusko, in the Australian Alps, although it was his first real experience in mountain climbing on skis. This interest, however, by another year had brought to its close a very promising, intensively lived young life. In the Australian winter of 1928, in August, Mr. Seaman went for a vacation in the snow to Mount Kosciusko. A party went out on skis, and Mr. Seaman and a companion pushed on ahead, making the trip to the summit. On their return, however, they became separated and, in the sudden blizzard which had arisen, both lost their lives. When found, all evidence pointed to the fact that Mr. Seaman had succumbed to exhaustion and sleep, while waiting on the right road for his friend, who had apparently gone far out of the way.

The writer of a memorial[2] speaks of Mr. Seaman thus:

"Of a quiet, retiring disposition, kindly and considerate in his make-up, he was one of Nature's gentlemen. A huge success generally, he possessed a host of friends, who loved him for his sterling worth. Although world travelled, he was not a man of the world, rather a man of the home, a genuine husband and thoughtful father, a stickler for the best things in life. Some fine fellows have departed this world; Laurie, one of them, left it, though still climbing."

Mr. Seaman was married on June 14, 1924, to Christiana Bell, of Sydney, Australia, who survives him, with two sons, Bruce Laurie and Ernest William Laurie.

Mr. Seaman was elected a Junior of the American Society of Civil Engineers on October 14, 1919, and an Associate Member on November 15, 1926.

---

## ERASTUS ROLAND SIMPSON, Assoc. M. Am. Soc. C. E.[1]

---

DIED SEPTEMBER 23, 1930

---

Erastus Roland Simpson was born in Harpswell, Me., on November 29, 1870. He was the son of Erastus C. and Minerva (Trufant) Simpson, and a descendant of William and Agnes L. Simpson who settled at Simpson's Point, in Brunswick, Me., in 1728.

Mr. Simpson entered Brunswick High School in September, 1890. He completed a four-year course in June, 1893, and entered the University of Maine where he was enrolled in the Mechanical Engineering Department. In June, 1896, he was graduated from the University with the degree of Bachelor of Mechanical Engineering. In 1903, he submitted his thesis and received the degree of Mechanical Engineer.

---

[2] "Australian Ski Book," 1929.

[1] Memoir prepared from information on file at the Headquarters of the Society.

Directly following his graduation Mr. Simpson entered the employ of the Hancock Inspirator Company, of Boston, Mass., as a Draftsman on general machine design. After a period of six months with this Company, he resigned to become Assistant Engineer with the Metropolitan Park Commission, in Boston, for which he was engaged in drafting, field work, and as an Assistant Engineer on construction. About a year thereafter, he entered the employ of the Contractors' Plant Company, of Boston, as Head Draftsman on Mechanical Construction.

Subsequent to a year in the service of this Company he went to Georgetown, S. C., where he was employed as Engineer for the Atlantic Coast Lumber Company on mill construction. His work on this engagement was in designing, laying out, and superintending the construction of three mills, two power plants, machine shops, railroad shops, and docks.

Mr. Simpson was then employed by the late Freeman C. Coffin, M. Am. Soc. C. E., Consulting Hydraulic Engineer, of Boston, as an Assistant Engineer in general practice. In March, 1900, he accepted a position as Engineer for the Chapman Double Ball Shafting Bearing Company, of Boston. In this position his work was similar to that of his previous engagements, being mainly in designing and its resulting duties. On May 9, 1903, he went to Toronto, Ont., Canada, as General Manager of the Mechanical Department for this same Company.

In 1912, Mr. Simpson again engaged in the private practice of engineering as an Industrial Engineer, in Boston, with an office at 176 Federal Street, which he retained until his death on September 23, 1930.

Mr. Simpson was a member of the Boston Society of Civil Engineers, the Revere Lodge of Masons, in Boston, and Beta Theta Pi Fraternity. He was unmarried.

Mr. Simpson was elected an Associate Member of the American Society of Civil Engineers on November 4, 1903.

---

## HAROLD DAVID STOLL, Assoc. M. Am. Soc. C. E.[1]

---

DIED JULY 9, 1930

---

Harold David Stoll, the son of Oscar P. Stoll and Alice (DePue) Stoll, was born on January 27, 1890, at Dalton, Pa. His early education was obtained in the public schools in the town of his birth and his technical training by private study and in the International Correspondence Schools of Scranton, Pa.

Mr. Stoll was first employed on the location of the Scranton and Binghamton Electric Railway, maintaining this connection until 1913, when he took a position with the Pennsylvania Department of Highways as Draftsman and Inspector on highway construction. In 1915, he associated himself with a local engineer in private practice in Scranton and vicinity. This work engaged his attention until 1916, when he went to the other end of the State to

[1] Memoir prepared by P. M. Tebbs, M. Am. Soc. C. E.

assist the Jones and Laughlin Steel Company in the development of town and property sites at Woodlawn, Beaver County.

It was just about this time that the Pennsylvania Department of Highways was looking toward the development of the State's roadways on a rather extensive scale. In the northwestern corner of Pennsylvania an engineering district, comprising the Counties of Susquehanna, Wayne, Wyoming, Lackawanna, Pike, and Monroe, was created and, in 1918, Mr. Stoll was made Assistant District Engineer, with headquarters at Scranton, a position he filled so creditably that in 1921 he was made District Engineer. The importance of road construction was manifesting itself more and more each year and successive Legislatures were appropriating increasingly large sums of money for that purpose. It thus came about that Mr. Stoll had no small part in laying the foundation of one of the most important activities in which the Commonwealth has been engaged.

Every section of the State was clamoring to have its main arteries of travel put under a hard surface. It was a time when conscientious and impartial distribution of funds, and loyal service were necessary. Consideration was given to all demands, but early in the program came the development of the Lackawanna Trail, from Stroudsburg north to the Pocono Mountains *via* Scranton, to the New York line near Binghamton. This well-known route through some of the most beautiful scenery in the Eastern United States was one of the outstanding projects upon which Mr. Stoll was engaged and bears mute tribute to his tireless and indefatigable efforts. Commendation for this accomplishment is merited especially since during the latter part of his tenure in this office he was suffering from the first stages of a baffling malady which later necessitated the amputation of one leg. This did not suffice to check the progress of the disease, and in order that he might better contend with it, he severed his connection with the Pennsylvania Highway Department and went to Florida, where for a year, as a Professional Engineer of that State, he practiced in and around Daytona Beach.

In 1926, Mr. Stoll returned to the Pennsylvania Department of Highways as an Assistant Engineer in the Central Office at Harrisburg, Pa. His duties in the field had given him a peculiar insight into the problems confronted by the engineers and contractors performing the actual operations of road building; he was thus unusually well fitted to be liaison official to serve alike the interests of both the Department and the commercial agencies employed by it.

The physical indisposition which had assailed him in 1925 was held in abeyance until 1928. It re-asserted itself, however, and in order to effect what was thought might be a permanent cure, the other lower leg was amputated. Nothing daunted, and notwithstanding the entire loss of the means of natural locomotion, Mr. Stoll continued to perform his duties and spared no effort to promote his work as a servant of the public. His fortitude, cheerfulness, and strength of character became proverbial, his life serving as a restraining influence on those who indulge in fancied grievances and complaints.

The admiration of all who came in contact with him was spontaneous, a tribute to his loyalty, courage, and devotion to what he conceived to be his duty.

It was while he was enjoying a vacation at Lake Kewanee, in Lackawanna County, during the week of July 4, that he developed a severe case of pleurisy, the result of being caught in the rain while on a fishing trip. In his already weakened condition, he was unable to withstand this final illness, and death came very unexpectedly on the morning of July 9.

Mr. Stoll built for himself an enduring monument not only in his work as a public servant, but as a benefactor. Little is known of his kindnesses to the many who, less fortunate than he, received favors at his hands. He directed such efforts so quietly that only the recipients themselves were aware of what he did.

His widow, Helen R. (Stoltz) Stoll, of Jersey City, N. J., to whom he was married in 1913, and a daughter, Dorothy Rae Stoll, survive him.

Mr. Stoll was elected an Associate Member of the American Society of Civil Engineers on September 10, 1923.

## FRANKLIN STEVENS STOREY, Assoc. M. Am. Soc. C. E.[1]

DIED OCTOBER 8, 1930

Franklin Stevens Storey, the son of the late Col. James Henry Storey, and Annie (Cheshire) Storey, was born at Brooklyn, N. Y., on December 15, 1881. He attended the public schools of Brooklyn and prepared there for Cornell University, from which he was graduated as a Civil Engineer in 1902.

On leaving college, Mr. Storey was appointed Leveler and Transitman with the Manhattan Elevated Railway Company, New York City; in October, 1903, he was employed as Assistant Engineer on the construction of the East River Tunnels, by the Rapid Transit Commission; and in September, 1904, he was engaged by the New York Dock Department as Assistant Engineer on the Chelsea Improvement, North River, and on the St. George, Staten Island, Ferry Terminal.

In June, 1906, Mr. Storey joined The Phoenix Construction Company as General Superintendent, laid out methods and details of construction, and had full charge of field work on the Company's numerous contracts in the vicinity of New York and along the Atlantic Coast. The work was generally of an interesting character and comprised piers, bulkheads, sea-walls, intakes, and discharge tubes for power plants, including the Ferry Terminal substructure, at Stapleton, Staten Island; the Subway Waiting-Room for the Erie Railroad Company, at Jersey City, N. J.; the Penhorn Creek Viaduct foundations for the main line of the Erie Railroad Company, over the Hackensack River; the Bronx Valley Sewer Outlet, at Yonkers, N. Y.; a bulkhead platform for the Ocean Steamship Company, Savannah, Ga., and Pier No. 5 for the West Shore Railroad Company, Weehawken, N. J.

On May 15, 1917, Mr. Storey was admitted to the first Officers' Training Camp, at Madison Barracks, New York, as a civilian candidate for a com-

[1] Memoir prepared by L. R. Gwyn, Esq., New York, N. Y.

mission; he was assigned to the Engineer Company, 3d Provisional Training Regiment, moved with his organization to Camp American University, Washington, D. C., and served at that place until August 15, 1917, when he was appointed a First Lieutenant, Engineer Officers' Reserve Corps. He was assigned to active duty the same day and on August 27, 1917, reported for duty with the 303d Engineers.

He sailed overseas on September 14, 1917, for France where he was assigned to duty on October 4, 1917, at Le Valdahon as Post Engineer Officer. He served at that place until May 11, 1918, when he was transferred to Bazoilles-sur-Meuse, to assist in the construction of a hospital. He was transferred on July 5, 1918, to the Engineer Officers' Construction Camp in the 14th Divisional Area, Recey-sur-Ource, and on October 3, 1918, to the Engineer Officers' Construction Camp at the 2d Corps Aero School, Chatillon-sur-Seine.

On October 26, 1918, Lieutenant Storey was promoted to the rank of Captain, Engineers, and on November 4, 1918, he was transferred to Donjeux as Engineer Officer in charge of construction. On November 20, 1918, Captain Storey was transferred to Verdun and, later was on duty at Bordeaux. On March 7, 1919, he was assigned to the command of Company D, 539th Service Battalion, Engineers, relieved from duty therewith on May 16, 1919, and honorably discharged at Gievres, France, on June 18, 1919.

Returning to the United States, he immediately took up the position of Chief Engineer of The Phoenix Construction Company, which position he held until his death. Until his health failed, he had charge of work which included the first section of the Coney Island Boardwalk and the screen well and discharge tunnels for the New York Edison Company's Power House at 14th Street, East River. He died after a lingering illness, at Saranac Lake, N. Y., on October 8, 1930, and was buried in the family plot in Greenwood Cemetery, Brooklyn.

Captain Storey made friends for the Company on every "job" which he undertook and, what is rarer, kept them throughout his life. His mind was of an unusually fine caliber and he solved many a problem of a most difficult nature in both construction and design.

He is survived by his widow, his brother, Henry M. Storey, of San Francisco, Calif., and three sisters, Mrs. E. K. Waterbury and Mrs. L. R. Gwyn, both of Scarsdale, N. Y., and Mrs. P. S. Mahood, of Kingston, Ont., Canada.

Captain Storey was elected an Associate Member of the American Society of Civil Engineers on May 6, 1914. He was also a member of the Engineers Club of New York.

---

## JOHN GERARD THEBAN, Assoc. M. Am. Soc. C. E.[1]

---

DIED MAY 13, 1930

---

John Gerard Theban was born on May 26, 1869, in New York, N. Y., the son of Theodore Adrian and Alice M. (Casey) Theban. He was graduated

[1] Memoir compiled from information on file at the Headquarters of the Society.

from St. Francis Xavier College, New York, in June, 1890, with the degree of Bachelor of Arts.

Mr. Theban's first position after his graduation was in the Engineering Department of the New York Central and Hudson River Railroad Company, where he began work in July, 1890. In June, 1892, he severed his connection with this Company and took a position with the Park Avenue Improvement Commission of New York City, which had control of all the work done in connection with the extensive changes made in the grades of the tracks of the New York and Harlem Railroad from Mott Haven Junction to 106th Street, along Park Avenue. In September, 1895, he re-entered the service of the New York Central and Hudson River Railroad Company as an Assistant Engineer for the New York and Harlem Railroad, the New York and Putnam Railroad, and its New York City Terminal System.

In June, 1896, he resigned his position with the Railroad Company to accept an appointment as Assistant Engineer of Construction in the Department of Street Improvements of the 23d and 24th Wards, New York City (now the Borough of The Bronx). In 1898, the first year of the City of Greater New York, Mr. Theban was transferred to the newly created Department of Bridges and was appointed Assistant Engineer in Charge of the Bridges over navigable waters in the Borough of The Bronx. From 1898 to 1912, in which latter year he became Engineer in Charge of the Harlem River and Bronx Division, when the two Divisions were consolidated, there were built in the Borough of The Bronx, under his charge, such structures as the City Island Bridge, the Westchester Avenue Retractile Draw Bridge, over the Bronx River, the fixed trunnion bascule bridge over Mott Haven Canal, at 135th Street, and the Scherzer rolling lift bridge with reinforced concrete arch approaches over Pelham Bay.

In January, 1913, Mr. Theban was made Engineer in Charge of the maintenance of the Queensboro Bridge, and in January, 1916, he became Engineer in Charge of the Williamsburg Bridge, both over the East River, New York City.

On April 30, 1916, he severed his connection with the City service to enter private practice. During the World War he was connected with the United States Navy Department as Supervising Engineer of Plant, Docks, and Structures, with headquarters at Akron, Ohio. At the time of his death, he was President of the Boretest Engineering Company, with offices in New York.

For years, Mr. Theban served as a Trustee and, later, became President of the McCadden-McQuirk Foundation, a trust fund established to assist deserving poor young men who wished to study for the Roman Catholic priesthood.

Mr. Theban was a man of refinement, a master of English, a skillful and accomplished engineer, and an efficient executive. He was also an accomplished pianist and a great lover of classical music.

In June, 1904, he was married to Sarah Lawrence Gunning, of South Orange, N. J. He is survived by his widow, two daughters, Alice and Evelyn, one son, John, and a brother, Theodore A. Theban.

Mr. Theban was elected an Associate Member of the American Society of Civil Engineers on March 3, 1897.

## WALTER CHECKLEY TIFFANY, Assoc. M. Am. Soc. C. E.[1]

DIED DECEMBER 9, 1929

Walter Checkley Tiffany, Jr., was born at Minneapolis, Minn., on January 23, 1891. His father is Walter C. Tiffany, now of Seattle, Wash., and his mother was Lila R. (Robinson) Tiffany. His early years were spent in the city of his birth, where his father practiced law. His primary education was by private tutor and in various private and public high schools. Although the tradition of his family inclined toward education at Harvard University, of which his father is a graduate, his own restless and impatient temperament early led him into the practical field of construction work. Later, he sensed the advantage to him of technical training, and he tied himself down for a period of study at the School of Mines at Butte, Mont. All through his active and adventurous life Mr. Tiffany was an assiduous student in his spare time. He had an insatiable appetite for facts, figures, and the experiences of others as set forth in technical articles and particularly in descriptions of construction work.

In his early professional life which began at the age of seventeen, Mr. Tiffany went through the usual progression of the "cub", as Chainman, Rodman, and Transitman on railroad location and construction in the Western States, filling in between jobs as Computer and Draftsman. His first engagement was as Chainman on the Los Angeles Aqueduct, in 1909. The next year he was with the Northern Pacific Railroad Company, in North Dakota; the following year on the Duluth-Frederick Division of the Milwaukee, St. Paul, and Sault Ste. Marie Railway, and at Wilton, Wis., on the Ontario Northern Railway. In 1912 and 1913 he was engaged as Instrumentman with the Southern Traction Company from Dallas to Waco, Tex., and during the following two years he was with the Pacific Telegraph and Telephone Company, at Seattle, and with the Standard Oil Company at Waco. At the outbreak of the World War he was employed as Topographer with the Stone and Webster Engineering Corporation in the Seattle District

As a Private and Sergeant in the Washington National Guard, Mr. Tiffany was prepared for the call to the Service. He attended the Third Officers' Training School at Camp Lewis, Washington, after which he was placed in the Field Artillery Replacement Depot at Camp Jackson, South Carolina. In May, 1918, he sailed for France where he attended the Saumur Artillery School. In September of that year he was assigned to the 330th Field Artillery and served as Second Lieutenant throughout the series of engagements in the Marne Region. He returned to the United States in April, 1919, and was honorably discharged at Camp Grant, Illinois.

The next eleven years was a period of almost excessive activity for Mr. Tiffany, with progressive increase of responsibility on a large number of construction jobs, including location work on the Minarets and Western Railway, in California; surveys and construction of the Caribou and Big Creek

[1] Memoir prepared by George Schobinger, M. Am. Soc. C. E.

Developments, in California; irrigation work, in Mexico; power plant and mining smelter development, in California and Arizona; and, later, in New York City, where he was Superintendent with Dwight P. Robinson and Company, Incorporated, on a large steam boiler plant. In 1927, he was assigned by that Company to work in Rio de Janeiro, Brazil, where he became its General Superintendent and Representative, in connection with the construction of a number of buildings, and of a large new shop development.

In all his assignments, and particularly in the later ones where the opportunities were becoming greater, Mr. Tiffany showed single-mindedness of purpose, capacity for work, and admirable ability to organize and to apply the results of his early experience, which appeared to assure a brilliant future. In his last year, however, perhaps as a result of overwork, exposure, and hardship in his earlier years and during the war period, a serious disability of his heart and lungs began to appear, which, at times, would strike him down at moments of intense activity. He refused to believe that he could have any physical limitations, and in spite of warnings from within and from his medical advisers, drove himself perhaps harder than ever. His only interest and his only desire in life was to finish successfully this last and largest job which he had organized and put in full working order. In November, 1929, he received an unmistakable warning of physical inability and consented to go to bed for ten days, but even then kept his bed stacked with reports and documents, and had the telephone within reach. The forced inactivity was too much; he snapped his fingers at the doctor and announced that he was going to "run" his job in spite of doctors. A week later he was fatally stricken a few minutes after returning home from work, and two days later, on December 9, 1929, died at the Strangers' Hospital, in Rio de Janeiro.

In 1923, Mr. Tiffany was married to Margaret Curtis, who shared with him the life of an engineer, "from town to camp and from job to job." Friends told him that in the intensity of his work, which occupied every daylight hour, and, in addition, many hours of the night, he was neglecting his family, but he knew that he was understood by his wife, and that he had her unwavering support and help in doing what he considered necessary to his job. He discussed many of his problems at home and benefited by the balance of judgment which comes from the application of a new point of view and a fresh mind.

He had a keen mind and a quick temper under perfect control; in many years of association none of his men ever heard his voice raised in anger, although there never was any question about the firmness of his discipline or his requirements that his orders be properly carried out. A "horse" for work, careful in detail, thoroughly familiar with costs, ambitious, a good disciplinarian, and able to enlist the co-operation and affection of all the men in his organization, he was an ideal construction engineer.

Walter Tiffany was an exceptional man. One of his former associates, answering inquiries as to his record, closed his letter with the following paragraph:

"From out of my profound admiration for Walter as an Engineer and my genuine affection for him as a friend there is little that I can add, except the words of Antony about his friend, that 'This was a man'."

The same associate wrote: "It has seldom been my good fortune to be associated with so capable, so earnest, and so energetic an Engineer."

He is survived by his widow and two small sons, Walter Checkley, Jr., and Francis Tiffany.

Mr. Tiffany was elected an Associate Member of the American Society of Civil Engineers on October 12, 1925.

## WILLIAM FRANKLIN WHITAKER, Assoc. M. Am. Soc. C. E.[1]

DIED NOVEMBER 20, 1930

William Franklin Whitaker, the son of David S. and Annie (Warren) Whitaker, was born on January 20, 1880, at Lebanon, Ind. He was educated in the schools of Lebanon and in 1899 entered Leland Stanford, Jr., University, California, from which he was graduated in June, 1903, with the degree of Bachelor of Arts in Civil Engineering.

Mr. Whitaker's first engineering work began when he was only nineteen years of age, and prior to his entering college, at which time he was employed on engineering parties for the Kern County Land Company, Bakersfield, Calif., and also with the City Engineer of Bakersfield. In 1902, during his college vacation, he was engaged also in engineering work, as Stream Gauger for the Buena Vista Lake Reservoir Association, measuring the flow of Kern River, and, under the supervision of the late Edwin Duryea, M. Am. Soc. C. E., on underground water measurements and pumping tests in the Santa Clara Valley, California.

After graduating from Stanford University, Mr. Whitaker was first employed, in 1903, as Draftsman in connection with reservoir surveys and, later, in charge of parties engaged on the measurement of stream flow in the Coyote River and other streams tributary to the Santa Clara Valley. In December, 1904, he accepted a position as Assistant Engineer with the Kern County Land Company of Bakersfield, of which Mr. Walter James was Chief Engineer. His work in this capacity involved surveys and a study of the irrigation system of Kern Delta. For two months in 1905, he also assisted in a study of the water-works system of the City of Bakersfield and the preparation of a full report on existing conditions, with recommendations for enlargement and betterment of the system for fire protection, etc.

From November, 1905, until 1917, Mr. Whitaker was Superintendent of Canals, and, from 1917 to the date of his death, Chief Engineer of the Kern County Land Company, having full charge of the maintenance and operation of more than 1 000 miles of canals and laterals serving about 200 000 acres of land in Kern County, California. In connection with this engagement, he designed and constructed numerous irrigation works and structures of magnitude, administered the irrigation system, and also acted in a consulting capacity on various other irrigation projects in California, Arizona, and New Mexico.

[1] Memoir prepared by a Committee of the San Francisco Section consisting of H. L. Haehl, M. Am. Soc. C. E., and Hugh S. Allen and A. L. Trowbridge, Assoc. Members, Am. Soc. C. E.

Mr. Whitaker was possessed of an especially pleasant personality, unusual force of character, and marked engineering ability. He will be particularly remembered among the young men of the profession who came in contact with him for his unselfish interest in their personal welfare and the untiring assistance and kindly advice he freely afforded them in their work. He was consistently interested and active in the affairs of the Society. He was also intensely active and influential in his community in civic, business, financial, and educational affairs. He was devoted to his family and his many friends, and leaves behind him an inspiring record of good works and charitable acts. He died of a cerebral hemorrhage on November 20, 1930, when apparently in excellent health and in the midst of an active and useful life.

Mr. Whitaker was married on August 10, 1907, to Gertrude Scribner, of Bakersfield, who, with four children—Elizabeth, Anne, William, and Ruth—survives him. He is also survived by his parents, a brother, Ralph W. Whitaker, Assoc. M. Am. Soc. C. E., of San Diego, Calif., and a sister, Mrs. W. E. Duthie, of Indianapolis, Ind.

Mr. Whitaker was elected a Junior of the American Society of Civil Engineers on April 4, 1905, and an Associate Member on November 6, 1910.

## ROBERT ELGENE YOLTON, Assoc. M. Am. Soc. C. E.[1]

DIED SEPTEMBER 10, 1930

Robert Elgene Yolton was born in Fayette County, Illinois, on December 25, 1879. He lived on a farm until he was twenty years old, at which time he entered Austin College, at Effingham, Ill., where he spent three years. He then went to the University of Illinois as a student in Civil Engineering, from which he was graduated in 1905.

After his graduation, Mr. Yolton was engaged with the Buda Company in Chicago, Ill., where he spent six years. He then worked for a short time for the Illinois Central Railroad Company, also in Chicago.

In the fall of 1916 he was called to Birmingham, Ala., as Chief Engineer of the Kilby Frog and Switch Company. Mr. Yolton spent ten years with this firm, during which time he did much to improve the plant; in fact, under his guidance it was increased to about twice its original size. In the summer of 1925 the Company was consolidated with the Weir Frog Company of Cincinnati, Ohio, and, in January, 1926, Mr. Yolton went to Cincinnati to become Chief Engineer of the Weir-Kilby Corporation, with which he remained until his death.

He was greatly interested in flowers and spent much time in his garden, which was always greatly admired by his friends. He was also active in church affairs and was an Elder in Presbyterian Churches in Chicago, Birmingham, and, at the time of his death, in the Norwood (Ohio) Presbyterian Church. He was a man who was greatly loved and admired by his friends. Mr. Kilby, former President of the Kilby Frog and Switch Company, said of him:

[1] Memoir prepared from information on file at the Headquarters of the Society.

"Mr. Yolton was a man of sterling character and of the greatest integrity. He was loved and respected equally by his employers as well as by his subordinates to whom he was always counsellor and friend."

Mr. Yolton was a member of Tau Beta Pi Fraternity and the National Geographic Society.

He was married in Melvin, Ill., on August 30, 1904, to Ella Maude Holmes, who, with two sons, Robert H. and John W., and a daughter, Jean Mildred, survives him.

Mr. Yolton was elected an Associate Member of the American Society of Civil Engineers on April 17, 1917.

## JAMES RUSSELL VAUGHAN, Jun. Am. Soc. C. E.[1]

DIED DECEMBER 16, 1930

James Russell Vaughan, the only child of Thomas M. Vaughan and Mae (McReynolds) Vaughan, was born in Indianapolis, Ind., on March 14, 1904. He was graduated from the High School at Lisbon, Ohio, with the Class of 1921.

From early boyhood, bridges and the building of bridges interested him greatly. By the time he had finished his high school studies, this interest had grown so strong that he decided to take up Engineering and devote himself to the design and construction of bridges. With this in mind he entered the Case School of Applied Science in the fall of 1921.

Lack of funds prevented Mr. Vaughan from completing the course in the customary four years. However, with characteristic energy and persistence, he worked his way through and received the degree of Bachelor of Science in Civil Engineering with the Class of 1927. While at College, he was much interested in athletics, having been a star halfback on the Case football team and a consistent performer in the dashes and hurdles. He was a member of the Kappa Sigma Fraternity.

From October, 1923, to September, 1924, Mr. Vaughan was in the employ of The Ohio Power Company, at Canton, Ohio, engaged in making surveys, checking property ownership, and mapping the right of way of the Company.

In August, 1927, he entered the drafting-room of The Mt. Vernon Bridge Company, at Mt. Vernon, Ohio, as a detailer of steel work. He was blessed with an unusually active mind and a strong and healthy body which enabled him to endure long hours of work and study. He not only did his office work faithfully and well, but spent most of his evenings and holidays studying the theory of structures and reading all available books on the design of bridges. Many times he worked far into the night checking the design of some bridge which he was detailing during working hours or working out a design for some bridge about which he had read.

Mr. Vaughan's ability attracted the attention of the older engineers of the Company and from time to time when extra help was needed in the Designing Department, he was chosen. The two most important contracts on which he

[1] Memoir prepared by James D. K. Lyman, M. Am. Soc. C. E.

assisted with the design were a 345-ft. swing span bridge for the Baltimore and Ohio Railroad Company over Curtis Creek near Baltimore, Md., and the equipment to be used in the erection of the 750-ft. three-hinged arch for the Westchester County Park Commission over Croton Lake near New York, N. Y.

The erection of this arch was of such a nature that the Mt. Vernon Bridge Company required the services of an engineer on the construction during erection. Mr. Vaughan being thoroughly familiar with the erection procedure was chosen for this work. During his work in the field, he won the respect and admiration of both the workmen and the other engineers with whom he came in contact.

On December 11, 1930, while Mr. Vaughan was checking the elevation of the top of a bent of falsework, a wrench slipped from the hands of a workman at the next panel point ahead and, in falling, struck the sloping bottom chord of the arch and glanced sidewise striking Mr. Vaughan on the head. The blow stunned him to such an extent that he fell to the ground, causing internal injuries from which he died on December 16, 1930.

His death is a distinct loss, not only to his friends and associates, but also to the Engineering Profession, for he gave promise of more than ordinary ability, and it is greatly to be regretted that a young life of so many possibilities should end so soon.

He is survived by his widow, Elizabeth Dieringer Vaughan, to whom he was married on Christmas Day, 1927, and his father and mother.

Mr. Vaughan was elected a Junior of the American Society of Civil Engineers on November 11, 1929.

## STEDMAN BENT, Affiliate, Am. Soc. C. E.[1]

DIED NOVEMBER 26, 1929

Stedman Bent was born in what is now the City of Chester, Pa., on June 10, 1876, the son of Luther Stedman and Mary Stearns (Felton) Bent.

After attending school in Philadelphia, Mr. Bent went to work, in 1896, for the Pennsylvania Steel Company at its Steelton Works. Two years later, in 1898, he was appointed Purchasing Agent of that Company and its various subsidiary companies, with offices in Philadelphia. He held this position until about 1914, when he became connected with the Raymond Concrete Pile Company and was placed in charge of its office for the Philadelphia District. He remained with this Company until his death on November 26, 1929, at his home in Overbrook, Pa.

Mr. Bent was a member of the Racquet Club, the Philadelphia Country Club, the Pennsylvania Athletic Club, the Seaview Country Club, the Merion Cricket Club, and the Lotos Club of New York. He was also a member of the Sons of the Revolution and the Loyal Legion.

He was a lover of animals. He took an active interest in raising fine cattle and was extremely fond of dogs, always having several of them around

[1] Memoir prepared by Edgar C. Felton, Esq., Philadelphia, Pa., John V. W. Reynders, Esq., New York, N. Y., and Thomas Earle, M. Am. Soc. C. E.

his home. He was also greatly interested in farming and found great joy in his garden, to which he devoted much time.

He was married on August 4, 1919, to Nanna (McElwell) Arnold, who survives him.

Mr. Bent was elected an Affiliate of the American Society of Civil Engineers on December 2, 1902.

## CLARENCE MARVIN FOSTER, Affiliate, Am. Soc. C. E.[1]

DIED FEBRUARY 18, 1930

Clarence Marvin Foster, the son of Maj.-Gen. Robert S. Foster and Margaret (Foust) Foster, was born in Indianapolis, Ind., on April 6, 1866. He completed his common and high school education in 1883.

From 1883 to 1887, Mr. Foster was associated with the firm of R. S. Foster Company, of Indianapolis, dealers in cement and building materials. In 1887, he started in business for himself as a General Contractor on concrete and masonry work. He continued in this business until 1892, when he disposed of it to become associated with the firm of Buntin, Shryer and McGannon, of Indianapolis, Duluth, Minn., and Kansas City, Mo., with which he remained until 1895. During his services with these various organizations, Mr. Foster had qualified himself as an expert on matters pertaining to cement and work in which cement was involved. Recognizing his value as an expert in matters pertaining to this type of work, he was engaged by the Utica Cement Association, manufacturers of hydraulic cement, as a Traveling Inspector. This work caused him to travel throughout the West.

In 1899, Mr. Foster left the Utica Cement Association to become Sales Manager for the Meacham and Wright Company, of Chicago, Ill. This Company was for many years one of the largest (if not the largest) jobbers of Portland cement in the United States. He continued in this capacity until the early part of 1914, when the Meacham and Wright Company discontinued handling Portland cement. He then became Manager of the Edison Portland Cement Company, at Philadelphia, Pa.

In April, 1915, Mr. Foster and J. Edward Cassidy, M. Am. Soc. C. E., organized the Foster Construction Company with headquarters in Newark, N. J., and engaged in the design and construction of reinforced concrete bridges. Mr. Foster, as President, was specifically charged with office administration and the purchase of materials and supplies for the operations of the Company. In the spring of 1917, when the United States entered the World War, the Foster Construction Company had a well-established business, and, at the time war was declared, had a number of bridges under construction. Mr. Cassidy, who was in charge of all the technical and construction work of the Company, was a Captain (later, Colonel) in the Engineer Reserve Corps and went on active duty the day following the finishing and acceptance of the last of the bridges under construction.

[1] Memoir prepared by J. Edward Cassidy, M. Am. Soc. C. E.

Although he was 51 years of age when war was declared, it was particularly fitting that Mr. Foster should take an active part in the service of the country, as his father, Maj.-Gen. Foster had had a very distinguished record in the Civil War serving in various capacities up to and including the command of a Division. His service further included the position of Chief of Staff of the 10th Army Corps, and afterward that of Major-General commanding the First Division, 24th Army Corps, Army of the James; this Division performed a 36-mile march in 24 hours to close the last gap around the Army of Northern Virginia at Appomattox, April 8 and 9, 1865.

Being especially fitted for work in connection with materials and supplies used in construction, Mr. Foster received an appointment in the Construction Division of the Army, was commissioned as a Captain, and, later, promoted to the rank of Major. He continued in the capacity of Purchasing and Contracting Officer, Construction Division, until October, 1919, when he left the service to become District Manager of the Barber Asphalt Company, with headquarters at Washington, D. C.; he remained with that Company until his death. During the period, 1919 to 1923, while his headquarters were in Washington, Major Foster compiled a great many valuable data on municipal work for which he received commendation not only from his own Company, but from a number of foreign countries.

In October, 1923, Major Foster was promoted to be District Manager of the Barber Asphalt Company on the Pacific Coast with headquarters at San Francisco, Calif., his territory covering a large group of Western States, the Hawaiian and Philippine Islands.

His death on February 18, 1930 occurred from a stroke of apoplexy. He had not been feeling well for days and on February 13, 1930, he came home early in the afternoon and shortly afterward suffered the stroke from which he never regained consciousness. He died five days later. Funeral services were held at his home in San Francisco, after which all that was mortal was taken to his old home in Indianapolis, and interred in Crown Hill Cemetery.

He was a member of the Military Order of the Loyal Legion, Indiana Engineering Society, and the U. S. Army Quartermaster Association.

Major Foster was a man of exemplary habits, and with his genial, pleasant disposition and courteous manner, had the faculty of making a host of friends wherever he went. His passing is a personal loss not only to his friends in many parts of the country, but to his numerous business associates with whom he was always a "hale fellow well met."

He was married on December 24, 1895, to Mary Margaret Roberts, of Indianapolis, who survives him, together with a daughter, Mrs. Maryanna Childs, of Detroit, Mich., and a son, Robert S. Foster, of San Francisco.

Major Foster was elected an Affiliate of the American Society of Civil Engineers on January 31, 1899.

## SUBJECT INDEX

**ADDRESSES.**

Presidential Address at the Annual Convention at Tacoma, Washington, July 8, 1931. Francis Lee Stuart. 1294.

**AIRPORTS.**

"Factors Governing the Location of —." Donald M. Baker. 269. Discussion: Stephen Child, Morris Knowles, George D. Burr, N. H. Angell, J. Ogden Marsh, Archer R. Norcross, John Nolen, S. N. Grimm, R. U. St. John, John F. Partridge, William J. Fox, Perry A. Fellows, W. W. Crosby, E. K. Smith, and Clyde M. Wood. 279.

**ARCHES.**

"Laminated Arch Dams with Forked Abutments." Fred A. Noetzli. (With Discussion.) 533.

"Plastic Flow in Concrete —." Lorenz G. Straub. 613. Discussion: B. F. Jakobsen, C. A. P. Turner, Edward Godfrey, J. H. Griffith, Charles W. Comstock, A. A. Eremin, J. Melan, Fredrik Vogt and Herbert J. Gilkey, E. Probst, Paul Bauman, G. C. Staehle, and A. Floris. 679.

**BARS.**

"The Training Wall Across the Liao Bar in Manchuria." P. N. Fawcett. (With Discussion.) 969.

**BIBLIOGRAPHY.**

— of current-meter characteristics by American investigators. 791.
— of ice in hydro-electric plants. 1145.
— of Niagara Falls power plants. 26.

**BRIDGE PIERS.**

"Construction of the James River Bridge Project." R. C. Wilson and Herbert B. Pope. (With Discussion.) 244.

**BRIDGES.**

— on the Chesapeake and Delaware Canal. 740 *et seq.*

"Construction of the James River Bridge Project." R. C. Wilson and Herbert B. Pope. 244. Discussion: Wilson T. Ballard, and William Willoughby. 262.

"Impact in Highway —. Final Report of the Special Committee." (With Discussion.) 1089.

"Plastic Flow in Concrete Arches." Lorenz G. Straub. (With Discussion.) 613.

**BUILDINGS.**

"Florida Hurricane. Final Report of the Committee of the Structural Division." (With Discussion.) 1118.

**CANALS.**

"The Chesapeake and Delaware Canal." Earl I. Brown. 716. Discussion: F. T. Chambers. 764.

**CITY PLANNING.**

"— as Related to the Smaller Cities." E. A. Wood. 1075. Discussion: John L. Starkie, O. H. Koch, and Stephen Child. 1080.

**CIVIL ENGINEERS.**

"The Engineer's Growing Civic Responsibilities": Address at the Annual Convention at Tacoma, Washington, July 8, 1931. Francis Lee Stuart. 1294.

**COLUMNS.**

"Steel Column Research. Second Progress Report of the Special Committee." (With Discussion.) 1152.

**CONCRETE.**

"Baldwin Filtration Plant, Cleveland, Ohio." J. W. Ellms, G. W. Hamlin, A. G. Levy, and J. E. A. Linders. (With Discussion.) 459.
— lining, Moffat Tunnel. 353.
Construction methods and plant layout at Coolidge Dam, in Arizona. 159.
Cracking of — in dams. 145.
"Plastic Flow in — Arches." Lorenz G. Straub. (With Discussion.) 613.

**CONTRACTORS PLANT.**

Construction methods and plant layout at Coolidge Dam, in Arizona. 159.

**COSTS OF WORK.**

Analysis of costs of the Baldwin Filtration Plant, Cleveland, Ohio. 512 *et seq.*
Comparative costs of different types of highways in and adjacent to New York City. 1050.
Cost data, Moffat Tunnel. 369.
"Factors Governing the Location of Airports." Donald M. Baker. (With Discussion.) 269.
